6. The *most common causes of sterility in woman* are: Gonorrhea, absence or errors in development of any part of the genital tract, malformations of genitals, fistulæ, lacerations, obesity, alcoholism, pelvic inflammations, dyspareunia, inflammations of uterus, tubes, or ovaries, elongated cervix. *Treatment* consists in removing the cause, if possible; curettage has been recommended; in the presence of developmental errors little or nothing can be done; atresia of cervix can be treated by dilatation; if the uterus is misplaced it must be replaced.

7. *Treatment of eclampsia* consists in: (1) Controlling the convulsions (by chloroform, veratrum, or chloral); (2) elimination of the poison or poisons which are presumed to cause the convulsions; (3) emptying the uterus under deep anesthesia, by some method that is rapid and that will cause as little injury to the woman as possible.

8. "When extrauterine pregnancy exists there are: (1) The general and reflex symptoms of pregnancy; they have often come on after an uncertain period of sterility; nausea and vomiting appear aggravated. (2) Then comes a disordered menstruation, especially metrorrhagia, accompanied with gushes of blood, and with pelvic pain coincident with the above symptoms of pregnancy; pains are often very severe, with marked tenderness within the pelvis; such symptoms are highly suggestive. (3) There is the presence of a pelvic tumor characterized as a tense cyst, sensitive to the touch, actively pulsating; this tumor has a steady and progressive growth. In the first two months it has the size of a pigeon's egg; in the third month it has the size of a hen's egg; in the fourth month it has the size of two fists. (4) The os uteri is patulous; the uterus is displaced, but is slightly enlarged and empty. (5) Symptoms No. 2 may be absent until the end of the third month, when suddenly they become severe, with spasmodic pains, followed by the general symptoms of collapse. (6) Expulsion of the decidua in part or whole. Nos. 1 and 2 are *presumptive signs;* Nos. 3 and 4 are *probable signs;* Nos. 5 and 6 are *positive signs.*" (*American Text-Book of Obstetrics.*)

Treatment consists in the removal of the product of conception by a laparotomy, as soon as the diagnosis is made.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION
Alabama*	W. H. Sanders, Montgomery	Montgomery June —
Arizona*	Ancil Martin, Phoenix	Phoenix July 4
Arkansas	F. T. Murphy, Brinkley	Little Rock May 10
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco Aug. 2
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver July 5
Connecticut*	Chas. A. Tuttle, New Haven	New Haven July 12
Delaware	J. H. Wilson, Dover	Dover June 21
Dist. of Col'bia.	Geo. C. Ober, Washington	Washington July 12
Florida*	J. D. Fernandez, Jacksonville	Jacksonville
Georgia	E. R. Anthony, Griffin	Atlanta
Idaho*	W. F. Howard, Pocatello	Oct. 4
Illinois	J. A. Egan, Springfield	Chicago June 9
Indiana	W. T. Gott, Crawfordsville	Indianapolis July 12
Iowa	Louis A. Thomas, Des Moines	Des Moines
Kansas	F. P. Hatfield, Olathe	Topeka June 14
Kentucky	J. N. McCormack, Bowling Green	Louisville July —
Louisiana	F. A. LaRue, 211 Camp Street, New Orleans	New Orleans May 17
Maine	F. W. Searle, Portland	Portland July 19
Maryland	J. McP. Scott, Hagerstown	Baltimore June 21
Massachusetts*	E. B. Harvey, State House, Boston	Boston May 10
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Ann Arbor June 14
Minnesota	W. S. Fullerton, St. Paul	St. Paul May 10
Mississippi	S. H. McLean, Jackson	Jackson May 10
Missouri	Frank B. Hiller, Jefferson City	Jefferson City June 13
Montana*	Wm. C. Riddell, Helena	Helena Oct. 4
Nebraska	C. A. Carr, Lincoln	Lincoln Aug. 3
Nevada	S. L. Lee, Carson City	Carson City
N. Hampshire	Henry C. Morrison, State Library, Concord	Concord July 6
New Jersey	H. G. Norton, Trenton	Trenton June 21
New Mexico	J. A. Massie, Santa Fe	Santa Fe July 11
New York	C. F. Wheelock, Univ. of State of New York, Albany	New York / Albany / Syracuse / Buffalo — May 24
N. Carolina	B. K. Hays, Oxford	Wrightsville June 15
N. Dakota	H. M. Wheeler, Grand Forks	Grand Forks July 5
Ohio	Geo. H. Matson, Columbus	Columbus June 14
Oklahoma*	F. P. Davis, Enid	Guthrie July 12
Oregon	B. E. Miller, Portland	Portland July 5
Pennsylvania*	N. C. Schaeffer, Harrisburg	Philadelphia / Pittsburg — June —
Rhode Island*	G. T. Swarts, Providence	Providence July 7
S. Carolina	H. H. Wyman, Aiken	Columbia June —
S. Dakota	H. E. McNutt, Aberdeen	Watertown July 13
Tennessee	C. A. Abernathy, Pulaski	Memphis / Nashville / Knoxville — May —
Texas	M. E. Daniel, Honey Grove	Austin June 28
Utah	R. W. Fisher, Salt Lake City	Salt Lake City April 4
Vermont	W. Scott Nay, Underhill	Burlington July 12
Virginia	R. S. Martin, Stuart	Richmond June 22
Washington*	T. C. McFadden, Seattle	Spokane July 5
W. Virginia	H. A. Barbee, Point Pleasant	Wheeling
Wisconsin	J. M. Beffel, Milwaukee	Madison July 12
Wyoming	S. B. Miller, Laramie	Laramie June 22

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Louisiana.—Hereafter this State will grant a license, without examination, to applicants who comply with the following conditions: They must (1) furnish the application form properly filled out, together with a recent unmounted photograph, and, if found eligible, (2) appear in person before the board; (3) present a diploma from a college rated Class A by this board (*i.e.* medical colleges rated between 70 and 100 per cent. by the Council on Medical Education of the American Medical Association; (4) present their permanent certificate of examination by and from a State board recognized by the Louisiana State Board, and have practised medicine for at least one year since they obtained said license; (5) present a sworn statement, either from the dean of the college from which they graduated, or from the secretary of the parish or county society in which they reside, or from the clerk of court of the parish or county in which they reside, certifying to their moral and professional character and their personal description as to weight, height, complexion, color of hair, and any marks of identification, etc.; (6) pay a fee of $25.

The National Confederation of State Medical Examining and Licensing Boards will hold its twentieth annual meeting at St. Louis, Mo., on Monday, June 6, 1910, in the Southern Hotel. The subject to be taken up at this meeting will be a consideration of practical clinical instruction in medical colleges, a report on medical education in the United States by a representative of the Carnegie Foundation, and a report on a proposed materia medica list by a special committee. The chief object of this symposium is to determine, as far as possible, whether clinical instruction in medical schools can be made sufficiently practical and thorough as to warrant the medical boards in demanding practical examinations in the principal branches of the medical course. The officers of the confederation are: *President*, Dr. A. Ravogli of Cincinnati; *Secretary*, Dr. Murray Galt Motter, 1841 Summit Place, N. W., Washington, D. C.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of April 30, 1910:

	Cases	Deaths
Tuberculosis Pulmonalis	605	188
Diptheria	443	55
Measles	1,555	27
Scarlet Fever	680	39
Smallpox	—	—
Varicella	132	—
Typhoid Fever	26	1
Whooping Cough	36	5
Cerebrospinal Meningitis	2	5
Malarial Fever	—	—
Totals	3,479	320

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended April 29, 1910:

		CASES	DEATHS
CHOLERA			
Colombo, Ceylon	Mar. 6–12	1	..
India, Calcutta	Mar. 6–12	..	80
Madras	Mar. 12–18	..	1

SOME NEWER CONCEPTIONS OF MYOCARDIAL DISEASE.*

BY THOMAS E. SATTERTHWAITE, M.D., LL.D.,

NEW YORK.

THE complaint of Bertin, the French internist, in 1821, that myocardial inflammation was wrapped in "a melancholy obscurity," seemed to furnish the stimulus for a long series of investigations which in the end have borne excellent fruit.

For, a hundred years ago there were no real distinctions between the many morbid changes that take place in the myocardium. So that when Laennec discovered fatty degeneration of the heart, the first positive advance was made in myocardial pathology.

But another quarter of a century elapsed before fatty degeneration was distinguished clinically from the fatty deposition of the fat heart. It was Stokes who traced the cause of this degeneration to infective diseases, notably typhus and typhoid fevers. Hayem confirmed Stokes' discovery by microscopic examinations. Meanwhile, in 1856, Ricord found that syphilis also attacked the musculature of the heart. Then Da Costa of Philadelphia, while studying the hearts of soldiers that had survived the campaigns of our Civil War, discovered his "irritable heart," the result of muscle strain, and reported his findings to the U. S. Sanitary Commission in 1867.

Up to this period our attention had been mainly riveted on the muscular tissue of the heart as the *fons et origo malis,* but Bristowe found that the interstitial tissue might also be involved. Soon after, diphtheria and scarlet fever were proved to cause acute myocarditis, and then Huchard traced the source of interstitial inflammation to the coronary vessels. Finally, von Leyden of Berlin, in 1878-9, gave us the most complete clinical picture, up to that date, of the several varieties of the fat heart. These contributions have removed much of the obscurity that Bertin complained of in his quaint language.

As a result, we can now say that all toxemias, acute or chronic, some dyscrasias and hyperemias, if long continued or severe, and other conditions to be mentioned later, produce definite morbid changes in the heart walls, evanescent or permanent, as the case may be. It has been more difficult, of course, to connect characteristic clinical phenomena with each particular change, but even this has been done with such a degree of definiteness that, though important pathognomonic signs are still absent, we can nevertheless picture in our minds the several myocardial affections and their stages.

*Address delivered by invitation before the Medical and Surgical Society of Washington, D. C., May 4, 1910.

But to the profession at large these matters are not so well defined. Their attention has been directed mainly towards diseases of the endocardium or pericardium. Indeed, many of us have been keen to establish the precise location and degree of some endocardial lesion, to the comparative neglect of the myocardial, whose condition was really of greater importance.

The word myocardium, referring as it does to muscle tissue as the preponderating element in the heart walls, is to be understood here as a synonym for the heart walls themselves (Fig. 1). But in the word myocarditis we have to face the fact that its use has led to much misapprehension. Some still use it indiscriminately, or as the equivalent of myocardial disease in general, while to the majority it means myocardial inflammation, and therefore does not include the most common of all myocardial affections, degenerative changes.

About two years ago I proposed a new classification, to include all forms of myocardial disease. It was as follows:

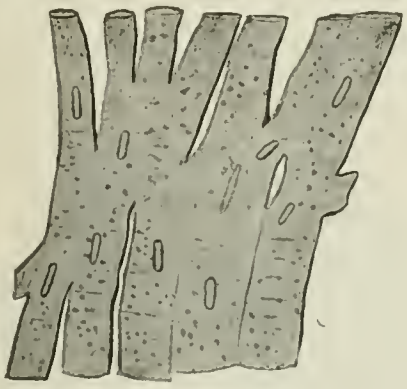

FIG. 1.—Normal heart muscle, x 250.

1. Acute parenchymatous myocarditis.
2. Aucte diffuse myocarditis, including the tuberculous, syphilitic, and suppurative forms.
3. Chronic myocarditis, including all of the diffuse inflammatory changes mentioned.
4. The fat heart.
5. The fatty heart.
6. Hypertrophies, whether due to severe exercise, vascular diseases, blood disorders, neurotic disturbances, possibly pregnancy.

To which I have added:

7. Atrophies.

Neither dilatation nor spasm is included in my table. They are incidents which occur at times in any of the varieties mentioned and cannot therefore be considered separately.

Some such classification as the above is essential for a clear conception of myocardial diseases, though many of the pathological phenomena here given are apt to be interconnected in any one instance. In fact, this complicated inter-relation has

led some internists to emphasize the clinical aspects of these affections at the expense of the pathological. Now it is true, in a general way, so far as symptoms and treatment are concerned at least, that chronic myocardial insufficiency is sometimes synonymous with myocardial abnormality or dis-

Fig. 2.—Acute parenchymatous change, x 250.

ease; but it is not so always. For example, the insufficiencies of the syphilitic heart and fat heart differ widely from others of the myocardial group, so that they need to be classed separately, while the more we study these subjects the greater will be the variations discovered. Hence the importance of considering the affections apart.

By those who are familiar with ordinary pathological views as to the origin of acute affections in general, it will be admitted that parenchymatous changes in the cell elements of a part are such regular precursors of inflammatory conditions that they are to be considered as early symptoms. And so a parenchymatous myocarditis may be but the first indication of the diffuse form, even though the character of the parenchymatous change is not fully understood. However, it is to be presumed, from what we know of similar processes elsewhere, that parenchymatous changes will not only produce fatty degeneration of the muscle cells, but necrosis as well, leading to dilatation and perhaps even to rupture of the organ.

Taking up another feature of myocardial disease, I will say that we have not duly appreciated its frequency. The statistics of Dr. Harlow Brooks* of New York illustrate this point. Of 457 cases taken from his post-mortem examinations, where death was credited to cardiac disease, in 330 the heart walls were diseased sufficiently to cause death,

Fig. 3.—Acute myocarditis, x 315.

while in many others heart wall disease contributed to the fatal ending; and yet in a considerable number the myocardial disease was not recognized during life, though, of course, much might have been done to arrest or control it. Now 126 of these

*Brooks, *New York Medical Journal*, February 9, 1907.

deaths, or 38 per cent., were due to uncomplicated degenerative disease of the heart walls.

My clinical records point to the probability that in 45 per cent. of my deaths in heart cases, degenerative changes in the heart were the chief disposing causes of death; though uremic poisoning or

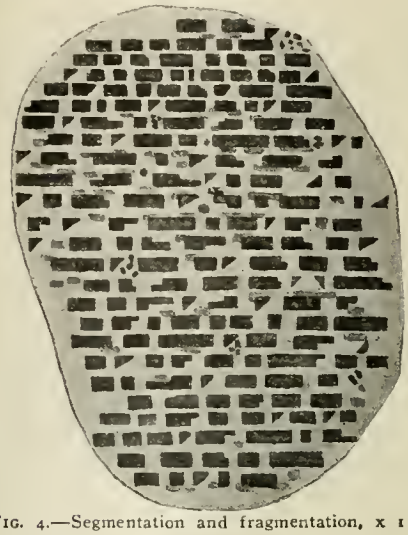

Fig. 4.—Segmentation and fragmentation, x 110.

other conditions may at times have been the actual causes.

Roemer of Tuebingen, while at Liebermeister's clinic, during a period of twenty years had a record of 44 per cent. of myopathic heart failures where there were no valvular symptoms, so that our clinical figures tally closely; while Brooks' figures, if applied to all his cases of myocardial disease, complicated and uncomplicated, might well corroborate mine.

Romberg has found chronic cardiac insufficiency (by which he means chronic myocardial disease) the most common of heart affections. At least, between the ages of 40 and 65 in men, and in women at a little later period, he found it more common than valvular disease. But I will go further.

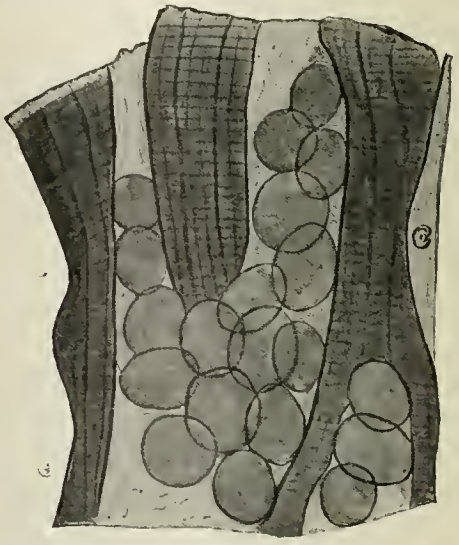

Fig. 5.—Abnormal deposition of fat, x 845.

If to these chronic forms we add all the acute myocardial affections associated with infections, dyscrasias, anemias, intoxications, etc., we can well believe that myocardial disease is more frequent than valvular disease. Other cardiac diseases, however, than the valvular and myocardial are very

rare, while valvular disease is tolerably sure to produce more or less myocardial disease; from which it is easy to see that the latter is the most common form of heart disease, and probably more so than all other forms combined. Schott (*New York Medical Journal*, Jan. 9, 1909, p. 65) says that diseases

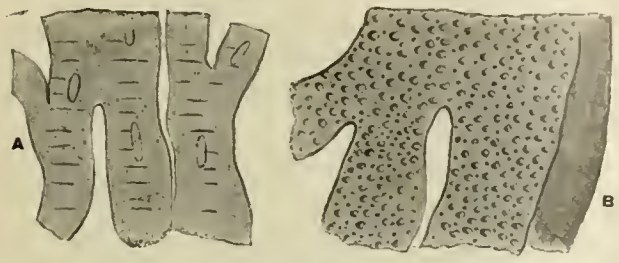

FIG. 6.—Fatty degeneration of cardiac muscle. *a*, beginning changes; *b*, complete degeneration, x 250.

of the myocardium, in comparison with those of the endocardium, are as five to two.

Taking up now the morbid changes of the tissues, parenchymatous alteration is the earliest of all. In diphtheria, for example, it may occur within the first few days, or at any time up to several weeks after the fever has subsided. Acute parenchymatous change is characterized, pathologically, by the occurrence of granules in the muscle cells, and the partial disappearance of the cross-striations. This early parenchymatous change is probably analogous to the "cloudy swelling" seen in the uriniferous tubules at the onset of an acute nephritis. (Fig. 2.) It antedates, I think, every other sign. Though diphtheria appears to be largely responsible for myocardial disease (Schmalz found it in 16 per cent. of his diphtheria deaths), it also occurs in rheumatism, with or without the articular signs; in tuberculosis, tonsillitis, measles, lobar pneumonia, erysipelas, epidemic influenza, septic processes, gonorrhea, and probably in all severe infections and intoxications. The parenchymatous change may be localized or general, usually the latter. Seen with the naked eye the muscle tissue is lighter colored than normal, while the cut surface is lack-luster in appearance, swollen, and moist. Microscopically the muscle cells are enlarged, less translucent than usual, and studded with minute particles derived from the protoplasm of the cells, and albuminoid in character, so far as microchemical tests show. In advanced cases the nuclei are similarly transformed. According to our present ideas, these changes are due either to the toxins of the above mentioned diseases or the continued fever. In alcoholism a similar condition has been noted. The mechanical effect of this change is naturally to limit the contractile powers of the muscle and cause cardiac debility sooner or later; so that the pulse may be increased in frequency in order to maintain the equilibrium of the circulation.

Now, inasmuch as we cannot dissociate these parenchymatous changes, clinically, from those of acute myocarditis that is a somewhat later event in the pathological chain, it will be convenient to describe the latter here. It presents a different microscopical picture. Here the muscle bundles are not only swollen with serum, filled with granules, and opaque, but the muscle striations may be nearly obliterated. Segmentation and fragmentation are said to occur occasionally. (Fig. 3.)

But we must not treat these conditions too seriously. They may be ante-mortem or post-mortem phenomena. (Fig. 4.) In all cases, however, the intermuscular tissue is swollen and infiltrated with blood globules, and the proliferating cells of the interstitial tissues and vascular sheaths.

What we are pleased to call acute myocarditis is therefore a diffuse inflammation in which the muscular tissue is only one of several elements involved. It may be localized or not. Occasionally the process may go on to suppuration. Usually the abscess is embolic and multiple, sometimes due to infective endocarditis, to pyemia, or some other infection. The abscess is usually fatal, discharging into one of the cavities of the heart, or into the pericardium, causing aneurysm, pyocardium, or even rupture of the organ. But the acute form may pass over into the chronic. For example, an acute tuberculosis of the heart walls, which, though rare, does exist, may go over into the chronic form; and so in syphilis and probably in gout, and some other affections. In fact, there is no doubt that in all of these instances the disease which at first originated in the larger cardiac vessels or their perivascular sheaths extends to the interstitial tissues along the lines of the smaller vessels. Even the elastic tissue may be involved, and it is a very important factor in the heart's action, expanding and contracting, and so aiding the muscular tissue.

Among other causes of cardiac hypertrophy apart from severe exercise are arteriosclerosis, congenitally small vessels, scoliosis, Graves' disease, and the neurotic heart of hysteria. In arteriosclerosis of the coronary arteries, the sclerotic process starts from the vessels or their sheaths, and then extends along their subdivisions throughout the heart substance, increasing its thickness and density.

If the congenitally small vessels described by Virchow are present, the muscular tissue of the heart may hypertrophy in order to propel the proper

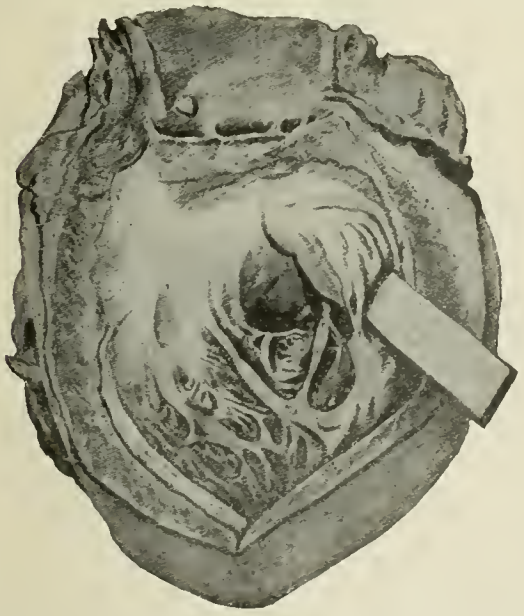

FIG. 7.—Fatty degeneration of heart, with thickened aortic leaflets and mitral stenosis (wooden wedge in button-hole opening), about one-half size.

amount of blood through the narrowed arterial channels. In scoliosis, as is now well established, the heart walls hypertrophy because the movement of blood through the heart chambers is restricted by the narrowing of the bony framework of the thorax, and some pressure must be brought to

bear on the right or left ventricle, as it may be, in order to maintain the circulatory equilibrium. In Graves' disease and in the hysterical heart the increased activity of the organ, due to the neurotic condition, increases the heart's rapidity and, if continued, eventually causes muscular hypertrophy.

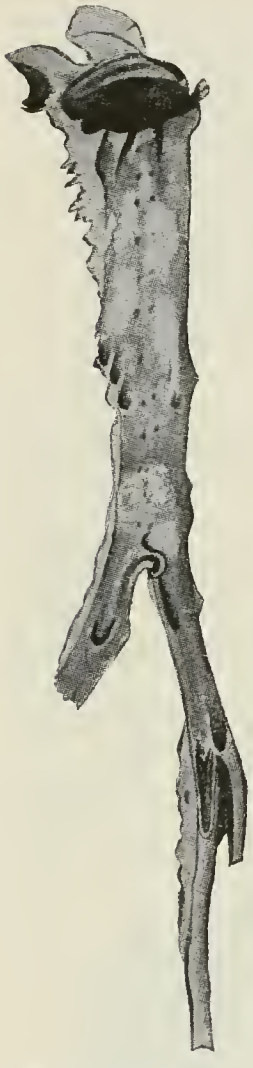

Fig. 8.—Arteriosclerosis of the abdominal aorta, reduced to about one-third size.

The terms fat heart and fatty heart imply some semblance of intimate structure. It is true they are closely allied, pathologically speaking, but in uncomplicated cases there is little clinical resemblance between them, as to natural history, diagnosis, and prognosis. In the fat heart, as we all know, there is a deposition of fat between the muscle fibers or bundles (Fig. 5), while the fatty heart is descriptive of a fatty degeneration of the muscle fibers themselves (Fig. 6).

In the fat heart there will not, as a rule, be any interference with the function of the muscle, though in advanced cases the fat may of itself interfere with the motility of the fibers by external pressure; while in fatty degeneration the protoplasm of the muscle itself has undergone a change that necessarily restricts its energy and may eventually destroy its vitality in whole or in part. There is no doubt, however, that the fat heart tends to degeneration; that is, it is apt to evoke in the muscle against which it presses, degenerative changes; but a fatty heart never becomes a fat heart.

The fat heart and corpulence are so closely allied that we cannot discuss one without the other. Quain, who made a special study of this subject, claimed that patients with fat hearts were invariably corpulent. I should modify his statement by saying that patients with fat hearts are generally corpulent. There is certainly a pretty constant connection between the two. And yet if a corpulent person is reduced by treatment the fat about the heart is apt to remain long after the external evidences of fat deposition have yielded.

On the other hand, beer drinkers and gluttons often put on bodily fat which their hearts do not share. With these exceptions, corpulence and the fat heart are practically coincident.

The fat heart may be said to occur at any age, but is rare in advanced life. For as the atrophic changes of senility set in, the deposits of fat usually disappear at the same time.

Von Leyden has claimed three varieties of the fat heart: (1) When there is a deposit of fat in the heart walls without organic affection of the muscle tissues. (2) A severe form associated with organic muscle disease. (3) A form complicated with disease of the aorta and coronary vessels, perhaps with kidney implication.

I am in doubt as to this third variety. As seen in Fig. 8, disease of the aorta is apt to be associated with the dilated heart of fatty degeneration, not fatty deposition. But there can be little doubt as to the occurrence of the first two varieties. Fatty degeneration, however, is more common than the fat heart. Just at this moment the evidence appears to favor the idea that the oily particles come from without, though it is more natural to believe that they come from within the muscle cells and are sequels to the albuminoid changes of acute myocarditis, especially as they are found in the very class of cases that suffer from acute myocarditis, as in the eruptive fevers, diphtheria, acute rheumatism, lobar pneumonia, influenza, tonsilitis, cellulitis, enteritis, or any acute attack of toxemia; also in chronic intoxications, such as lead poisoning or uremia.

But fatty degeneration (Fig. 7) is also found in wasting diseases like carcinoma and paralysis, in prolonged fevers after mechanical injuries or surgical operations, severe depression of the system, in pregnancy, and in senility. It is important to recognize these facts in order that we may be prepared for a sudden crisis. For when, in the affections named —especially in the toxemias due to diphtheria, in eruptive diseases, cellulitis, suppuration after operations—sudden death occurs, the probability is that the mischief is due to fatty degeneration of the organ, and the cause a toxemia rather than an

Fig. 9.—Bramwell's "withered apple" heart; natural size.

embolism, heart clot, or cardiac paralysis, which in times past were terms used to explain these accidents. In fact we may go so far as to say that diseases of the heart substance in which fatty degeneration plays an important part are the chief causes of death in heart disease.

Predisposing if not governing causes of fatty degeneration, however, are cardiac hypertrophy, fibroid disease, the fat heart, endo- and pericardial diseases, including tuberculosis, new growths, and arterial disease; overexertion, overexcitement, abuse in eating or drinking, very likely anemia. It is unfortunate that coronary arteriosclerosis has been regarded by some as the main predisposing factor in fatty degeneration. Evidence does not sustain this view. Coronary arteriosclerosis is, in my opinion, one of the rarer causes of fatty degeneration. While it may occur at any age, the grosser forms are certainly associated with other degenerative changes that are the concomitants of senility. It is certainly more common in advanced age than middle life. So that being both the most dangerous form of heart disease and comparatively frequent, the importance of an early and correct diagnosis is apparent.

Fig. 10.—Callosity at apex of heart in a case of purpura hæmorrhagica, about one-half actual size.

Unfortunately, its diagnostic features are not strongly marked, and in mild cases may be absent. In fact, there may not be any appreciable dilatation, and this is the one sign of paramount importance.

I have little to say about cardiac syphilis. It has been known to exist for more than fifty years, but my experience has told me that the danger of it has not been appreciated. One reason is that it usually occurs very late after the initial lesion, even 8 to 10 years, when the patient has begun to forget that he ever had the disease; or if he has had it, has thought it cured. It should also be remembered that cardiac syphilis may be hereditary. Some years ago I found from my clinical records that syphilis positively existed in five per cent. of my heart cases and probably in five per cent. more. I hold to this position still. Certainly there is a class of heart cases with a previous syphilitic history, or perhaps with locomotor ataxia, or some other affection of the central nerve system, where treatment will be ineffectual without the use of mercury or the iodides.

Atrophy of the heart occurs, but is comparatively rare. It may be a family peculiarity, or due to arrest of development, starvation, or some wasting disease, such as cancer or phthisis, or simply old age, when it is to be regarded as physiological. The atrophic heart has been known in adults to weigh only about three ounces, in fact a little less. These hearts in uncomplicated cases have a dark reddish-brown color and are in the condition that has been called "brown atrophy." The muscle fibers have yellow-brown pigment about the nuclei. Sometimes the organ is so shrunken that its vessels are thrown out into relief, "the withered apple heart." (Fig. 9). But there are no very distinctive physical signs of it during life. Of course, in uncomplicated instances, the heart's area will be smaller than usual. Otherwise the signs that have been described, such as faint turns, singing in the ears, palpitation, irregular pulse, precordial distress, and confusion of mind, will be suggestive, in conjunction with the diminished area, but they cannot be called pathognomonic. However, any one of us may be called in to see such a case, and the diagnosis will be made with reasonable certainty, if the heart is anatomically small in old age, or in any of the affections mentioned, especially if the pulse is weak and irregular, and there are fainting turns with cardiac distress. Such a heart came under my observation at a meeting of the New York Pathological Society, some years ago. It was taken from the person of a young man who died of sarcoma in the practice of Dr. R. E. Van Gieson. The heart weighed less than five ounces. In Bramwell's female cancer patient, the heart weighed only two ounces, twelve drachms, and ten grains. Fig. 9 is a life-size copy of Bramwell's case. According to Gibson, Quain knew of a more remarkable instance in a girl of fourteen, whose heart weighed only one ounce, fourteen drachms.

Fig. 10 is the heart of a female patient of mine who died at St. Luke's Hospital of purpura hæmorrhagica. The subserous hemorrhages are seen beneath the endocardium. There were similar effusions beneath the submucous tissues of the intestine and uterus. She had been under my care previously for a double lobar pneumonia, and had recovered without leaving any permanent fibrous adhesions in the pleural cavity, so that the idea then prevailing that fibrous pleurisy is never recovered from was disproved. At the postmortem was found (Fig. 10) a cardiac callosity, or invading fibrosis, which, as no other explanation offered, may perhaps have resulted from a previous pericarditis.

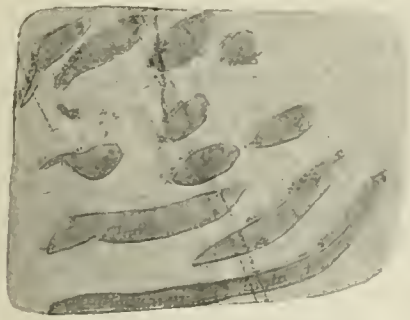

Fig. 11.—Fibroid invasion of the myocardium, x 210.

In Fig. 11 we see how an invading fibrosis can squeeze the muscular tissue.

Another method by which cardiac fibrosis develops is shown in Fig. 12. Supposing that in aortic endocarditis, as in Fig. 7, a particle is dislodged and finally arrested in a coronary artery; an infarct (white) may result. For the coronary vessels, though not terminal as in the brain, have really very slight capillary connections,

and the plugging of an arterial branch may cut off from the neighboring territory so much blood that it is practically starved to death. As a consequence, the muscle tissue involved (with such vessels as exist) atrophy, and the whole area is supplanted by fibrous material. The cardiac walls are then correspondingly weakened, and lose a portion of the tissue which regulates the contraction and expansion of the organ.

The life of cardiac hypertrophy consists in a gradual thickening of the heart's tissues, with dilatation and enlargement of the muscle cells; perhaps an increase in their number.

During this period, which may be called the first stage, the pulse is irregular, but its strength increases, the accentuation of the second pulmonary sound at the base indicating that the right ventricle has become enlarged. This stage is completed when the hypertrophy has been sufficient to propel the blood column with the required amount of force.

The second stage is marked by a return of the action of the heart and pulse to their normal conditions. This stage may continue indefinitely, so far as we know.

If, however, the dilatation increases, as it may from various causes, we then enter upon a period of failing compensation. This is the third stage. But now a sudden further dilatation will mean heart failure, and, if no relief is given, immediate death. Loss of rest, excitement, insufficient nourishment, unusual exposure, sudden strain, may, any one

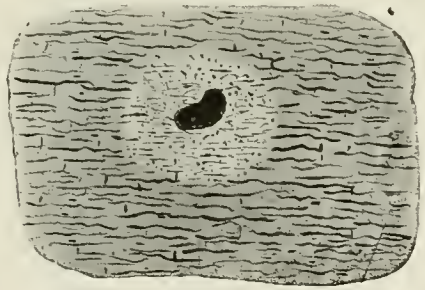

Fig. 12.—Cardiac fibrosis and the white infarct, x 67.

of them, cause sudden dilatation of the heart and death. And yet we should remember that cardiac hypertrophy itself is in all instances a benign process, devised by nature to relieve a worse condition. For in all these cases, even in the hypertrophied heart of an athlete, the muscular tissue has doubtless been reinforced in order to restore the tone of the organ, in recompense for a strain, or in other words a laceration.

The diagnosis should present little difficulty. Except in very stout persons or women with pendulous breasts, the outline of the heart can usually be made out with sufficient accuracy. Even if it cannot well be defined, the apex beat can be located by the stethoscope.

Cardiac hypertrophy therefore indicates the existence of some systemic primary defect or disease, that governs the prognosis; unless there happens to be some intercurrent incident or accident to provoke heart failure. Cardiac hypertrophy in nephritis should not, of course, be taken too seriously; the nephritis is the chief danger. But the athlete's heart is more liable to suffer from excitement or sudden strain than the normal heart, so that he should be warned, in order to guard himself against sudden dilatation. In mild cases, however, the hypertrophy may entirely disappear.

A patient of mine out hunting suddenly realized that he had strained his heart in attempting to roll over a heavy log to build his camp. He was a physician, and was fully alive to the fact that his heart had been permanently disabled. Subsequently, under a sudden dilatation from a cause incidental to the life of any busy practitioner, he was taken off without warning. The fatal issue in his case could hardly have been avoided, so long as he discharged the duties of his very responsible and arduous position.

In my experience, also, a patient may suffer for years from a severe strain, and ultimately recover from it. A male patient of mine, twenty-eight years of age, has almost recovered from a severe cardiac strain which happened six years ago.

In any case of suspected dilatation, it is extremely important to determine how much hypertrophy is present, certainly to the extent of noting the altered location of the apex beat or sound. Dilatation is, as we all know, characterized by a soft, weak, and irregular pulse, which is usually more rapid, unless the nervous system is implicated, or there is renal toxemia. The dilatation may be more or less extensive. But, clinically speaking, if the left margin of the heart does not extend beyond the nipple, it is not an alarming sign; if much beyond that point, the prognosis is unfavorable. In mild cases, however, the dilatation (as shown by the apex beat) will not reach to the nipple.

If, now, in the course of or after typhoid fever, diphtheria, or any of the acute or chronic toxemias mentioned, the pulse becomes weak and irregular, no matter what its rapidity, attention should be directed to the probability of some myocardial affection, and if there is precordial distress, or cyanosis, dyspnea, some edema, or, in extreme cases, anginoid attacks, a diagnosis of acute dilatation can be made with a reasonable degree of probability, which will amount to a certainty, if it is found that the heart's dimensions have suddenly been enlarged.

In such instances we should give the heart, as far as practicable, relief by rest in bed; for the horizontal position relieves the weakened heart, the diminished number of cardiac contractions accomplishing the same as a greater number when the body is vertical. If the parenchymatous change is associated with a pyrexia, sponging of the surface with alcohol and water will reduce the temperature, while there may also be a field for an antipyretic drug, such as aconite in small doses.

In apyretic cases, as in the various forms of chronic cardiac disease, it is more logical to relieve the peripheral pressure by warmth to the extremities, or by the use of nitrites or nitrates, than to stimulate the heart. For whatever temporary gain may be obtained for the tired heart by a cardiac compressor, cardiac activity will diminish as soon as the physiological effects of the drug have passed away.

We should also hesitate to give drugs merely for the purpose of lowering or increasing the pulse rate, because the rate may be adapted to the pathological condition. Through the influence of the nerve centers, central or peripheral, there is always a compensatory action of the heart, adapting its speed or pressure, more or less certainly, to varying conditions. Of course, when the acute symptoms have received proper attention, no time should be lost in endeavoring to eliminate the toxins (if there has been toxemia), by such means as are

calculated to remove or nullify the primary cause of the dilatation.

Von Leyden's views as to his first two varieties of the fat heart are valuable. In the first of them there may be shortness of breath, asthmatic attacks, and a rapid pulse, even when the heart muscle is not involved, caused by the extraordinary efforts made in the movements of the obese, owing to mechanical interference of the various fat deposits with respiration and circulation. Such persons seldom live to old age and succumb very easily to intercurrent infective diseases. This form, however, is curable under appropriate treatment, such as baths, exercises, gymnastics, and diet. But under certain circumstances, such as psychic disturbance, overeating or drinking, or training, it may pass into the second form.

In his second form* the prognosis and treatment are different. The prominent symptom is heart weakness, with precordial distress at any time, and orthopnea, while the blood is apt to stagnate in the veins, and there is cough and bloody expectoration, swelling of the liver and atrophy. The heart dilates, but the auscultatory sounds vary. The normal sounds are weaker, however, the apex beat less easily recognized; or there is a splitting of the sounds, or sometimes a systolic murmur at the apex due to muscular weakness at the mitral. The second sound above the aorta is usually stronger than the pulmonary. The action is also arhythmic, showing a defective action of the left ventricle. The pulse is small and irregular, but may be slowed or hastened.

When arteriosclerosis is detected in the peripheral vessels; or the contracted kidney by urinary analysis, we can realize that a fat heart already weak is meeting increased resistance which must tend to dilatation and heart failure.

Passing over its etiology, the diagnosis of the fat heart is comparatively easy, though always a matter of inference. It cannot be determined by physical signs. However, as Quain says, in stout people when the pulse is small and weak, the first sound feeble, the impulse weak, and the heart's area enlarged, it may be judged that there is a fat heart, with a fair degree of certainty.

So far as treatment is concerned, it does not present much difficulty, provided the patient takes his condition seriously, and will faithfully carry out some rational plan. A physician, seventy-six years of age, weighing 377 pounds, and unable to walk without assistance, I reduced over forty pounds in a few months, with very little difficulty, relieving his rheumatism and chronic eczema, so that he was able to resume, to some extent, his outside practice. He took several courses of the Nauheim treatment, and adhered to the rigid dietary I laid down.

Some, however, women especially, are quite willing to take any prescribed course, provided only their dietary is not restricted, and consequently treatment with them is a failure.

My dietary avoids fat meat, bread that contains much starch, and coffee, but includes often the use of sodium bicarbonate, advocated by Trousseau. I have found that my plan will reduce at the rate of from four to ten pounds a month, a rate that is sufficiently fast. Nor does it preclude tonics, wine, or other stimulants in moderation. As a matter of fact I have not had occasion to use alcoholics. My dietary is as follows:

*Russ. Med. Rundschau, 1907, S. 276.

8 A.M. Breakfast; three ounces lean meat without fat; one ounce gluten or whole-wheat bread, toasted; a cup of postum with milk, or lemonade.

10.30 A.M. A cup of beef-tea.

1 P.M. Five ounces of lean meat or fish; salad with French dressing.

3.30 P.M. Eight ounces of milk and Vichy water (half and half).

6 P.M. Three ounces of rare meat or fish, with pickles or salad; one ounce graham bread, toasted; stewed fruit.

8.30 P.M. Eight ounces of milk and Vichy water (half and half).

Vichy or plain water can be taken as desired during the day. This is not a severe dietary, as compared with some that have been recommended.

The general principles under which I practise reduction are restriction in the amount of sugar, starches, and fats eaten. Enough water should be taken to cause the normal amount of urea to be excreted. Oxidation should be increased by resistance exercises and by carbonated baths, which stimulate the skin and so improve the capillary circulation. Tea and coffee appear to restrict oxidation, and should for that reason, if for no other, be prohibited, or taken in extreme moderation.

Acid fruits and drinks should be taken very sparingly. An excess of them produces indigestion. They are better cooked. Sometimes all fruits should be forbidden.

In general, however, small fresh fruits may be taken with discretion, in their season. Sometimes the amount of both liquids and solids has to be much reduced. Laxatives should be taken so as to produce two full fecal movements daily; and stomachics also, if indigestion is acute. The patient should also take regular walks on level ground, of a given distance, and the distance should be gradually increased. Carbonated baths and resistance exercises are also valuable as auxiliaries in the treatment. But the vitality of the patient should never be reduced. On the contrary, it should constantly increase.

Stubborn cases may require the use of the hot box, or some other form of hot air apparatus.

With these methods it is practicable to reduce the weight without detriment to the general health.

In any case, however, before instituting treatment we should determine whether the fat heart belongs in Leyden's first or second class, and order the treatment accordingly. Obesity after middle life should be handled with extreme caution. A few years ago a contractor past middle life consulted me for heart weakness associated with obesity. He was leading an active out-of-door life. I put him on a restricted dietary, directed him to lead a less active life, and advised him of danger, in case he neglected my warnings. He did not visit me again, and within two weeks fell dead, dancing at a ball.

This man was to external appearances in robust health, notwithstanding his obesity. The lesson from such a case is obvious. As old age approaches the danger to life advances progressively in obesity, so that after middle life, as I have said, we should always be cautious in the treatment of these patients.

Romberg maintains that coronary disease is the most frequent cause of fatty degeneration, and that the diagnosis of coronary disease as its cause is certain whenever there is angina pectoris or cardiac asthma with sclerosis of the aorta, in a person over forty years of age. In this country most attacks

of angina pectoris are held to be of nonorganic origin. This is my view. Sclerosis of the aorta cannot be positively determined during life, and cardiac asthma is common to heart failure in any heart affection.

Some years ago I divided fatty degeneration into three stages, making the pathological changes conform to the clinical signs, and gave instances of each, as proved by my post-mortem examinations. According, however, to more recent views, the first fatty changes I then described are to a certain extent coincident with changes of an inflammatory nature, as in typhoid, and subsequent investigation may show that the changes I then described are secondary to more acute manifestations, so that my first stage of fatty degeneration was coincident with inflammation of the heart walls. This is a matter that requires further study. In my first stage, (the period of acute myocarditis of some) the duration is not long (as in the eruptive fevers, typhoid, or other acute toxemias), and the symptoms, such as a weak and intermittent pulse, feeble beat, or distant sound at the apex, with faint tones, and more or less dilatation, precordial pain and distress, will mark the first stage.

These signs I noted as early as 1879 in a fatal case of yellow fever that occurred at the Presbyterian Hospital, when I was pathologist to that institution. Of this I have my post-mortem and laboratory notes. In this stage the heart may stop; not, however, from the fatty degeneration observed by Hayem in the sudden death of typhoid fever, but from the toxemia, causing defective innervation. For the central nerve system regulates the action of the heart, though it may have nothing to do with its rhythmic activity. To put it physiologically, the contraction and relaxation which characterize the rhythmic action of the heart are due to the interaction of an alternating kind between the sodium, potassium, and calcium ions, and the contractile substance of the heart muscle.

In the second stage, the signs of a dilated heart are more pronounced. The left ventricle may reach to the left nipple, or extend beyond it; the right ventricle an inch or more bevond the right border of the sternum. The apex may be in the fifth, sixth, or seventh space, and the apex beat feeble. The pulse will usually be soft, intermittent, and infrequent. There may be, and often is, a lack of harmony between the heart and pulse-beats. These manifestations of arrhythmia are apt to be seen in persons who have passed middle life, and are inclined to be stout, but are at the same time anemic. In these instances there is often a distinct whiteness about the face, which is a noteworthy sign. This is common among the upper classes, especially with those who lead a rather inactive life.

The apex beat will be located with difficulty, or not at all. There will be dyspnea and some precordial oppression, with occasional attacks of dizziness. Abdominal symptoms will always be in evidence; occasionally gastric crises alternating with anginoid attacks. Cyanosis will occur at times. Such patients will often be irritable or whimsical, or nervous about trifles, and always concerned about their health. There will be a disinclination to undertake anything new, even to walk, and the gait may be uncertain. Occasionally, there will be hemorrhages, usually in the form of epistaxes. Edema of the face, hands, and feet will occur at times. Independent of valve murmurs due to obstruction, there may he systolic murmurs from leakage at the mitral, and if there is hypertrophy of the right ventricle, there will be accentuation of the second pulmonary sound. If acute dilatation takes place there will be precordial distress, pain, and dizziness, or a faint feeling. And there will be sharp anginoid attacks, if the dilatation is very acute.

If there has been corpulence it will help in the diagnosis; also if there is dyspnea after exertion.

Other signs which I regard as very important are—that the apex beat is not to be detected in persons of otherwise normal build; also, that the patient must sleep high at night with several pillows, or resting on his arms.

The urine may contain a little albumin and often a little sugar. This stage may last from two or three, to ten or fifteen, or even twenty years, depending on the degree of the degeneration and the ability of the patient to care for himself intelligently.

In the third stage there is implication of other organs. For example, there may be attacks of cerebral thrombosis or embolism due to abnormal heart action; or thrombosis of peripheral veins, but the circulation may be reestablished, and the patient resume an otherwise tolerably active life. Or, from a variety of causes, perhaps from indigestion, there may come a fatal attack of heart failure. Or, in old people particularly, a low form of meningitis, usually basilar, will develop the Stokes-Adams group of symptoms, with possibly the so-called "heart block." And yet even here the symptoms may yield and life be continued for months or even years, as in one of my cases of the Stokes-Adams type. Finally rupture of the heart may occur. But it must be exceedingly rare. Nephritis is the common terminal affection.

In the first stage the patient should be treated by rest and an appropriate but rather restricted diet, and general tonics, among which strychnine should have some part. It should be given in small doses, say from 1/50 to 1/60 of a grain, for adults, and should not be administered continuously for more than two weeks at a time. This, I hold, is important.*

In ordinary cases of fatty degeneration the patient, if anemic, should be put on iron: if tuberculous, on malt preparations and creosote or cod-liver oil; if arteriosclerotic, on the iodides; if rheumatic, on an antilithemic diet and antilithemic remedies, in conjunction with the hot-air treatment.

In the second stage the Nauheim system is appropriate in selected cases. In the third stage, where all hope of cure is at an end, the use of strophanthus and drugs of the digitalic group, the nitrites and nitrates, including glycerol nitrate and erythrol nitrate, camphor, and finally oxygen gas, have each their distinct fields of usefulness.

There is a tendency, however, to use adrenalin in these cases, so that the experiments of R. M. Pearce (Studies from the Bender Hygienic Laboratory, Vol. III., 1906, p. 51) should serve as a warning. Injecting 1/10 to 8/10 of a cubic cm. of this drug into a series of rabbits, sufficient to cause death sooner or later, the heart muscle showed more or less edema, and in one instance wide separation of muscle fibers. In another series, each rabbit heart was dilated, while there was granular and hyaline degeneration of the fibers, and some were necrotic. Adrenalin contracts the arterioles, and it is conceivable that the contractions of the coronary and other vessels produce temporary ischemia in the heart walls. In some of the

*"Diseases of the Heart," etc., N. Y., 1905.

rabbits there was a diffuse myocarditis. To be sure, adrenalin produces prompt physiological results when injected into a vein. But I have seen five minims of an intravenous 1/1000 solution, (1/200 grain) produce distressing symptoms in a patient, causing a blood pressure of nearly 200 in forty seconds, and a coresponding fall in from one to two minutes.

I have, however, been in the habit of employing the suprarenal extract in doses of one to three grains of Armour's powder, in capsules, three times a day, as a substitute for glycerol nitrate in the weak heart, and have found it useful, and have observed no bad effects from it. But in reference to the adrenalin chloride, we must realize that there is a lack of constancy in its action. I am prepared from my experience to say that the same amount given to the same person will not always have the same effect. These statements are confirmed in a measure by two blood-pressure charts of T. C. Janeway. (Clinical Study of Blood Pressure, 1904.) In one, ten minims of a 1/1000 adrenalin chloride solution were injected into the substance of the tissues. No effect was produced. In another case, twenty minims of the same strength were injected into the median basilic vein. In fourteen minutes the pulse had risen to 145 and the pressure to 225, but the latter had fallen at the end of thirty-three minutes to 55, and, in fact, no pulse was palpable, when it was found necessary to inject two grains of caffeine sodium salicylate, strychniæ sulphate, etc., to restore pulse and pressure.

I recently saw, in consultation, a patient where, in my opinion, the fatal issue was hastened by adrenalin. Physicians should, therefore, be on their guard against the internal administration of this particular preparation; viz., the adrenalin chloride. Its prompt action in surgical shock should not blind us to the fact that the primary action is followed by a dangerous depression.

So far as prognosis is concerned, in myocardial diseases, we must assume from analogical reasoning, together with clinical experience, that parenchymatous changes, if not excessive, can disappear with convalescence, and yet, by analogy, we must equally well hold that they can lead up to acute diffuse myocarditis; and may terminate in fatty degeneration also. In very many cases, however, we know that the patients recover wholly; at least so far as we can determine by clinical tests.

The same process of reasoning leads us to believe that even in acute interstitial disease the fibroid deposits may at times disappear entirely. So in tuberculous myocarditis there may be a disappearance of all signs of the tubercles, as in tuberculous peritonitis. The same may be said of syphilis. Moreover, a moderate degree of fatty degeneration is present in almost every adult heart, and if the post-mortem examination displays the so-called "tiger's heart," where the striations of fatty degeneration show in places through the transparent endocardium, one would hardly call it abnormal.

Reverting for a moment to cardiac syphilis, Huchard has claimed that angina pectoris is an important sign. This has not been my experience. Herzog's three signs are light precordial pain up to angina, tolerably rapid cardiac enlargement in young people or persons of middle age, with aortic insufficiency. Whether these points have value, time only will determine. Certainly organic disease of the arch of the aorta, or any thoracic aneurysm, would point towards syphilis. But cerebral signs are also suggestive. I had some years ago under my care a physician of New York past middle life, who gave no subjective specific symptoms of syphilis, but had suffered from chronic cerebral pains, in connection with his cardiac disease. A thorough course of mercurials and iodides, together with Nauheim baths and exercises, put him on his feet, and he is now, or was until quite recently, actively at work. So that the prognosis is not altogether bad. If the diagnosis is made early and the proper treatment instituted, success may be expected. In fact, there is no reason why a cure cannot be made. Even in advanced cases, where there is tabes dorsalis, for example, great improvement can sometimes be effected. Iodides and mercurials are the proper remedies, but mercury is the sheet anchor. Sometimes both of them should be given for months, with brief interruptions of a few weeks.

Apropos of the diagnosis of cardiac insufficiency as shown by the soft, rapid, and often intermittent pulse of myocardial disease in general, it is well to remember that there may be persons whose hearts functionate sufficiently well, until they are subjected to some special strain, physical, mental, or psychic. Then the insufficiency is apparent. Often a few steps about a doctor's office is all that is required. To determine the amount of this weakness various methods have been tried for more than a century. In fact, the determination of the functional capacity of the heart is a matter of very great importance, not only from the point of view of diagnosis, but for the purpose of controlling the effects of treatment. But the methods used have been open to so much criticism that internalists have usually given the subject a pretty wide berth. The first material advance was made by Spengler, in 1887, when he noted the effect on the pulse in typhoid fever convalescents after exercise and change of posture. Of all the methods proposed, three may be taken as examples of the most recent that have been published.

Katzenstein's, published in 1905, consists in compressing the femorals or iliacs below Poupart's ligament and noting the effect on the brachial artery. In healthy persons he has claimed an average rise of 5 to 15 mm. Hg. in from two to five minutes, as shown by the sphygmomanometer. In weak hearts, he has reported that the pressure either rose slowly or not at all, or fell, according to the grade of weakness present.

As to the accuracy of the method, reports have differed. In acute cases it is, of course, inapplicable. Compression of these vessels is not an easy task; an assistant is necessary to take the pulse. In ordinary private practice, a patient might very reasonably object to the procedure.

Herz has proposed a more practical plan—counting the pulse long enough to determine its average rate per minute. He then has the patient sit down and slowly flex and extend the right forearm, continuing the movement a minute, without contracting the muscles to any marked extent, the physician controlling the flexion and extension, but not using any force. In the normal heart the rate is not affected, but in the weak heart it is slowed from five to twenty beats per minute.

The older method of Schapiro (*Deutsche med. Woch.*, Feb. 9, 1905, s. 215) is another good one that should be practised more than it is. The pulse is taken first in the recumbent and then in

the sitting position. In health, there is an increase of frequency when the individual has assumed the sitting posture (after lying down) of from three to ten beats per minute. In the weak heart, there is an absence of or a diminution of this frequency in changing from the recumbent to the sitting position. I have used this method for the past two years, with a fair degree of success.

We have no better methods available than those of Herz and Schapiro, and, inasmuch as they are simple, practical, and fairly reliable, we should use one or the other to test the functional capacity of the heart, certainly until something better presents itself.

THE CRUX OF THE TUBERCULOSIS PROBLEM.*

By LAWRENCE E. FLICK, M.D.,

PHILADELPHIA, PA.

The crux of the tuberculosis problem is prevention of implantation. Without the tubercle bacillus there can be no tuberculosis, and without implantation there can be no new cases. There are many predisposing causes to tuberculosis which facilitate implantation and growth, but they are secondary, and in their greatest potency cannot produce the disease. On the other hand tubercle bacilli when scattered about freely enough may produce implantation without any of the predisposing causes. In other words, there is no environment, however bad, no poverty, however degrading, no hardship, however great, which can produce tuberculosis in the most susceptible person unless the tubercle bacillus is there to be implanted; and there is no environment, however good, no wealth, however ennobling, no ease, however sparing, which will prevent tuberculosis in the most resistent individual, if enough bacilli are continuously scattered in his whereabouts for a long enough period of time. There, no doubt, are individuals who can resist the development of tuberculosis to a fatal termination under any amount of exposure, but in such cases implantation probably takes place and dies out.

As there is only one essential cause of tuberculosis, so there is only one positive prevention of it. Prevention of implantation is positive; improvement of sanitary, sociological, and financial conditions is problematical. When these are bad they predispose to tuberculosis and their improvement may contribute to prevention but cannot in itself prevent the disease. These facts should be kept in mind in selecting measures when financial resources are limited.

Incarceration and destruction of the tubercle bacillus at the time and place of exit from a host without contamination of person, place or thing constitutes the essential element of prevention. This can be accomplished in consumptives by depositing the broken-down tissue in a paper box or cup while holding it close to the mouth, wiping the mouth with a paper napkin, folding up the paper napkin and placing it in a paper bag and finally burning the sputum box, paper napkin, and bag. Such a practice makes a tuberculous subject non-contagious and implantation from him impossible. The prevention of tuberculosis in its last analysis consists of making every person suffering from tuberculosis in a contagious stage follow this practice.

*Read before the Medical Association of the Greater City of New York, March 21, 1910.

What constitutes a contagious tuberculous subject? This question may be answered in a theoretical and in a practical sense. Theoretically every person who has tuberculosis and gives off tubercle bacilli is contagious. All persons with tuberculosis do not give off tubercle bacilli. As a rule the tuberculous subject does not give off tubercle bacilli until he has an open tuberculosis or ulcerative process. Exceptionally a tuberculous subject may give off bacilli in the urine through the kidneys without ulceration. It also has been claimed that a tuberculous subject may give off tubercle bacilli by the bowel, and through the secretions without ulceration, but the most recent investigations make this doubtful. Practically, a tuberculous subject is contagious when he gives off tubercle bacilli in sufficient numbers and continuously enough to produce a contagious environment capable of giving an implantation.

Tuberculosis is a contagious disease technically and practically. To get a clear idea of the contagiousness of tuberculosis one must learn to think about contagious diseases in a botanical sense. This is the only way in which one can reconcile the application of the word contagion at the same time to such diseases as measles, scarlet fever, smallpox and tuberculosis. The thistle and the corn are propagated in the same way, namely, by the production of seed and its deposit in soil. When the thistle ripens its seed is scattered far and wide by every current of air, and its distribution cannot be restricted except by placing an enclosure around the stalk and thus shutting off all soil. When the corn ripens the seed is enclosed in a husk and is fastened to a cob which is securely attached to the stalk. Unless assisted artificially it finds its way into the soil with much difficulty. The elements ultimately release the cob from the husk and the seed from the cob and the air currents carry it into the soil, but much time is consumed before this can be accomplished and, meanwhile, the corn can easily be taken from the field without scattering a single seed and destroyed. Measles, scarlet fever, and smallpox are like the thistle. The seed is scattered by every current of air and is deposited in all soil within reach. Prevention of the spread of these diseases can only be accomplished by keeping susceptible people away from them. Tuberculosis is like the corn. Its seed is given off in coarse, broken-down tissue, which has to be macerated and triturated by the elements in order that it may be distributed by the air currents, and which can easily be destroyed without dissemination before it can become macerated and triturated. One who knows how to handle a consumptive can be about him continuously from the beginning of his contagion to the time of his death without any risk of implantation.

Herein lies the secret of the prevention of tuberculosis. Every contagious case of tuberculosis should be placed in the custody of some one who knows how to dispose of the broken-down tissue which is given off without contamination of person, place, or thing and destroy the life in it. General directions to take care of the sputum are insufficient because they are seldom understood well enough to mean anything in practice. To most people they mean spitting into handkerchiefs, rags, and spittoons with contamination of clothing, bedding, floors, and furniture; the very thing which should not be done. Many half-informed people conscientiously refrain from spitting on the street

where the sputum could not produce an implantation, a practice which nevertheless should be discouraged, and deposit their sputum in a handkerchief then place the handkerchief in a pocket of their clothing, thereby contaminating their clothing; and at home they spit into a spittoon, into a toilet-bowl, or receptacle of some kind at a distance from the body and in the act spray the sputum over their clothing and upon the floor and furniture. Self-satisfied that they are taking every precaution against the spread of the disease they produce conditions dangerous to themselves and capable of giving implantations to others. Often they believe they are religiously following the instructions of the doctor, and in a sense they are, as the instructions are usually so general and indefinite that it is impossible to gather from them just what is necessary for safety.

It is probable that all ambulant cases of tuberculosis can be made non-contagious outside of their homes by such education and training as can be given them in the dispensary and in the office. Nearly all of them, however, gradually produce a contagious environment in their homes, and as the disease advances, unless under supervision, a contagious environment of high potency. The data bearing upon tuberculosis now at our command indicate that mere casual contact with the tuberculous subject, mere momentary existence in a place in which there are tubercle bacilli outside of a host, nay, even intermittent contact with a tuberculous subject, and intermittent existence in a place where there are tubercle bacilli outside of a host when the intervals are fairly long do not ordinarily give an implantation. The death-dealing powers of the elements, the physical impediments to entrance of bacilli-bearing matter into the organism and the disease fighting powers of the tissues of the body militate against it. Every person has his own measure of resistance to the tubercle bacillus, and this is increased by the struggle of the organism against the bacillus so long as the number of bacilli which gain admission remains within the capacity of the organism to resist. It is only in the home and in the workshop where the consumptive lives that a contagious environment is produced of sufficiently high potency to overcome the resistance of the average individual. The nearer the death point of the patient the higher the potency of contagion, so that it is probable that most new cases are implanted during the terminal stage of old cases.

This conclusion is supported by the ratio of developed cases to exposures. At present the number of new cases is less than the number of cases which prove fatal. Even before preventive measures were put into practice the number of new cases apparently did not exceed the number of fatal cases as the death rate did not increase. It is probable that the average duration of tuberculosis in human beings from implantation to death is at least ten years. During the greater part of this time it is non-contagious or intermittently contagious. The average time of contagiousness of sufficient potency to give an implantation is probably about six months. For every fatal case of pulmonary tuberculosis on an average three people have been exposed to what may be called a competent contagious environment in the home of the patient. To this must be added the number exposed in the workshop where advanced consumptives often work until they can stand up no longer and in houses which have been vacated by advanced consumptives who frequently change their places of residence. With these added it is probable that for every fatal case of tuberculosis on an average five people have been exposed to a competent contagious environment, and yet it is evident that out of five opportunities for implantation less than one implantation of sufficient vitality to terminate fatally takes place.

May we not conclude from these facts that in everyday life implantation of tuberculosis ordinarily takes place only in a competent contagious environment, and that for the prevention of the disease we may rest content with seeking out all competent contagious environments and abating them. Every fatal case may produce a competent contagious environment during the dying stage of the disease when besides the intensity of contagion we have the lowered resistance from sorrow, want and hardship, which follow in the wake of the disease, as it reaches its terminal stage. By supervising the stricken individual during this terminal stage we probably have it in our power to prevent new implantations.

The history of the progress of tuberculosis throughout the civilized world confirms the correctness of these deductions and would in itself force us to the conclusion that for preventive purposes all our efforts should be concentrated on making the terminal stage of the disease non-contagious. Whenever and wherever an effort has been made to remove the consumptive in the advanced stage of the disease from the family circle and put him under control there has been a reduction in the death rate from tuberculosis commensurate with the amount of work done, and in no place where isolation has not been practised has there been a very perceptible reduction in the death rate. It is true a gradual reduction in all parts of the world has followed immunity from prolonged exposure to the disease, improved conditions of living, and advancement in civilization, but this is in striking contrast with the reduction which has followed isolation where isolation has been practised.

In the Kingdom of Naples isolation of consumption was legally instituted in 1782 and was strictly enforced for at least half a century with a drop in the death rate from possibly 10 per thousand to approximately 1 per thousand—from what was looked upon by the whole world as a scourge to almost a complete extermination of the disease. In London following the establishment of consumption hospitals with isolation of contagious cases the mortality from tuberculosis dropped from about 5 per thousand to less than 2 per thousand between 1848 and 1910. In Germany, following the establishment of hospitals and sanatoria for the treatment of tuberculous subjects in all stages the mortality dropped from 3.7 per thousand in 1885 to 1.72 per thousand in 1906. Everywhere in the world where the consumptive has been isolated there has been a reduction in proportion to the isolation. In Paris where there has been no isolation of consumptives practically the same death rate exists as one hundred years ago, and in Austria, next to Italy, with practically the same climate where there has been little isolation, there is still a death rate of between 5 and 6 per thousand in some parts and nearly 4 per thousand for the whole country. So closely does rapid reduction in the mortality follow isolation of advanced cases that one cannot doubt the relationship between the two, and it is possible to work out ap-

proximately the relative ratio between them. One can almost calculate mathematically what the relative preventive value of isolation of a given number of cases would be during a given period of time and how long it would take to stamp out the disease in a given community with a certain definite isolating capacity for that community. In a careful analysis of the influence of the work of the Henry Phipps Institute in Philadelphia on the mortality from tuberculosis in that city it was found that the preventive value of isolation was by far the best of that of any of the work done by the institute.

How are we to isolate advanced consumptives? The most sensible way would be to admit them into separate departments of general hospitals. This could be done without danger to anyone and at relatively small expense for alterations. In Pennsylvania there are enough vacant hospital beds every day in the year to isolate all the advanced consumptives in the commonwealth, and what is true of Pennsylvania is probably true in some degree of other commonwealths. It is a waste to spend money for new equipment when adequate equipment already exists, and the money which is expended in this way ought to be used for maintenance. The Neapolitans over a hundred years ago, although they had the most exaggerated ideas about the contagiousness of consumption, successfully isolated their cases in their general hospitals. According to DeRenzi, out of 5,282 admissions into one of the general hospitals in Naples in 1828, 1,108 were consumptives and out of 1,366 deaths which occurred in that hospital during that year 699 were from consumption. One of the chief advantages in opening up the general hospital to consumptives is in the location of such hospitals in the centers of population near the homes of the people from among whom the stricken ones are to be taken. The poor are loath to permit their dying relatives to go beyond walking distance of their homes and the sentiment which is at the bottom of their objection must be taken into consideration in any broad scheme for isolation. It is much easier to isolate with the cooperation of the public than against its obstruction.

738 Pine Street.

PHTHISIOPHOBIA.*

By JOHN H. LOWMAN, M.D.,

CLEVELAND, OHIO.

PROFESSOR OF CLINICAL MEDICINE IN WESTERN RESERVE UNIVERSITY.

Fear has undoubtedly been one of the greatest promoters of human progress. For to fear an enemy is to study his resources, question his motives, spy out his movements, and strive by all efficient means to prevail against him. But when fear grows to be hysterical it is emasculated and is no longer a well-balanced element of power; it rather, in fact, sinks into weakness and stupidity, and from being a stimulating factor in human affairs, becomes a benumbing one. A word may sometimes convey unjustly this paralyzing influence and confuse our ideas. Phthisiophobia connotes unreasonable fear and carries with it an over-emotional quality. It suggests rather the attitude of the perfumed Paris than of the doughty Hector and is an unfortunate term. Words are very ancient, at least in their roots, and do not change their meaning with the swiftness of ideas. We come upon a word and think we have happened on a solution, whereas we have simply touched a problem. Thus sometimes a word actually blocks the way. Were I to express the actual attitude of the scientific world towards tuberculosis I would rather say that it entertains a wholesome fear of it, and that with this fear goes intelligence, courage, and a desire to extend protection from it. To show the correctness of this position and to bring the world to adopt it should be one of the objects of medical science. We should cultivate phthisicophilia rather than phthisiophobia, since we are deeply interested in the consumptive, for the very reason that he is the infecting center whence radiate many of our woes. To fear tuberculosis is to run from an idea, but to protect the tuberculous from others and from themselves is sane, sound, and effective; the very act of resisting a common danger energetically will dispel unreasonable fear. Ghosts have always frightened men out of their wits and always will. One should dispel the vague and nebulous ideas that project themselves in terrifying forms and strive for accurate and exact presentation, for known dangers incite us to caution, while the unknown excite panic and phobias. When we have a precise knowledge of tuberculosis and its effect on mankind, and can show that many places have been freed from its ravages, and can demonstrate the exact means by which this has been accomplished, we will have taken a long step toward substituting prudence for fright. That the world fears tuberculosis is undoubtedly true. The great mortality, the wide extent, the painful consequences, and the contagiousness of the disease are reasons enough for this. These features have always been characteristic of the disease, but they have recently been brought more vividly before the public by organized educational bodies, and designedly so. This has been done not, however, for the purpose of increasing their fears, but in order to promote their intelligence. It is the knowledge that an inundation is possible and the fear that it may come that has made the Dutch so careful and so skillful with their dikes; the result of their precaution is that a threatening disaster is controllable.

Tuberculosis is contagious, but its contagion is controllable. Typhoid fever is also contagious, and the new statistics show that there is a much larger proportion of secondary cases than had been supposed. In a small epidemic of typhoid fever in Willoughby, a town near Cleveland, which was carefully studied, only seven of the fifty-two cases could be traced to primary sources, such as infected springs and water courses, the rest were all secondary to these seven and due to associating with them, caring for them, eating infected food in their houses, to flies, etc. Yet typhoid fever is absolutely controllable as a contagious disease, so that if proper precautions are taken other patients may lie side by side with the victim of typhoid fever in hospital wards without having cause for the slightest fear, so long as they can have confidence in the attendants. The study of the individual tuberculous patient shows that in him also the contagion is controllable, and that he also may be rendered harmless to his fellows. It is this knowledge of what is possible in the case of the individual that must root out the fear of the disease generally. A vast amount of educational propaganda has been made in this direction, and it is effective in proportion as the people are receptive, i. e., as the people are intelligent. You cannot preach down un-

*Read before the Medical Association of the Greater City of New York, March 21, 1910.

reasonable fear, you must substitute something for it. Replace the generic idea of the disease by the thought of the individual. Replace the fear of illness by the fear of penalty from a vigorous administration of the law and the public will have something tangible to think about which will not scare it and which it will respect.

There are two groups of facts which placed in juxtaposition cause one to reflect. These are the relation of sound individuals in tuberculous homes, under what may rightfully be called natural conditions, and sound individuals among the personnel and attendants of tuberculosis institutions, under what we may call artificial conditions. The former residents in tuberculous houses become infected, the latter remain sound. Children associating with tuberculous mothers are exceedingly liable to contagion, and of all children living in infected houses twenty per cent. have tuberculosis. Sound clerks associating freely, and may I not say naturally, with a few, a very few, who are unsound, in the same ill-kept room contract the disease; one unsound animal in an otherwise immune herd will, within two or three years, render one-third of the whole herd unsound, while a separation of the sound from the unsound animals quickly makes and keeps the former immune. Some of the statistics of the Granchet Societies for the Preservation of Children are startling. The removal of the healthy children from infected families to houses in the country protects and preserves these favored ones, while 50 per cent. of their brothers and sisters who are left behind fall victims to the infection. On the contrary, in tuberculosis institutions, where so-called artificial conditions obtain, a case of infection among the personnel was almost unknown until v. Leube published his cases among nurses two years ago. Turban says that there has never been but one instance of infection among the attendants and officers of his institution and that that case could be easily explained and might have been prevented. Thus in one group we have occasion for fear and in the other sufficient reason for the annihilation of the fear. Under ordinary conditions, in a tuberculous family infection is the probable result, under artificial, or to speak more conventionally, under sanitary conditions infection is less probable than in the usual ordinary human intercourse. One cannot, therefore, resist the conviction that with tuberculosis we are in the presence of a controllable contagion. Thence comes the justification of the heroic endeavors undertaken by many municipalities, especially by New York. These measures, if carried still further to the point where the public can see without analyzing them, and adopt them easily, without that fatigue of thinking which many persons dread, will banish forever phthisiophobia.

It is impossible here even to touch upon sources of contagion, modes of infection, portals of entry, the relation of bovine and human tuberculosis, and many other subdivisions of the subject, the principles of which have been well established, even though the details have not yet been completely worked out. To extend this study to anything like even practical completeness will require the cooperation of a larger part of mankind, sick and well, than has yet by any means obtained. As this is to be a study of the individual, the individual must participate in it. The more he participates, the more his interest will grow; with increasing interest come increasing curiosity, sounder knowledge, and a greater protection for all.

This is the only way in which Koch's second law can be fulfilled. The first law, namely, to discover the infecting center, *i. e.* man and his habitat is comparatively easy to enforce. The second law, namely, to stamp out these centers, is the real difficulty. We can not, of course, literally stamp them out, but if we can render them innocuous we have effectively annihilated them as infecting centers and the law is fulfilled. Nothing can so win the confidence of a people as the conviction that there is a systematic and logical procedure by which an enemy of the public health can be destroyed. These two laws, which Koch early with the prescience of genius formulated, will contribute much to this social confidence after they have been still further applied. It must be understood that all this struggle has as its object to render tuberculous subjects less harmful and less numerous. With this conception of the tuberculosis movement there would be less antagonism to the building of new institutions for the sick poor, less fear on the part of nurses in caring for the sick, and less solicitude among friends lest the disease separate them; there would, in a word, be less general unreasonable fear.

Each individual man has a certain more or less well-defined place among his fellows. In the vast majority of persons this is so circumscribed that classifications can be made and people fall into groups of varying sizes. Every person is exposed to certain dangers; he takes certain risks in his very living, and the risks increase with the increased pressure of civilization. Each group of people has also its peculiar risks to which each individual constituting the group is exposed. If the precise attitude of each one could be ascertained and his proportion of exposure estimated, his liability to misfortune could be in a measure known. A knowledge of this measure of risk would replace the bogey which is based on an indefinite conception of human conditions and is often simply an impression derived from false observation and false reasoning. We would then have to do with a synthesis of accumulated facts rather than with an analysis from false premises, and would be much nearer the truth. Our factor of safety would be very much larger. It would probably be impossible to work this out from individual instances, but a study of the classes into which men group themselves would be simple and doubtless quite as accurate since the physical conditions surrounding many individuals of a certain group are astonishingly similar. If we peer into many of these groups we will find much that is not edifying, such as the inertia of custom, reflexlike automatic movements and mechanically associated ideas and crass obliviousness. This search will reveal such a mass of stupidity and entire forgetfulness of common lessons that it will lead to discouragement. The great mass of mankind are so intensely conservative as regards personal habits and live on such a level, unchanging plane that they resent an inspection of their lives and much more do they resent any modification of them. They are cast in plaster and can not be remolded. There are, however, certain basic facts that can be learned and from them certain fairly reasonable deductions can be drawn, which enable us to make a faithful picture of the individual lives about which we are concerned; pictures which are true, although they are not accurate.

From the standpoint of tuberculosis one can thus know the risks entailed by associating one's self with certain groups of men and estimate in a way

the percentage of the increment of fear which he should entertain. Lest such a knowledge should lead to pessimism or indolent optimism, which is equally subversive, it should be associated with the corollaries which indicate how the group may be lifted to a plane where fear is less justified. We would make fear then a motive to better one's condition and a stimulus for wide knowledge.

When one enters the large group of industrial operatives he immediately undertakes certain obligations and entertains certain casualties. He runs the risk of 1 to 2 of dying from tuberculosis. If he enters a group of sedentary workers such as clerks he runs the risk of 1 to 4 and 5 of dying from tuberculosis. The young child group which is housed with the parents runs one chance in twenty-five, but when the boy has been two or three years at school he runs one chance in ten of dying from tuberculosis. When he leaves school and goes to work he immediately enters a group in which the mortality is double that of his previous group.

There must be some analyzable cause for this gradually increasing mortality. As we walk along the way of life, passing as we are compelled to do from one group to another group, why should our feet become clogged with the mire of civilization and our footsteps grow so heavy that we sink into the slough long before our time? Every member of a group participates in the dangers of the group. Every animal that leaves an immune herd and enters an unsound herd will become unsound. The wise herdsman knows this and prevents it. Every one has a right to know what his chances of mortality are and what risk he runs. Having once learned this he can choose his way. Will he move along with the mass of his group in a natural way doing what the average member does, which is easy, or will be open his eyes, pick his way and follow what I have called an artificial path? If he selects the latter he can diminish his own risk and reduce his own mortality, and, in proportion as he does this, mitigate his own fears, although the mortality of his group remains unchanged; and if a sufficiently large number of his immediate companions act with him the mortality of the group will be modified in proportion to the number thus acting in common. If a little company of cigar makers persists in working in low, damp, dark rooms, sitting on opposite sides of the same table so that when one coughs he sends a gust of his breath into the face of his companion opposite, the mortality of that band will average 75 in 100. If it ventilates the rooms, inculcates personal cleanliness, and the members sit on one side of the table only the mortality will be reduced 25 per cent. and more, and the morbidity statistics will correspond. The rules for the control of any acute epidemic are simple and easy of execution, except when the victims are massed in a small area, because the demand is for the isolation of every individual for a short time, no matter what his civil condition. If a citizen has smallpox the duty of the patient and health officer is clear—there is but one thing to do. On the contrary, if the citizen suspects tuberculosis, one thing is necessary if a stone cutter, another thing if a cobbler, another if a clerk, and another if a housemaid or a laundress; one set of rules is necessary for the subject and other rules for the associates and those in the radius more or less extensive of the contagion. While the extremist may demand isolation for the advanced cases of tuberculosis, he is obliged to agree with the opportunist that the incipient, early, and arrested cases call for special rules. Moreover, the rules will be as numerous and as variable as the individuals attacked. We find ourselves, therefore, in a maze almost as impenetrable as life itself. For this disease is life tubercularized. Yet hysterical fear, phthisophobia, has no place here.

One of the causes of restlessness among the people is the sudden, irrational, intermittent, and desultory acts of over-zealous officials. It is the unexpected that puts the public on the defensive. Therefore, every procedure that is likely to interfere with customs and habits should be well considered and gradually and logically introduced. The farmers have at times been brought into direct antagonism to the whole tuberculosis movement by the rash conduct of unwise health officers, and this is likely to happen whenever the milk question springs suddenly into too great prominence. Notwithstanding the fact that the tuberculosis movement is a varied and complicated form of human effort, its solidarity is most complete, one part depends so intimately upon another that the whole should move evenly and compactly. The hospital, sanatorium, dispensary, and house visitation are integral parts of the one idea, worked out in different ways, and each one is essential to the perfect development of the other. House inspection and disinfection, registration and municipal surveillance are even more intimately connected than the agencies for treatment and cure; medical inspection of schools, children's camps, and all the armament necessary for the protection of the child are very closely knit together. All these departments must be made practical and popular that there may be a place for every person who needs any one of them. A disproportionate growth of one part obstructs the free, smooth movement of the whole. There is a broad and rather even development of the tuberculosis activities throughout the country, but they are not closely enough correlated. This is particularly true of public and private charities which are sometimes widely dissociated. To make these agencies co-operate as component parts of one harmonious whole requires a thorough organization, and this should begin with the federal government; then and then only will the weak places be discovered and strengthened. Should the national government determine to direct, regulate, and control the movement against tuberculosis, it would find itself at once in possession of an army of eager volunteers ready to be led. I doubt if anything would give more confidence to the nation in its efforts against consumption than an active, well-organized government control and nothing would more quickly banish fear. The belief of the average citizen in himself, in the organizing power of his fellows and in the power of his country, together with our great local jealousy and pride would give this centralized body an enormous centrifugal force that would be felt the length and breadth of the land. Institutions would multiply under the fostering care of intelligent leadership, and it would not be long before the slogan, "no tuberculosis," would begin to have a real significance.

You may have read the last part of the last chapter of Selma Lagerlöf's "Saga," where she tells of little Ruster, who went as a drummer boy at the head of a Swedish regiment when in 1813 it marched into Germany and who could never weary of telling stories of that wonderful land in the south. The people were as tall as church towers, the swallows were as big as eagles, and the bees as geese.

"Well, but the bee hives?"

"The bee hives were like our ordinary bee hives."

"How did the bees get in?"

"Well, that was their own lookout," said the little Ruster.

The ideas that have been suggested for the control of tuberculosis are very large bees, gentlemen, and how they will come into the bee hives of everyday practical life is something that will have to be found out sometime. In the meantime, we shall have to admit that a wholesome fear is our strongest defense.

1807 Prospect Avenue.

AMEBIC DYSENTERY IN NEW YORK.*

By HENRY S. PATTERSON, M.D.,

NEW YORK.

CHIEF OF CLINIC AND ASSOCIATE IN APPLIED THERAPEUTICS, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY, NEW YORK.

In a previous paper, the writer reported three domestic cases of amebic dysentery, one infected on Manhattan Island, one in Brooklyn, and one on the Hudson River between New York and Fishkill. A review of the literature at that time showed records of about fifteen cases infected in and about New York City. Conversation with physicians and surgeons indicates that there have been many unrecorded cases. A study of the cases does much to abuse one of the idea that amebic dysentery is exclusively a tropical disease.

In order to emphasize the purpose of the former paper, and to again point out that amebic dysentery is endemic in New York, this additional case is reported.

History number 1602; admitted to the Hudson Street Hospital, July 9, 1909; male, 25 years of age; U. S.; single; driver. Family and past history unimportant. Present illness began about five months ago with frequent, yellow, watery movements, without pain, tenesmus, or other discomfort. He had about six or seven passages daily, one after each meal, and they were sometimes streaked with blood. The number of stools has increased up to the day of admission, so that today he has had ten movements accompanied with pain and tenesmus. The patient has and is still losing weight. One month before admission he began to have vomiting directly after meals. He has had slight epigastric pain and nausea. Pain has been relieved by vomiting; vomitus has not been noticed. Chief complaint, diarrhea. Physical examination unimportant. Examination of mucus obtained through sigmoidoscope and examined on a warm stage, reveals many motile amebæ.

Much controversy has taken place concerning the pathological significance of the *Ameba dysenterii*, some authors claiming that its occurrence in the stools is not of etiological importance. Perhaps the majority of observers has credited the ameba with being able to produce dysentery, and excellent evidence has been advanced in favor of that view in the fact that the organisms are found in the walls of the intestinal lesions and in the pus of secondary manifestations occurring in the course of the disease. For a long time evidence, however, was lacking which could be regarded as proof of the pathogenicity of *Ameba dysenterii*, because of the inability to grow the organism on culture media. In 1904 Musgrave and Clegg[1] working in the Philippines, were able to grow the ameba in symbiosis with organisms harmless to animals and man, and to reproduce the disease in man from these cultures, as well as in animal, by feeding experiments. Lesage[2] has reported the successful culture of ameba on leucocytes of the guinea pig, dog, cat, rabbit and man. He does not state how he made his leucocyte preparations, but says that "in culture the ameba has all the characteristics of the parasite studied in the human products. It reproduces amebiasis." Gauducheau[3] has succeeded in growing amebæ in symbiosis with bacteria. The amebæ no longer grew, if what he calls the nourishing bacteria were wanting.

In a large city like New York, it is reasonable to suppose that if infection took place through drinking water, there would be many more cases of amebiasis. It is a difficult matter to explain the city cases, but it seems a possibility that the domestic cat will be proven the source of infection in some endemic cases. Lesage speaks of "spontaneous dysentery" in the cat, and says that its organism is identical with the ameba of human dysentery. He believes that experimentation, showing that infection by puncture or injection into the nasal fossæ produces an amebiasis, explains those cases where no portal of entry accessible to food or to drink can be found. The objection might be raised that in this case the infection was bacterial, and the occurrence in the stools of amebæ a coincidence. The type of amebæ found in the present case, as well as in the three previously alluded to, was the large, phagocytic type, the organisms containing in their centers many red cells. The harmless type is smaller and nonphagocytic. It may also be added that the occurrence of amebæ in the stools of healthy persons is practically unheard of in this part of the country.

Diagnosis: Many cases of amebic dysentery are unrecognized, because physicians are satisfied with the examination of a stool collected in the usual way. The motility of the organism is lost soon after it comes to a temperature below that of the human body, and it succumbs below 65° F. Consequently, if a stool is to be examined, it should be passed into a bed pan which has been warmed just before the examination is to be made, and should contain water heated to about the temperature of the body. The mucus obtained in this way should be examined immediately on a warm stage. If the search through a specimen from a stool fails to disclose the ameba, mucus should be obtained through a proctoscope, and an immediate examination on a warm stage will make the diagnosis in a few moments. Amebæ are often easily found in this way, when repeated stool examinations have been negative. The occurrence of small ulcers close to the so-called internal sphincter is quite characteristic.

The endemic disease in New York characterizes itself by a suddenly appearing diarrhea, with a gradual undermining of the general health and strength. In the present case and in the other cases observed by the writer, there was no history of fever. The persistence of the disease for weeks and months and the positive findings in the stools when examined with the proper technique should make the diagnosis fairly simple. It may at times be difficult to determine whether a case is one of amebic dysentery, in which the organisms have not yet been found, or one of intestinal cancer with diarrhea. The writer has seen one case of chronic

*Read before the Medical Section of the New York Academy of Medicine, November 16, 1909.

dysentery probably amebic, mistaken for carcinoma, and two cases of intestinal cancer, which were wrongly diagnosed as chronic dysentery.

The treatment of this disease seems to have been firmly established, especially in tropical countries, where the medical treatment is apparently better understood than in temperate regions. Medical measures include diet and drugs. The diet should be one which leaves as little irritating residue as possible. Wilson and Pressby[4] report excellent results from the use of a diet of turnip top purée, and ascribe to it a curative effect. The drugs used are numerous. Perhaps the one remedy to attract the most attention at present is ipecac, its use having been revived, according to Woodhull,[5] some years ago by Docker in Bengal. It is given in large doses, up to a dram a day, either in single or divided doses. Its administration has been preceded by morphine hypodermically to prevent vomiting, but recently it has been administered coated with salol, which prevents emesis equally successfully. Raymond[6] in giving the results with ipecac in the tropics, advocates it in the highest terms, and quotes Manson as believing that ipecac is possessed of specific powers in amebic dysentery. Woodhull, while admitting the fallibility of all remedies, states that in a wide experience in the Philippines, he has never seen it fail. Thornburg,[7] on the other hand, admitting that it lessens the number of movements, does not believe that it kills the ameba, and says that its use is nearly always followed by relapse.

Another drug which has in recent years acquired a great reputation for efficiency in the treatment of amebic dysentery is kho-sam (*Brucea sumatra*, or *B. antidysenterica*), a plant found in Abyssinia, Cochin China, and Sumatra. Lemoine[8] regards it as a specific, if used early. In later cases, he says, it is more rapidly curative than any other drug, and succeeds where ipecac fails. Its action is hemostatic, astringent, and antiparasitic. Lemoine says that the ameba being hematophagic, the principal action of the drug is brought about by depriving the ameba of its chief article of food. Schneider[9] in corroborating Lemoine's recommendations of kho-sam's effectiveness, advised the powdered drug in one grain pills, three or four times daily. The literature in praise of this drug is very extensive.

At the same time that medicine is given, local treatment should be carried out, in the form of irrigations of quinine solutions, silver nitrate, argyrol, ice water, or the direct application of tincture of iodine to accessible ulcers, through the sigmoidoscope. The success of medical treatment depends on early diagnosis, and in the tropics, especially in the hands of our army surgeons, seems to be considerable. Many cases in this part of the world come to surgical treatment, possibly on account of too late recognition. Surgical treatment is indicated where medical measures have repeatedly failed, and consists of colostomy or appendicostomy and through and through drainage.

Addenda. Opportunity is here taken to report another case which came under observation after the preceding communication was made.

A. D., 31 years, male; lithographer; U. S.; married. Family and past history unimportant. Eight months ago, after feeling perfectly well, he was suddenly taken with diarrhea. He had eight or nine movements in twenty-four hours, several at night. They were foul smelling and bloody, but unaccompanied by tenesmus. The diarrhea kept up until the first week of January, 1910, with varying intensity, the patient occasionally having formed movements in the periods of improvement. He lost considerable flesh and strength, but apart from the bloody stools he had no complaint. He has not been out of Brooklyn, except to work in Manhattan, for over five years. About the first week of January he visited the Vanderbilt Clinic, where a provisional diagnosis of amebic dysentery was made, and the patient was sent to the Hudson Street Hospital. A negative stool examination was made, but mucus obtained in the eye of a rectal tube showed under the microscope many motile amebæ.

A CASE OF FATAL HOOKWORM INFECTION.

By BOLLING LEE, M.D.,
NEW YORK.
ASSISTANT VISITING SURGEON TO BELLEVUE HOSPITAL,
AND
HARLOW BROOKS, M.D.,
NEW YORK.
VISITING PHYSICIAN TO THE CITY HOSPITAL.

Hookworm infection is a subject of enough general interest, we believe, to justify us in recording the following instance of fatal infection which came under our observation in April, 1905. This case is perhaps of special importance, since it represents a quite typical example of the more acute and active types of the disease, whereas most of the cases which have been recorded in New York have been of the more chronic form, which rarely terminates in early death, at least without serious secondary complications.

But very little was generally known here in New York concerning the disease when this case was under our study. A striking illustration of this statement is perhaps afforded by the fact that the Board of Health registrar held up our death certificate until it had been investigated.

The patient was a male aged 32 years. He gave an excellent family and personal history, and up to the time of the present sickness his health had been even exceptionally good. He had recently returned from his wedding trip, which had been spent in Europe, whence he had returned by the southern route. While in Rome he drank unboiled and unbottled water on at least one occasion, and had also probably eaten salads and uncooked fruits, any of which might have been the portal of infection entrance. On his return to the States he noticed while in St. Louis that he was passing dark colored stools, but he was feeling perfectly well at this time.

Dr. Lee was called to attend him on the morning of April 24, 1905. He was then complaining of acute pain in the epigastrum, had vomited, and had

several diarrheal movements. Inasmuch as he gave a history of having dined indiscreetly on the previous evening the case was looked upon at this time as one of simple acute indigestion, and a saline cathartic was prescribed.

Seen later in the day, his pallor was pronounced and striking; he had a rapid shallow pulse, with labored breathing and gave the general picture of impending collapse. Inspection of a recently discharged stool showed it to be composed almost entirely of dark fluid blood.

Blood examination showed the following: Hemoglobin, 15 per cent.; red corpuscles, 972,000 per c.mm.; leucocytes, 8,400 per c.mm.; clot formation, very slow and incomplete. The alkalinity of the blood was also enormously diminished, only 80 mg. per 100 c.c. being present, calculated as NaOH. The red corpuscles showed all manner of malformations and variations in size. Both normoblasts and megaloblasts were abundantly present, and endoglobular and chromatophilic, as well as the less advanced types of degeneration were shown. The relative leucocyte count showed normal proportions, but a great many pigmented leucocytes were present as well as free pigment in the serum. No malarial organisms were found. In brief, insofar as the blood picture alone went, the picture was that of a very severe grade of primary or cytolytic anemia.

Examination of the feces showed the presence of large quantities of blood clot and partly digested blood, together with ova of a tapeworm, which subsequently proved to be the *Tænia saginata*. In addition to these, the movements contained large numbers of desquamated epithelial cells and considerable amounts of mucus.

A tentative diagnosis of duodenal ulcer complicated by tapeworm infection was made, and concurred with by Drs. Janeway and Flint, who had been called in consultation.

A second examination of the feces showed, however, in addition to the eggs of the tapeworm, ova of the *Ankylostoma duodenale*. The last mentioned were, however, found in lesser numbers than the former. On account of the almost collapsed condition of the patient it was thought best not to administer an active anthelmintic, but 5 grains of thymol was prescribed to be taken three times daily.

One day later the hemoglobin had fallen to 12 per cent., with a red cell count, curiously enough, precisely that of the previous day. Normoblasts and megaloblasts soon disappeared from the circulating stream, however, and the degenerative alterations in the cells became more marked. The alkalinity had fallen to 75 mg. per 100 c.c., a change, however, well within the range of technical error.

Under treatment chiefly of forced nutrition with salts of lime and iron, after three days the hemoglobin was raised to 18 per cent., with a slight fall in the red cell count to 960,000, a small increase in the leucocytes to 11,800 and a slight decrease in the coagulation time of the blood. Most significant of all, normoblasts reappeared in considerable numbers. On May 4, four days later, the hemoglobin had fallen to 17 per cent., but the red cells had increased to 1,080,000, and the clot formation was still more rapid. The alkalinity of the blood had risen to 96 mm. of NaOH per 100 c.c.

Following this temporary improvement in the blood picture the discharge of the tapeworm from the gut took place probably from the frequent diarrheal movements rather than as a result of the small doses of thymol. The parasite was a *Tænia saginata*, and about twelve feet in all were discharged. The head was not recognized. Ova of both tape and hookworms still persisted in the movements, the former in rapidly decreasing numbers.

Soon after this, a severe purpuric condition developed, with almost constant and uncontrollable oozing from the nasal and intestinal mucosa, and with frequent submucous and dermal hemorrhages. Rapid decline in the hemoglobin percentage and red cell count took place, while clotting became so slow and incomplete as practically not to occur at all.

In general, the subsequent management of the case was that of purpuric hemorrhage, in the hope that the vitality of the patient might be sufficiently aroused to permit of later specific treatment for the parasitic condition. Notwithstanding the most active measures in the way of stimulation and supportative treatment, including means designed to increase the coagulation of the blood, the hemorrhages proved to be uncontrollable, and the patient died from exsanguination ten days after he first came under observation.

This case represents in general an entirely typical form of the acute types of infection with the hookworm. In some respects, however, it is atypical. thus eosinophilia, usually present, was wanting in this instance, probably accounted for by the severe character of the infection and the slight body resistance to it. The association of the tænea with the hookworm is by no means an infrequent one, and there can be no doubt but that the presence of the tapeworm manifestly increased the severity of the symptoms.

Insofar as we are able to judge from the number of hookworm ova present in the stools the infection was not numerically a large one, but as has been frequently shown, this is oftentimes a relatively secondary factor as compared to the susceptibility or resistance with which the tissues of the patient combat the disease.

Probably this patient had been passing blood for a considerable time before he came under observation, and active symptoms did not arise until the case took on more or less hemophilic tendencies. these being first manifested by the profuse intestinal hemorrhage and later on by the multiple mucous and subcutaneous extravasations.

Although no parasites were actually recovered from the stools, no doubt can exist as to their presence on account of the absolutely typical appearance of the ova, although after incubation we were unable to procure the larval form from them, a respect in which we have also failed in other cases.

Attention should be attracted to the fact, now well recognized, that the blood picture alone was precisely that of a pernicious anemia, and had no examination of the stools then been made the case might well have passed as one of pernicious anemia terminating with intestinal hemorrhage or complicated by duodenal ulcer.

The failure to dislodge any of the parasites by the saline cathartic or by the subsequent small dosage with thymol is entirely what is to have been expected and corroborates our experience in other examples of this disease, where we have usually found it necessary to administer thymol in large doses in order to produce the desired effect. The condition of the patient being practically that of collapse from shortly after the time when he came under observation up to the time of his death definitely precluded any such measures being undertaken in this case.

Insofar as we may judge from the size and appearance of the eggs, they were those of the *Uncinaria americana*, although we are not at all certain that we were able to distinguish the ova of our domestic parasite from those of the European form, especially at this time, when our experience with the parasite and its ova was very limited.

The case was probably hopeless when it came under observation on account of the great loss of blood, the resulting grave anemia, and the evidently severe toxic condition of the patient. The usual stimulants were administered in massive doses, saline infusions and enemata were given and attempts to accelerate clotting of the blood were made by the administration of the lactate of calcium. It is possible that adrenalin might have been used to advantage, but we doubt very much if the ultimate outcome of the case could have been altered by any means even now at our disposal.

WHAT THE FIGHT AGAINST TUBERCULOSIS HAS ACCOMPLISHED.*

By STEPHEN J. MAHER, M.D.,

NEW HAVEN, CONN.

First. It has saved the lives of tuberculous human beings. It has prolonged the lives of more tuberculous human beings. It has stamped out some local epidemics of tuberculosis among cattle.

Second. It has taught all people and all governments in the civilized world the enormity of the losses that they suffered from the prevalence of the disease and secured their adhesion to a plan of campaign against the common enemy.

Third. It has brought home to the minds of young and old, rich and poor, lettered and unlettered, a comprehension of the importance of fresh air, not only for the treatment of this disease, but for the treatment of many other diseases, and for the general purpose of the prolongation of life.

Fourth. Its stimulation of the pity and generosity of the rich has resulted in hitherto unheard-of benefactions for the study and cure of the diseases that affect mankind, benefactions that will continue to improve human life long after tuberculosis shall have been banished.

Fifth. It has established bonds of fraternity between the enthusiastic crusaders of all classes and all races and all countries, bonds that make for racial understanding and international good will.

These accomplishments, made possible only by great effort and sacrifice on the part of individuals and communities, are worthy ones, worth all that they cost; but are they as great as they ought to be at this stage of the battle?

To answer this question, one must look forward as well as backward. One must consider (1) the unparalleled size and resources of the attacking force, and (2) the present position of the enemy.

As to the first, you know them as well as I. You have seen the sanatoria, the special hospitals and dispensaries, the day camps, the out-door schools, the registration laws, the research laboratories, the visiting nurses, the aroused public opinion, and the golden flood of private and public donations.

But the enemy, how fares he? If he were to issue bulletins, would he not boast: "Yes, you have won a few skirmishes, but my principal positions are still intact. The children are mine; active men and women are mine; many of the aged are mine, as they all always have been. The farm is mine, as well as the city's slum, or the hold of the ship.

"You claim to know me. You call me the tubercle bacillus. But whether my relations in the cow and the bird are allies of mine or not, you do not know. You frighten into a panic all the friends of my victims by saying that they are a danger to everybody near them, but you fail to explain the immunity of most husbands and wives of consumptives, and of the attendants and physicians at your special hospitals.

"You spend energy and money, making criminals of all who spit in the streets, but many of your leaders say that it is impossible for me to enter the body through the air passage. You claim that your recent organized attack on me has reduced the number of my victims; but all your statistics show that my appetite for victims was decreasing at just the same ratio for fifty years before your hysterical sanatorium era. You say you know all about me now, that I am easily recognized. Well, do I have a prebacillary stage, as some of your skirmishers claim, or am I always an acid-fast bacillus? Know all about me! Then where do I come from? Was I made the tubercle bacillus by God Almighty in the beginning, and have I been the tubercle bacillus ever since? Or am I a pathogenic form of bacterial life developed from a non-pathogenic form by the influence of environment? And does this evolution take place now every day, or did it occur only once, some ages ago?

"And your vaunted fresh air cure that was to be my destruction! Most of the patients who were inmates of the best sanatoria five years ago are already dead, and most of those who are suffering the misery of sleeping in the open air this past winter will be mine five years from now. A few you have saved, but how few! In your desperation, even in your sanatoria, you have fallen back on the use of the discredited tuberculin that gave me such a series of victories twenty years ago. And those that you save, you don't know what saves them. 'The fresh air,' you say. But what does the fresh air do? Does it injure me? I grow better in the air than without air.

"You don't know me. You don't know my resources. You don't know my places of retreat. You don't know my allies. You don't know how to explain the few successes that you have had. How then can you expect to defeat me by your campaign of educating the people? Educators must know. You don't know. At least most of what you know about me is not so.

"What doth it profit Man to have beautiful sanatoria if the tuberculous die in the old way and at the old rate? What doth it profit him to have the death records show fewer deaths from tuberculosis if the stringency of the laws makes doctors report their dead consumptives as victims of bronchitis or pneumonia?

"Bah! Your crusade against me is vain. It was conceived in pious ignorance and has been carried on with the methods of a Chinese army, with much noise and many banners, and no guns!"

Of course it is not the part of wisdom to take too seriously the claims of our enemy, but in estimating the value of what we have accomplished, it is necessary to know what remains to be accomplished.

EUGENICS AND MENDELISM.

ANYONE who thinks about the matter at all knows full well that in European overcrowded countries and in cities in all parts of the world the condition of the masses is susceptible of great improvement from every point of view. This statement, indeed, puts the case mildly, for in the largest cities the state in which the very poor live is a direct and constant menace to the nation and to the white race generally. Too many individuals are born nowadays who are handicapped from the outset by physical and mental disabilities, due to poverty, heredity, that is, if heredity plays an important part in the physical and mental make up, environment, and an upbringing which renders them unfit to wage successfully the battle of life. Such persons are a detriment to the nation to which they belong, and the most disquieting feature of the situation is that they increase at a far more rapid rate than the better class of citizens. This brings about the tendency not merely to further degeneration, in itself sufficiently alarming, but what is even more alarming, a deterioration of the general average. Thus certain countries of Europe are faced with these disturbing facts, that not only is the population of their towns degenerating, but the race, as a whole, is deteriorating in body and mind. The nations whose inhabitants are chiefly in towns are in the worst position, but even in America affairs in this respect do not give cause for unmixed satisfaction. In a few words, it may be stated as an undoubted fact that in all parts of the civilized world the least desirable part of the population from a physical and mental standpoint is producing the more numerous progeny, and it would seem that unless means can be devised to stay this flood of the unfit, in the course of time the entire race must descend to a lower level as regards physical and mental qualities. Men of light and learning everywhere recognize the gravity of the position, and various measures have been suggested, some of which have been in part adopted, to keep the race at a high standard.

Of late the aid of eugenics and more recently still that of Mendelism has been invoked in this direction, and by some enthusiasts it is declared that in the practice of these theories the solution of the problem lies. In this country, during recent years, a great deal has been heard of stirpiculture and the physical examination of those wishing to be married has been strongly urged. So far as the doctrines of Mendel and his disciples are concerned, less interest appears to have been taken in these in America. However, in Europe and perhaps, particularly, in Great Britain, the followers of Mendel have been strenuously insistent that in the adoption of these teachings rests the salvation, or rather, the physical and mental regeneration of the race. A few far-seeing persons have attempted to stem this tide of enthusiasm and to indicate the exact state of the case. Among these is Dr. Squire Sprigge, the editor of the *Lancet*, who in the *Contemporary Review* for November, 1909, subjects the matter to close scrutiny and throws the clear searchlight of common sense upon the points at issue. In the first instance, he very appositely draws attention to the fact that the problems of heredity are not yet solved, so as to be able to lay down any hard and fast dicta as to inherited predisposition to disease. At a debate on heredity from the standpoint of disease held by the British Royal Society of Medicine in 1908, it was shown that certain obscure and rare nervous diseases were hereditary and that organic epilepsy might be inherited. With regard to cancer some of the most prominent authorities deny that this disease can be proved to be hereditary, while several of the recent workers on tuberculosis believe that the condition is in no wise inherited, and a well known British authority confessed himself as sceptical of even a predisposition to tuberculosis being inherited. Of course, the obvious degenerates, drunkards, imbeciles, and those profoundly tainted with blood poisoning, as syphilis, should be debarred, if possible, from propagating their kind, but outside this class, who, in the present position of knowledge regarding the laws of heredity, is to say which couple is fit to mate and which is unfit?

The followers of Mendel assert that in the teachings of the remarkable Abbot of Brünn is to be found the solution of the fundamental riddles of heredity, and if this be so there is reason to believe that the question of suitable marriages may be successfully attacked by them. It must be borne in mind though that neither the truths laid bare by Mendel himself, nor the advance on these truths made by his disciples has up to the present solved the problem. Mendel discovered marvelous facts by his experiments in flower culture, notably in pea fertilization, and his followers have greatly improved on his experiments in fowl and rabbit breeding. But the result of experiments thus far do not authorize the statement that human breeding can be influenced in a similar way, although they may point to a possibility in that direction. Indeed, even in flower culture it is not known, except by individual experiment, what qualities will respond to the Mendelian notation, and whether such will be dominant or recessive in action. The possibility of avoiding the transmission in certain plants of certain qualities has been demonstrated by

avoiding certain alliances, and if any practical rules as to the transmission of disease can be given to medical men by the Mendelists, a great step in advance will have been made in regard to the position of Mendelism in eugenics. Now, according to Sir William Gowers, with respect to disease, the Mendelian theory appears to be borne out in the transmission only of pseudohypertrophic paralysis. The Mendelian theory has infinite possibilities in regard to the betterment physically and mentally of the human race, but as yet these are but possibilities. On the whole, Sprigge is far from being convinced of the value of the medical certificate before marriage, as one of the chief planks of the eugenic platform, until the Mendelians have supplied the medical profession with more accurate knowledge of the workings of heredity upon which to base their decisions.

It is the desire and object of medical and scientific men to improve the breed of human beings, but, on the other hand, it is not the intention of these men to lead the ignorant astray as to the chances of so doing. A little learning is a dangerous thing, and it is those who know little who are generally most certain concerning partially known scientific truths. This is the case with respect to eugenics and Mendelism. The learned biologist may hope and imagine that the most sanguine expectations of the Mendelists may be realized, but the dabbler in science is positive they will be and talks as if they were already realized.

THE ETIOLOGY OF CAISSON DISEASE.

The great feats of engineering which have been successfully accomplished on the two sides of Manhattan Island during the past few years and have resulted in the construction of the various tunnels, which give promise of adding so much to the comfort of the inhabitants of this city and its suburbs, are the products not only of the mentality of great mechanical geniuses and the expenditure of vast sums of money, but of no inconsiderable amount of suffering and loss of life as well. The chief cause of this latter factor has been the frequency of caisson disease, which has resulted from the tremendous air pressure under which the workmen were obliged to labor while forcing the steel tube through the soft mud and rock of the river bottom, a pressure sufficiently high to counteract the weight of the mud and water lying above. This disease, known to the workmen as "bends" from the attitude assumed by the sufferers, an acutely agonizing affection, has been more or less prevalent wherever work has been carried on under increased atmospheric pressure. Probably in few instances, however, has the liability to it been so great as in the present piece of work, for in few construction problems have as many men been engaged for so long a time under such high pressure.

Many theories as to the etiology of caisson disease have been advanced. The generally accepted opinion that it is due to the concentration of the normal gases of the atmosphere in the tissues of the body by the increased external pressure and their sudden expansion due to undue rapidity in changing from high pressure to low, thus explaining the disease on a purely mechanical basis, has been questioned by various authorities, who have claimed that the disease is due less to the normal gases under pressure than to the absorption of certain abnormal gases, as carbon monoxide and dioxide, nitric oxide, marsh gas, and sulphureted hydrogen, found in the tunnels by blasting, by decomposition, and by the exhalations from the bodies of the workers. In an effort to settle this question, J. E. McWhorter, one of the surgeons to the constructors of the Pennsylvania Railroad East River tunnel, has made a new and careful study of the disease, not only by close observation of the cases which have come under his care during two and a half years' service, but also by carrying out of systematic analyses of the gases found in the tunnels at various times and under differing conditions. In his article upon the subject, which appears in the *American Journal of Medical Sciences* for March, 1910, he states that whereas the usual conservative estimate of the amount of carbon dioxide which may safety be allowed in a tunnel is 0.1 per cent., as a result of several thousand analyses, he could show that at no single time did the maximum exceed this amount, that the minimum amount found was 0.045 per cent., and the average 0.07 per cent. Furthermore a study of the daily fluctuation in the amount of this gas, as compared with the number of cases of "bends" reported, showed no relation whatever between the two conditions. A study of the carbon monoxide also showed that this gas never exceeded the comparatively safe amount of 0.045 per cent., and reached this limit only for a few minutes just following the discharge of a blast. A clinical analysis brought out the fact that the pressure and the number of workers being the same, the prevalence of "bends" did not vary in relation to the amount of blasting, and so could not be dependent upon the carbon monoxide content of the air. Methane was never found in the air of the tunnels, and nitric oxide and sulphuretted hydrogen in only the most minute quantities. The ventilation in the tunnels was thoroughly adequate, between seven and eight thousand cubic feet of air passing through per man each hour.

The two most striking positive results of the present investigation were the finding at autopsy in a fatal case of "bends" that the right side of the heart was filled with gas, 80 per cent. of which consisted of nitrogen and 20 per cent. of carbon dioxide, and the relative great susceptibility of new and green men. In regard to the latter point McWhorter shows that of green men who entered the tunnel, 15.5 per cent. had attacks of "bends"; of the new men who claimed to have worked under pressure before, 9.4 per cent. were affected, and of the old workers, but 0.43 per cent. The investigation is certainly of value in confirming the old theory that the disease is of a purely mechanical nature, due to the absorption of an excessive amount of nitrogen, and in pointing out the relative susceptability of new men and the gradual acquiring of immunity to the unnatural conditions of life.

Bursitis of the Tendo Achillis.

Chronic disabling pain at the tip of the heel, aggravated by walking, and lasting for a long time, is a fairly well-known condition, and is frequently called "neuralgia of the heel," or "achillodynia," under the sheltering mantle of neuralgia, have in be very widely appreciated that many of these cases, as so frequently happens in diseases cloaked under the sheltering mantel of neuralgia, have in reality a perfectly definite pathological lesion underlying them, and causing the pain. In the *Deutsche medizinische Wochenschrift* for March 31, 1910, Franz König reports a series of such cases. In four of them there was an uncomplicated bursitis of the bursa lying anterior to the tendo Achillis, while in two others there was a bursitis associated with more or less marked exostoses. These exotoses have often been noted in conjunction with achillodynia and frequently have been removed in the hope of relieving the suffering. According to König, however, such bone hypertrophies are purely secondary and protective to the chronic inflammation in the bursæ. In his operation upon the bursæ, he has found the latter to be thickened, coarse, and callous, the inner surface to be red and swollen, and the cyst contents as a rule to be clear, though at times slightly turbid. The treatment advised by König consists of radical operative destruction of the bursæ, either by excision or by means of caustics. The etiology of these cases is varied. They may be due to direct trauma, or to a sudden strain on the tendon. More commonly, however, they are of infectious origin, occurring bilaterally, and most frequently traceable directly to an infection with the gonococcus. In persistent cases of this condition the excision of the bursa seems to be indicated. Where, however, the disease follows closely upon a urethritis, it would seem advisable, before resorting to a radical operation, to give the patient a thorough trial with an antigonococcus vaccine or serum.

The Cause and Prevention of Typhoid Fever.

After many years' search for the source of typhoid fever epidemics in the water and milk supplies of various communities, and an unsuccessful attempt to prevent this disease by guarding the purity of drinking water and the production of milk on farms, we are now turning from these measures, or rather adding to them new ones, in quite another direction. Modern investigations of the etiology of many epidemics has shown that there was frequently some connection to be found with certain persons, who had had the disease some time before, and whose feces and urine were found to be producing and distributing wherever they went millions of the bacilli of Eberth. One of these bacillus carriers, "Typhoid Mary," has become celebrated in the annals of the City of New York, for the number of her employers and their families she unwittingly infected, and the length of her sojourn under the protecting wing of the Health Department, a sojourn which was far from voluntary. H. Rondet in *Lyon Médical*, for November 28, 1910, gives many striking illustrations of the propagation of typhoid fever all over France by these typhoid carriers, who either infected the wells or the streams near their sources, the water of which was very soon drunk by the inhabitants, or who, like Mary, carried the germs on the unwashed hands in preparing viands for the table. The author contends that instead of saying that this is a water-borne disease, we should say that is of human origin. Whenever these germs find a person with weakened organism they attack his intestine and he succumbs to the disease. He believes that the bacillus coli, usually saprophytic in the intestine, under certain conditions becomes virulent and takes on the characteristics of the bacillus of Eberth. The chief prophylactic measure under these conditions should be the universal education of the public in frequent washing of hands and disinfection of stools and urine when these are not carried away immediately by the sewers.

Thermal Hyperesthesia in Insular Sclerosis.

Though a well marked case of insular sclerosis, characterized by nystagmus, scanning speech, and intentional tremor, is probably as definite and easily diagnosed an affection as any which comes to the attention of the neurologist, the diagnosis of the disease in its earlier stages and in atypical forms is at times far from a simple problem, and confusion with various other organic or functional disorders is not uncommon. Recently, Michael Sugàr of Budapest has investigated twenty-five cases of multiple sclerosis in respect to their thermal sensations, and he reports some distinctly interesting results in the *Deutsche medizinische Wochenschrift* for March 24, 1910. He has found, in every case of multiple sclerosis, isolated patches of skin over which, though at first examination with the cold and hot test tubes, the thermal sensibility appeared to be normal, and the tubes were easily and properly differentiated, if the cold tube were placed upon the skin and then quickly replaced by a warm tube at a temperature of 120° F., the second tube produced a sensation of painful heat, to such an extent that the patient cringed or jerked the part away. This peculiar phenomenon of intense heat hyperesthesia following cold, having been found in every case of insular sclerosis and never having been elicited in normal cases or in patients suffering from myelitis or hysteria, the author suggests that it may be of some value as a pathognomonic test in the earlier stages of insular sclerosis. He is now carrying his investigations further to ascertain the specificity of the test for this disease. If his results are as uniform in this as they have been in the series of examinations already made, he bids fair to give to the neurologists a diagnostic aid of no small usefulness.

News of the Week.

The Public Drinking Cup.—A law went into effect in Oklahoma, May 1, forbidding the use of public drinking cups in railroad stations and trains, parks, schools, and all public places.

An Amendment to the New York State Medical Law passed the Assembly in Albany on May 5, 1910, in the form of Assembly bill No. 2290, proposed by Assemblyman Wilkie. The chief change between the present bill and that of three years ago is in the exception to the paragraph allowing registered physicians only to practise medicine. In the old law this read: "This article shall not be construed to affect the practice of the religious tenets of any church." In the Wilkie bill this exception is changed to read: "This article shall not be construed to affect the practice of circumcision as the religious

tenet of any church." The passage of the Wilkie bill through the Senate is to be vigorously opposed by the Christian Science organization, which believes that the new amendment will interfere with their rights.

Examination for Bacteriologist and Pathologist, Philippine Service.—The United States Civil Service Commission announces an examination on June 8, 1910, to fill a vacancy in the position of bacteriologist and pathologist in the Bureau of Science, Manila, P. I., at a salary of $2,250 per annum, and a vacancy in the position of assistant professor of bacteriology and pathology in the Philippine Medical School at a salary of $2,000 per annum, and vacancies requiring similar qualifications as they may occur in the Philippine service. It will not be necessary for applicants to appear at any place for examination. Their eligibility will be determined upon the evidence furnished in connection with application and examination Form 375 concerning their education, training, and experience. The qualifications desired of applicants for these positions are as follows: (*a*) They must be graduates in medicine. It is preferred that they shall have received a doctor of philosophy degree (or have had an equivalent training) from a first-class institution. (*b*) They must be trained in bacteriological laboratory work and must have good technique. (*c*) They must have a good thorough fundamental knowledge of pathological anatomy. (*d*) They must have a knowledge and training in immunity and serum therapy. (*e*) They must be young, healthy, and energetic, and capable of doing research work; in fact, they should have all the qualifications needed by a first-class laboratory research worker. Each applicant for these positions will be required to submit with his application a photograph of himself, taken within the past three years, as a means of identification in case he receives appointment. An unmounted photograph is preferred. The name and date of examination, the competitor's name, and the year in which the photograph was taken should be indicated on the photograph. The age limit is 18 to 40 years on the date of the examination. Applicants should at once apply to the United States Civil Service Commission, Washington, D. C., for application Forms 2 and 375.

Smallpox in Boston.—Five cases of smallpox have been discovered in London street, East Boston. The infection is supposed to have been imported from Cape Breton.

Reception to Dr. Jacobi.—The Medical Society of the State of New York gave a reception to Dr. Abraham Jacobi at the Academy of Medicine, May 6, 1910, in honor of his eightieth birthday. Dr. Joseph D. Bryant made the address of welcome and Dr. Charles Jewett presented the guest with a bronze medallion of himself. This was unveiled by Miss Ruth McAneny, the granddaughter of Dr. Jacobi.

Dr. James Tyson.—A complimentary dinner was given to Dr. Tyson on May 5, on his retirement from the chair of the principles and practice of medicine in the University of Pennsylvania and on the completion of forty years of medical teaching. Dr. W. W. Keen acted as toastmaster, and addresses were made by Dr. Frank Billings of Chicago, Dr. Reginald H. Fitz of Boston, Dr. George A. Peirsol of Philadelphia, and the Hon. John Wanamaker.

Dr. John M. Swan of Philadelphia, Secretary of the American Society of Tropical Medicine, has been appointed medical director of the Glen Springs Sanatorium at Watkins, N. Y.

Abuse of Street Privileges by Physicians.—According to an ordinance recently passed, physicians' automobiles now have the right of way in the streets of Baltimore and are allowed to speed, as are fire engines and ambulances, other vehicles being obliged to make way for them. This is a senseless law, liable to abuse, and one which other municipalities will do well not to copy.

The Abolition of Smallpox Quarantine was recommended at a recent meeting of the Fort Madison (Iowa) Medical Society. This is in response to a query by the Iowa State Board of Health as to the advisability of the abolition of quarantine in order to promote more general vaccination.

The Crawford Long Infirmary is soon to be built in Atlanta, Ga., for the care of the students of the Georgia State University.

Employer's Liability Bills.—The two workmen's compensation bills, introduced by the Commission on Employer's Liability, have been favorably reported by the judiciary committees of both the Senate and Assembly in Albany.

Phipps Institute for Tuberculosis.—In the conduct of the Phipps Institute under the control of the University of Pennsylvania, Dr. Paul A. Lewis of the Rockefeller Institue will be Director of the Laboratory, Dr. H. R. Landis, Director of the Clinical Department, and Mr. Alexander Wilson, Director of the Sociological Department.

University of Pennsylvania.—A course in sanitary engineering, public water supplies, sanitation of buildings, inspection of foods, and kindred subjects covering a year's study is to be established open to the graduates of the medical department. Courses in tropical medicine, protozoology and entomology, and clinical work in tropical diseases are also in contemplation. Dr. Paul A. Lewis has been elected assistant professor of pathology.

The Drake Medical School Fund, which is being raised in order that the school may not be discontinued has reached the sum of $100,000. The sum needed is $150,000.

Charitable Bequests.—By the will of the late Harriet Abbey of Philadelphia the sum of $10,000 is bequeathed to the Episcopal Hospital for the endowment of two free beds, and the sum of $5,000 to the Home for Incurables for the endowment of a free bed. By the will of the late Samuel E. Shoyer of Philadelphia the sum of $5,000 is bequeathed to the Jewish Hospital Association for the endowment of a free bed in the name of Gabriel and Louise Shoyer. By the will of the late Lucinda Dodson of Muhlenberg, Pa., the sum of $8,000 is devised to the Methodist Hospital for the endowment of one or more free beds.

The American Gastroenterological Association will hold its thirteenth annual meeting at St. Louis, Mo., June 6 and 7, 1910, at the Planter's Hotel.

The Illinois State Medical Society will hold its sixtieth annual meeting at Danville, May 17, 18, and 19, 1910. The president of the society is Dr. Benjamin Gleesen and the secretary and treasurer Dr. Solomon Jones.

The Fairfield County (Conn.) Medical Association held its 118th annual meeting at Bridge-

port April 12, 1910. The officers who were elected were: *President,* Dr. Herbert E. Smyth of Bridgeport; *Vice-President,* Dr. William L. Griswold of Greenwich; *Secretary,* Dr. Frank W. Stevens of Bridgeport; *Treasurer,* Dr. James Douglas Gold; *Counsellor,* Dr. Samuel M. Garlick; *Censors,* Drs. Edward M. Smith, David C. Brown, and Samuel Pierson.

The Homeopathic Medical Society of the State of Michigan will hold its forty-first annual meeting in Grand Rapids, May 18 and 19, 1910, at the Hotel Pantlind. The president of the society is Dr. Charles G. Crumrine, and the secretary Dr. Dean W. Myers of Ann Arbor.

The New York Society of the American Urological Association, at the annual meeting on April 27, held a symposium on "Movable Kidney," in which members of the society, as well as invited guests from the New England Urological Society, participated. The following officers of the New York Society were elected: *President,* Dr. Edward L. Keyes, Jr.; *Vice-President,* Dr. Terry M. Townsend; *Secretary,* Dr. G. A. De Santos Saxe, and *Treasurer,* Dr. W. B. Brouner. *Executive Committee:* Drs. C. R. O'Crowley, V. C. Pedersen, W. J. Robinson, and Terry M. Townsend.

The Medical Association of the State of Alabama held its annual meeting in Mobile, April 18 to 22. The following officers were elected: *President,* Dr. W. H. Blake of Sheffield; *Vice-President,* Dr. Charles Lee Guice of Gadsden; *Censors,* Dr. V. P. Gaines of Mobile, and Dr. T. L. Robinson of Birmingham.

The Suffolk District (Mass.) Medical Society held its annual meeting in Boston, April 30, 1910. The following officers were elected: *President,* Dr. George H. Monks; *Vice-President,* Dr. F. B. Harrington; *Secretary,* Dr. David D. Scannell; *Treasurer,* Dr. A. K. Stone; *Librarian,* Dr. B. Joy Jeffries.

The Berkshire District (Mass.) Medical Society held its annual meeting at Pittsfield, April 28, 1910. The following officers were elected: *President,* Dr. H. B. Holmes of Adams; *Vice-President,* Dr. C. S. Chapin of Great Barrington; *Secretary,* Dr. I. F. S. Dodd of Pittsfield; *Treasurer,* Dr. J. D. Howe of Pittsfield; *Commissioner on Trials,* Dr. J. J. Hassett of Lee; *Councilors,* Dr. J. F. A. Adams, Dr. O. J. Brown and Dr. L. A. Jones of North Adams, Dr. H. A. Stockwell of Stockbridge; *Censors,* Dr. J. F. A. Adams of Pittsfield, Dr. M. M. Brown of North Adams, Dr. J. C. Burton of Pittsfield, Dr. J. B. Thomes of Pittsfield, Dr. A. T. Wakefield of Sheffield.

The Edgar County (Ill.) Medical Society, at a meeting held at Paris, Ill., April 28, elected the following officers: *President,* Dr. Harry Lycan of Vermilion; *Vice-President,* Dr. B. G. R. Williams of Paris; *Secretary,* Dr. Nettie A. Murphy of Paris; *Treasurer,* Dr. G. H. Hunt of Paris.

The Litchfield County (Conn.) Medical Society held its annual meeting at Winsted, April 27, 1910. The following officers were elected: *President,* Dr. G. H. Wright of New Milford; *Vice-President,* Dr. F. H. Lee of Canaan; *Secretary and Treasurer,* Dr. F. S. Skiff of Falls Village; *Councilor,* Dr. Elias Pratt of Torrington.

The Randolph County (Ark.) Medical Society met at Imboden, April 22. The following officers were elected for the ensuing year: *President,* Dr. J. W. Brown; *Vice-President,* Dr. L. H. Hall; *Secretary,* Dr. W. E. Hughes; *Treasurer,* Dr. Carl Shield.

The Worcester North District Medical Society held its annual meeting at Fitchburg, Mass., April 26, 1910. The following officers were elected: *President,* Dr. William N. Cowles of Ayer; *Vice-President,* Dr. C. J. Pierce of Shirley; *Secretary,* Dr. W. F. Sawyer of Fitchburg; *Treasurer,* Dr. F. H. Thompson, Jr., of Fitchburg; *Councilors,* Dr. Bigelow, Dr. E. P. Miller, Dr. E. A. Sawyer, Dr. Thompson, Jr.; *Censors,* Dr. E. P. Miller, Dr. Pierce, Dr. J. B. Donnelly of West Gardner, Dr. W. H. Page of Baldwinville, Dr. E. J. Tully of Fitchburg; *Librarian,* Dr. A. P. Mason of Fitchburg.

The Southwest Missouri Medical Association, at a convention held at Springfield, Mo., April 29, elected the following officers: *President,* Dr. W. J. Rabenau of Fordland; *Vice-Presidents,* Dr. O. N. Carter of Republic and Dr. J. E. Dewey; *Secretary,* Dr. H. S. Hill; and *Treasurer,* Dr. Lee Cox of Springfield.

The East St. Louis Medical Society held its annual election of officers, April 26, with the following results: *President,* Dr. L. D. Applewhite; *Vice-President,* Dr. U. S. Short; *Secretary and Treasurer,* Dr. C. W. Lillie.

The Alexandria (Va.) Medical Society has elected the following officers: *President,* Dr. S. B. Moore; *Secretary,* Dr. R. L. Wilkins; *Treasurer,* Dr. Llewellyn Powell.

Obituary Notes.—Dr. Howard T. Ricketts died last week at the American Hospital in Mexico City from typhus fever, a disease which he had been investigating in that city for some months. Dr. Ricketts was a graduate of the Northwestern University in 1896. Until recently he had been associated with the University of Chicago, but at the completion of his present researches was to have become professor of pathology at the University of Pennsylvania.

Dr. James Decker Spencer of Watertown, N. Y., died at his home, May 5, aged 62 years. He was a graduate of the Bellevue Hospital Medical College in 1870, and was a member of the American Public Health Association, the New York Academy of Medicine, and the Jefferson County Medical Society, and an ex-president of the Medical Society of the State of New York. Dr. Spencer was consulting surgeon to the Watertown City Hospital

Dr. William F. Barbat of San Francisco died suddenly in his office April 24, 1910, aged 36 years. He was a graduate of the University of California in 1895 and a member of the San Francisco County Medical Society, the Medical Society of the State of California, and the American Medical Association. Dr. Barbat was a former member of the San Francisco Board of Health in which capacity he did valuable work in connection with the plague in Chinatown. He was secretary of the San Francisco Medical Society, and on the executive board of the State society.

Dr. Oliver Barber of Saginaw, Mich., died at his home, April 26, 1910, aged 60 years. He was a graduate of the Bellevue Hospital Medical College in 1870, and immediately after graduation settled in Saginaw. Dr. Barber was attending surgeon to the St. Mary's, the Saginaw General, and the Woman's hospital, and at one time was professor of surgery in the Saginaw Valley Medical College and the Michigan College of Medicine.

During the Spanish War he was surgeon-major of the Thirty-fifth Michigan Volunteers and later division surgeon. He was at one time health officer of Saginaw. He was a member of the Saginaw County Medical Society, the Michigan State Medical Society, and the American Medical Association.

Dr. John J. Gilhuley of Bridgeport, Conn., died April 25, 1910. He was a graduate of the Bellevue Hospital Medical College in 1894 and a veteran of the Spanish-American War.

Dr. W. H. Kennedy of Kennedy, Ala., died, at his home April 24, aged 84 years. In 1872 he represented his county in the State legislature.

Dr. James B. Robertson of Clayton, N. C., died at his home April 28, 1910. He was a graduate of the University of Pennsylvania in 1861.

Dr. Hartwell A. Sibley of Dorchester, Mass., died at his home April 27, aged 61 years. He was for many years city physician of Chelsea. He was a member of the Suffolk County Medical Society and the Massachusetts Medical Society.

Dr. Andrew Jackson Weidener of Little Rock, Ark., died at his home April 26, 1910, aged 53 years. He was a graduate of the American Medical College of St. Louis and secretary of the State Eclectic Medical Board of Arkansas.

Dr. Hardy Murfries Banks of Englewood, N. J., died in New York May 6, 1910, aged 79 years. He was a graduate of the New York University, and was a member of the Bergen County Medical Society and the Medical Society of New Jersey.

Dr. Peter J. McCourt of Mount Vernon, N. Y., died at his home recently, aged 69 years. He was a graduate of the New York University in 1890, and was a member of the Westchester County Medical Society, the Medical Society of the State of New York, and the American Medical Association.

Dr. Henry Belt of New York died at his home May 6, 1910, aged 42 years. He was a graduate of the Long Island College Hospital in 1898, and was a member of the New York Academy of Medicine, the Medical Society of the County of New York, the Medical Society of the State of New York, and the American Medical Association.

Obituary.

EUGENE HODENPYL, M.D.

NEW YORK.

Dr. Eugene Hodenpyl died of pneumonia at his home in New York on May 5, 1910, after a short illness, in his forty-seventh year. Dr. Hodenpyl was of Dutch parentage. His preliminary studies were pursued at the Brooklyn Polytechnic Institute. He was graduated from the College of Physicians and Surgeons in New York in 1885. After hospital service and studies in pathology, especially in Tübingen and Vienna, he became a teacher in pathology at the College of Physicians and Surgeons, passing through the grades of assistant and instructor to the adjunct professorship. His long and faithful service at this institution was marked by enthusiastic devotion, especially to morphological phases of pathology, by numerous painstaking and fruitful researches, and by his skillful and highly successful teaching of undergraduate students. His demonstrative courses in gross pathology formed for a long period one of the most noteworthy features of the medical curriculum at this institution. He was for many years pathologist to the Roosevelt Hospital ,a member of the American Association of Pathologists and Bacteriologists, of the New York Academy of Medicine, and of the New York Pathological Society, of which he was at one time president. Upon his retirement from academic work in 1909, he devoted his entire time to the pathological service of the Roosevelt Hospital.

The later months of his life were given to the development of a new conception of the possibility of the successful treatment of carcinoma by transudates derived from cases of this disease, which had recovered or had long persisted. His first experiments upon animals were so promising that he felt justified in soon proceeding to the treatment of the disease in man. Here, too, such remarkable and encouraging results were obtained that in February of the present year, he published a preliminary note on his method of treatment, without, however, permitting himself to make any claims for the discovery of a cure for cancer. With admirable reserve in a few clear terse sentences, he framed his working hypothesis, set forth the significant effects of the injections upon tumor tissues, outlined the necessity for prolonged observations and obvious controls, and warned against hasty conclusions. Then he turned to the observations on his series of cases, upon which alone the final judgment must rest. But this task he was not permitted to complete. The suggestion which inevitably became public, that he had found a new way of treating cancer, brought to him a flood of urgent demands for help from all over the world, mostly from inoperable and hopeless cases. The great responsibility involved in a new mode of treatment, the ceaseless pressure of pitiful appeal, and the unremitting physical and mental strain bore heavily upon him. But the possibilities of service to science and more directly to his suffering fellowmen outweighed all personal considerations and led him to ignore the warnings of his professional friends. So at last he was able to offer but slight resistance to what seemed at first a relatively slight attack of pneumonia.

It is yet too early to judge of the significance of Dr. Hodenpyl's method in the treatment of carcinoma. The work of adequate proving can and will be taken up by others where it has fallen from his hands. But the passing of the genial spirit, the whimsical humor, the ready helpfulness, and the example of unselfish devotion to a life of service will be long and sincerely mourned by his many friends.

FREDERICK TILDEN BROWN, M.D.

NEW YORK.

Dr. Frederick Tilden Brown of New York City died suddenly in Bethel, Maine, May 7, 1910, aged 55 years. He was a graduate of the College of Physicians and Surgeons, class of 1880; a consulting surgeon for the Presbyterian and Nassau Hospitals, an attending surgeon at Bellevue Hospital, a member of the Academy of Medicine of New York, the American Medical Association, the Greater New York Medical Association, the New York Surgical Society, and the American Association of Genitourinary Surgeons. Dr. Brown was a skilful surgeon, a hard student, and devoted to his profession—too devoted, indeed, for the nervous breakdown which led to his untimely death was the direct result of overwork.

Correspondence.

THE FAR EASTERN ASSOCIATION OF TROPICAL MEDICINE.

(From Our Regular Correspondent.)

MANILA, P. I., March 15, 1910.

THE seventh scientific session of the Far Eastern Medical Association was held at 9 A. M. on March 12, 1910, in the Administration Building of the Philippine General Hospital and consisted of papers on tuberculosis and miscellaneous subjects. The first paper, entitled "Statistics on Intestinal Parasites in the Philippine Islands, with Especial Relation to Intestinal Amebæ," was read by Dr. Y. K. Ohno of the Bureau of Science. Dr. Ohno stated that he had made a large series of investigations as to the prevalence of intestinal parasites both by race and month; it was found that the Chinese had the smallest percentage of infections and the Filipinos the largest. The infection among the Chinese was exceptionally small. With regard to the prevalence by months, his record showed that in May the largest number of cases occurred among the admissions to the Civil Hospital, and that the least number occurred in March. He also collected statistics from Bilibid Prison which indicated that the largest number of infections occurred in August.

In the discussion which followed Dr. Heiser stated that he was much interested in the paper by Dr. Ohno: that the large number of charts he had prepared illustrating his subject could not help but have considerable value. He was, however, of the opinion that the deductions reached by the author with regard to the largest number of amebic infections occurring in August are not of any great value in determining the period of the year at which these infections are most prevalent outside of Bilibid Prison. At Bilibid only sterilized drinking water is used and the amebic infections depend upon two factors which are not much influenced by the morbidity rate of Manila: First, the cases which are present in prisoners at the time of admission from provincial jails, and, second, those which occur in prisoners who are sent to the different provinces (where the seasons are also different) to carry out large public works, and who are returned to the prison after they become infected. He stated that in his opinion the statistics for the Civil Hospital were a better index because patients are admitted as soon as they contract the disease on the outside; that in this connection it was interesting to note that the largest number of cases occurred in May, which month corresponds to the onset of the rainy season; that this also agrees with experience in the United States and Europe with regard to intestinal diseases, like typhoid, which always increase during autumn, when the rains begin.

The next paper, entitled "Beriberi," was read by Dr. Gorosaku Shibayama, delegate from His Imperial Japanese Majesty's Government. Dr. Shibayama stated that during the past two years he had been a member of a commission appointed by the Japanese Government for the purpose of making an investigation into the etiology of beriberi; that in pursuance of these instructions he had observed a number of outbreaks, one of which occurred in a tin mine, and every effort had been made to associate it with the rice, but that no connection could be traced. He was of the opinion that the theory advanced by Dr. Fraser with regard to the etiology of the disease would not explain outbreaks which had occurred in Japan.

In the discussion which followed Dr. Highet of Siam stated that his experience in the Straits Settlements showed that multiple neuritis was quite common among workers in tin mines and was probably due to arsenic, and it seemed to him probable that what had been diagnosed as beriberi in the tin mines of Japan might have been neuritis due to arsenical poison, in view of which the data presented by Dr. Shibayama did not in any way nullify the rice origin of beriberi.

Dr. Aron stated that he was much interested in the food analysis which had been made of the food which was supplied to the tin workers, but that in view of the fact that no mention was made of phosphorus the analysis could scarcely be used in discrediting the rice theory of beriberi. Analyses of foodstuffs made by the ordinary methods showed only the amount of protein, carbohydrate, etc., which was not sufficient in view of the recent work on beriberi. He also desired to draw attention to the fact that he believed that the absence of phosphorus might not be directly connected with the outbreak of beriberi, but that its absence might simply interfere with the ingestion of nitrogen and also that, in his opinion, there might be other factors concerned in the causation of beriberi than the phosphorus alone.

Dr. Fraser stated that in his opinion in the cases mentioned by Dr. Shibayama arsenic or some other poison which might cause multiple neuritis had not been adequately excluded, but he desired again to reiterate his statement that he did not believe that there was sufficient evidence at the present time to show that the absence of phosphorus alone was responsible for beriberi.

The next paper, "Observations on Various Subjects of Tropical Medicine," was read by Dr. Aldo Castellani, delegate from the Government of Ceylon. The author gave a brief description of an acute condition of the bronchial tract which resembled acute bronchitis or the early stages of phthisis in which he was able to isolate the mycetoma organism which he regarded as the etiological factor. He also drew attention to his publication of 1905, in which he showed that dobie itch was not due to the trycophyton corpora; that the organism in this affection showed well-marked and different characteristics. He emphasized the importance of the use of iodide of potassium in cases of yaws, which in his opinion was the best treatment available at the present time.

The next paper, entitled "Mycetoma," was read by Major A. Hooton, I.M.S. delegate from the Government of India. In this paper the author gave a brief history of several cases of mycetoma which had occurred in one of the provinces of India. He showed photographs characteristic of this disease. He called particular attention to one case in which there had been secondary infection in the groin from the foot. He also called attention to the rarity of autoinfection.

The next paper, entitled "A Quick, Simple, and Accurate Method of Making Differential Blood Counts in Wet Preparations, and Its Advantage in the Diagnosis of Surgical and Tropical Diseases," was read by Surgeon E. R. Stitt, U. S. Navy. Surgeon Stitt stated that it was rare to find any large hospital in which the surgeons placed implicit reliance upon the leucocyte count, but that surgeons did not attach much importance to the differential count. This was due to the fact that the counts differed so much that no reliance could be placed upon them. He called attention to the experience of the yellow fever party which was sent out by the Marine Hospital Service of Washington. More than 5,000 slides of blood from yellow fever cases which were taken for the purpose of studying the white cells and making differential counts, but when this work was completed the commission reached the conclusion that it would be possible to prove almost anything desired with regard to leucocytes from their specimens. This led him to experiment with various substances, so that a more reliable method for making the differential count might be devised; he finally found that a 2 per cent. solution of ordinary commercial formalin gave most excellent results. The red blood cells found do not show any crenation. In fact, his experience was that the method could well be used in making malarial examinations. The white cells took on a slight purplish tinge and they could be easily counted and differentiated.

The next paper, entitled "Tuberculosis Among the Filipinos," was read by Dr. W. E. Musgrave. Dr. Musgrave gave a brief outline of his experience at the outpatient tuberculosis department of the Philippine General Hospital during the past year and gave statistics for 954 cases. These showed 45 per cent. of intestinal cases, as against an average of 15 per cent. reported by authors in the United States and Europe. In the second portion of this paper with regard to blood pressures of white races in the tropics he showed that during the first year the pressure remained about the same; that during the second year it often dropped to 120 millimeters. This drop continues and depends upon the length of residence. After ten years' residence the blood pressure drops to approximately 110 millimeters. The average blood pressure in Filipinos was found to be about 125 and did not show any great changes by years.

The next paper, entitled "Tuberculosis in the Philippines," by Dr. Isaac W. Brewer, Medical Reserve Corps, U. S. Army. Dr. Brewer called attention to the large

percentage of tuberculosis which exists in the Philippine Islands, and gave statistics which showed that the disease was more prevalent here than elsewhere.

In the discussion which followed, Dr. Heiser stated that the percentage of total deaths from tuberculosis is approximately the same in the Philippines as in other countries, that while there were many more cases here, yet that the percentage relationship to other diseases remained about the same, so that if it was reported that there were 15 cases of tuberculosis, for instance, among a thousand, to only 10 cases in the United States or Europe, that this did not necessarily mean that the percentage relationship was greater here.

The next paper, entitled "Notes on Amebæ, etc., at Baguio," was read by Dr. Bowman, of the Bureau of Science. Dr. Bowman stated that in three months' residence at Baguio he was unable to trace a single case of malaria or dysentery contracted in Baguio; that the examination of spring water around there failed to show amebæ, and the amebæ which had heretofore been reported by other authors as being present in surface waters was in all probability due to paramesia, and that it was almost impossible to distinguish the difference between these organisms and amebæ when both were in the encysted stage; that he based his conclusions upon the fact that he was unable to cultivate amebæ. He stated that on account of the fact that the Igorrotes are uncleanly in their habits, he naturally expected to find a large percentage of hookworm infection, but upon examination they were found by him entirely free from these parasites.

In the discussion which followed, Dr. Heiser stated that it might be of interest to the Association to know that the records of the Baguio Hospital for the past seven years show that no cases of malaria or amebic dysentery could be traced to infection contracted in or near Baguio, and also that the climate seemed to be ideally suited for the treatment of amebic dysentery, that it is the customary routine in the majority of cases of amebic dysentery received from the lowlands to give them no other treatment than rest in bed and proper diet, no drugs usually being required.

The eighth scientific session on climate, hygiene, and sanitation met at 9 A. M. on March 14, 1910, at Baguio, Benguet. The object of holding the session in Baguio was for the purpose of giving the foreign delegates an opportunity of inspecting the summer capital of the Philippine Islands. The meeting at this resort proved to be a most agreeable change from the hot lowlands and the session was held in perfect comfort, the thermometer registering about 70° Fahrenheit. The day previous the visitors were shown by automobile the hospitals, tuberculosis camp, markets, fields for outdoor sport, and other points of interest.

The first paper read was entitled "Unsolved Health Problems Peculiar to the Philippines," by Dr. Victor G. Heiser, Public Health and Marine Hospital Service, and Director of Health. The author stated that it was the object of the paper to present in condensed form a few of the unsolved problems which yet confronted the health administration and that he hoped that the delegates who came from countries in which similar problems had been encountered would give the benefit of their experiences in order that the same might become available here. In offering a solution the general conditions here must necessarily be kept in mind. First, that the country had a poverty stricken people with a poor physical inheritance, strongly imbued with superstition and habits which were the antithesis of the simplest health doctrines and practice, a people who lacked ambition productively to till the soil, a people the most of whom were apparently content in their ignorance and poverty and resigned to and uncomplaining of their many ailments; that work among them was handicapped by the inaccessibility of many of the islands by roads which, though being improved at a remarkable rate, were yet unfit for travel in many instances during portions of the year; and that they were handicapped with the lack of a common language, for as many as fifty or more dialects were spoken, and that English or Spanish were intelligible to only a small percentage of the population. That medical employees who were sufficiently interested in the cause of humanity to undergo the innumerable hardships and discomforts which accompany medical service in the tropics were rare, but that untold credit was due those who were carrying on the work, the burdens of which fell all the more heavily upon them owing to their limited numbers, and that the whole situation was complicated by a treasury of which it was quite possible at times to see the bottom, so that the proposition was not, "do all that is possible regardless of expenditure," but "your expenditure must not exceed this or that," so that one of the principal problems was, should a little be done toward each problem or should the efforts be concentrated upon one problem. So far the policy had been to do a litle toward each.

He pointed out that there were over 12,000 deaths annually from malaria, that great progress had been made in reducing the mortality by distributing quinine, draining land, etc. The engineering problems involved and money required to carry out projects for the elimination of mosquitos were in many instances far beyond the financial ability of the community concerned.

The surface waters in the islands, except the thermal, or those strongly charged with minerals, were infected with ameba, which made it imperative that a safe water supply be secured. Artesian wells were being rapidly bored, but there were many sections in which these were unsuitable, and the problem now was to find a way to furnish a safe drinking water in large quantities.

The disposal of excreta was another unsolved problem in places where the water carriage or sewage was not practicable; whether the pail system should be adopted and its contents used in fertilizing mulberry trees, and thus promoting the silk industry, was the best solution, or whether some other method might be available, were questions which were urgently awaiting solution.

The author stated that over six million persons had been vaccinated, but that work among the remaining two millions was complicated by the fact that it was not possible to send a potent vaccine into the remote sections in which they lived; that in this climate glycerinized lymph did not retain its efficacy for more than ten days and the dry points had also been unsatisfactory; that the distances and delays were such that cold storage was an impossibility.

With regard to tuberculosis, the author stated that this problem was much the same as in other portions of the world, but that certain features peculiar to the Philippines had to be added to it. On account of the poor physical inheritance and the unsuitable food which the natives eat they form much better soil for the implantation of the tubercle bacillus than people of a more hardy race. Also, that the well-nigh universal habit of chewing beetle nut and expectorating in the most promiscuous manner gave much freer distribution of the tubercle bacillus than occurred in other countries.

He stated that cholera was easily controlled after it once made its appearance, but that the fact still remained that outbreaks were constantly occurring over widely separated sections of the country in which the source of the infection could not be satisfactorily explained, and that this often happened in a remote section, so that before the news reached headquarters and relief was sent an epidemic frequently of large proportions was well under way. Cholera carriers had lately been shown to be responsible for some of these outbreaks, also that the change in morphology which the cholera organism undergoes also made it quite likely that deaths that were due to cholera were frequently overlooked or ascribed to other causes.

The infant mortality is another problem which gave considerable cause for concern, over 50 per cent. of the total number of deaths occurred in children under one year of age. Lately considerable work had been done in ascertaining accurately the causes of such deaths and it appeared now that improper diet was practically the principal cause. How best to supply the people with a suitable food which would be within their means was one of the greatest problems with which we are confronted; fresh milk in large quantities offered the best solution, but cow's milk is not available because these animals generally succumb to diseases like rinderpest and are unable to use the herbage here. Goats offer probably the best solution and efforts are now being made to breed a stock suitable for this climate.

The author stated that it frequently happened that the best efforts of the Bureau of Health still had to be devoted to stamping out the conflagration of disease which had been started before the American occupation and that this consumed a large amount of money and effort, but that until these had been entirely eliminated it was not possible to put any large amount of time upon the more constructive health projects. If

funds could be available here in the proportion that they were available in Cuba and Panama, for instance, that the health conditions in the Philippines could be much more rapidly improved, but that notwithstanding this fact results had been obtained here which would compare favorably with the two places just mentioned.

The next paper, entitled "An Experiment with Orange-Red Underwear in the Tropics," by Captain J. M. Phalen, United States Army, was read by Major W. P. Chamberlain in the absence of the author. The author stated that the Surgeon-General of the United States Army had ordered that an experiment should be made for the purpose of testing the value of the color of orange-red, in order to ascertain whether there would be any difference in the sick report under those affections which are ordinarily described as being due to the effects of climate; that is, nervousness, debility, irritability, loss of weight, failing memory, etc. One regiment for a period of one year was dressed in orange-red underwear and another regiment acted as control. The conclusion of the author of the paper was that there was practically no difference in the sick report of the two regiments, but that from the amount of testimony available it was evident that in spite of the fact that the weight of the underwear was practically the same as that of the white underwear, yet the men almost invariably complained of its being hotter. An experiment was made for the purpose of testing this complaint by placing a thermometer between the skin and the inner surface of the underwear and placing the subject in the sun for ten minutes, and then performing the same experiment with white underwear. This was done with various modifications and repeated a number of times, with the practical result that the thermometer was found to be in almost every instance five degrees higher in those who wore the red underwear than in those who wore the white underwear. The author also stated that in observations made upon persons who had been in the Philippine Islands more than nine years and had continuously worn khaki that in such parts of the body as were protected by it there was no evidence of pigmentation in the skin, from which he concluded that khaki was probably as protective as the orange-red.

In the discussion which followed Dr. Heiser stated that the data given in the paper of Captain Phalen were very interesting to him. As he understood it, these experiments were carried out with soldiers who wore khaki outer clothing and that controls also wore khaki but had white underwear instead of orange-red. Furthermore, if he understood correctly, the author stated that he had observed individuals who had been in the tropics for six years or more and wore khaki clothing continuously and that in such persons the protected skin showed no pigmentation, from which he inferred that the tropical light was effectually excluded by khaki. If that were the case, it seemed to him that in order to draw correct deductions it would have been better to make these experiments with soldiers who wore white outer clothing and orange-red underwear and with controls who wore white outer clothing and white underwear, or that one regiment should have been dressed entirely in white and compared with a regiment that was dressed in khaki.

Dr. Highet of Siam stated that it seemed to him also that no definite conclusions could be drawn on account of the fact that the question of the color of the khaki could not be eliminated.

Major Hooton stated that he agreed with Dr. Heiser that no correct deductions could be drawn from this experiment as to the effect of color on the human body in the tropics.

Major Chamberlain, on behalf of the author of the paper, stated that the question of the khaki did not seem as important to him when it was considered that the soldiers spent much of their time with their coats off, and that in this way they fulfilled, to a certain extent at least, the conditions of the experiment as it had been suggested.

The next paper, "The Relationship of Food to Physical Development," by Captain David McCay, I.M.S., Medical College of Bengal, Calcutta, was read by title.

The next paper, "Hygiene of Pregnancy," by Dr. Katherine C. Woodhull, Foochow, China, was read by title.

The next paper, "Community Measures Against Mosquitos," by Mr. Charles S. Banks, Biological Laboratory, Bureau of Science, was read by title.

Mr. Dean C. Worcester, the Secretary of the Interior, then gave a brief account of the climate of Baguio and contrasted it with that of Simla in India. He stated that it was a most remarkable thing that, even though Baguio was only 5,000 feet above sea level and in latitude 16, yet the average temperature was lower than in any similar known region in the world; that frost was a common occurrence in December and January, and that 30° Fahrenheit had been observed in temperatures taken in hollows near the ground. Another strange instance was that the temperatures were frequently from six to eight degrees higher eight feet above the ground than near the ground.

The mean maximum annual temperature of Baguio is 76.25° F., the mean minimum annual temperature is 52.44° F.; on an average rain fell three days in December, three days in January, two days in February, and seven days in March, and then it increases rapidly to twenty-six days in September and gradually decreases again to the rate given in December. He pointed out the beneficial effects produced in Baguio in those who were run down during the prolonged heat of the lowlands and of the favorable results it had upon amebic dysentery, and he stated further that no malaria existed there.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

DISINFECTANTS—INDIGESTION—GALLSTONE FORMATION—SCARLET FEVER OUTBREAK—INSPECTION OF SCHOOL CHILDREN—MEDICAL SOCIETY OF LONDON'S 137TH ANNIVERSARY—SATURDAY FUND—RED CROSS—OBITUARY.

LONDON, April 22, 1910.

DISINFECTANTS occupy the attention of both sanitarians and general practitioners, though the point of view may not be always the same. The Society of Medical Officers of Health lately held a discussion about them, begun by Dr. T. N. Barlow, who held that many differences of opinion as to certain disinfecting work depended on the advocacy of persons who were not medical men. He said much work done as disinfection was really useless and some was even quackery in its worst form. He took a wide view of the uses to which disinfectants are commonly put, *e.g.* watering streets, sprinkling ash pits, sluicing drains, and so on. So-called ozone producers and evil-smelling tablets came in for a word not very complimentary, reminding me of the old definition that a disinfectant is something that makes such a horrible smell as to compel you to open the windows and let in fresh air. Their only rational use, in Dr. Barlow's view, was in infectious diseases, to destroy the germs and so prevent them spreading. In these cases much is done on mere assumption, for want of exact knowledge of the factors at work in infection, and the dangers of relying on the indiscriminate scattering about of strong-smelling things is obvious. Cleanliness is more important than disguising one offensive smell by another.

Dr. William Butler said if disinfection were abandoned the public would cry out that proper precautions were neglected. He disinfected after erysipelas as specially dangerous to puerperal women. One advantage of doing so was the house was thoroughly cleansed; another that a sheet suspended at the doorway of an infective sick room would be more certainly kept damp if a disinfectant were used.

Dr. F. J. Allan insisted on the necessity of more thoroughly cleansing school buildings rather than distributing disinfecting fluids or powders.

Dr. Lawrence said less would be used if the Medical Officers of Health did not allow them so freely to be distributed, but in all cases ordered what they considered desirable. Dr. Calwell Smith said he not only ordered them himself but insisted on their application being carried out by his own staff.

Indigestion, subject always with us but never exhausted, came before the Harveian Society on the 14th inst. in a practical paper by Dr. E. I. Spriggs, based on 425 cases. He said diagnosis from symptoms alone could not be exact. Analysis of the contents of the stomach would often prove such a diagnosis incorrect. When possible the stomach contents or the vomited matters should be examined. Many patients objected at first to the passage of a tube, but it was not so unpleasant as they imagined. Of medicines he seemed to think most of alkalies combined with carminatives, or of bismuth carbonate.

Dr. Young seemed to have more faith in drugs, mentioning particularly creosote and charcoal. He agreed that the tube was not so disagreeable as many supposed and that washing out the stomach before the evening meal was of great use in dilatation.

Dr. Leonard Williams said the stomach was often too much pampered and much talk about diet was nonsensical. Nasal obstruction and eyestrain might give rise to indigestion, as no doubt may numerous disorders.

The rate at which gallstones may be formed was illustrated by a case related at the Clinical Section by Drs. Hertz and Adams. A woman had typhoid in December, a relapse from January 14 to 24. On February 1 had epigastric pain and vomited, with tenderness over gall-bladder. Attacks of vomiting followed from time to time and suppurative cholecystitis was diagnosed. On operation 4½ ounces of pus and clear fluid were evacuated and 25 faceted gallstones removed. The *Bacillus typhosus* was found in the pus and fluid. It was also found in the center of some of the stones. This was 68 days from the onset of the fever.

An outbreak of scarlet fever of a somewhat unusual type is reported at Ingatestone, Essex. Sixty-eight cases have been notified. Dr. Thresh, Medical Officer of Health for the county, reported to his board on Tuesday that he had spoken of it to three officers of the Local Government Board. The cases were mild among adults and half showed no symptoms at the beginning. He concluded that two diseases had been present—influenza and scarlet fever, the latter being spread by personal contact with very mild cases.

Dr. Thresh has also lately completed an inspection of all the schools in his county. He says the chief defects he met with were due to eyestrain and impeded respiration, both being partly remediable, but in a greater part preventable. He therefore urges his educational committee to apply remedies—proper illumination of the school rooms and the teaching of breathing exercises and the importance of nasal respiration. Parents should be persuaded to submit their children to medical treatment as soon as inspection shows the need of it.

The Medical Society of London celebrated its one hundred and thirty-seventh anniversary last month. You will remember that this venerable society remained outside the amalgamation of several others into the Royal Society of Medicine—not from any feeling of opposition to the scheme, but from difficulties connected with its finances and other circumstances. The Fellows were attached to the old constitution and felt there was plenty of room to continue its useful and prosperous career. Time has justified the decision, the fear that some expressed that it might decrease in numbers has proved groundless, and the number of Fellows is actually increasing. As Sir J. Tweedy said at the dinner, the Medical Society fosters the best talent of its time and he hoped would do so for another 140 years. The arrangements for the present session bid fair to contribute their share to continued success.

The Countess of Aberdeen presided on Tuesday at the annual meeting of the Health Association of Ireland, for which she has done so much and of which there are now 168 branches. In moving the report, Lady Aberdeen reviewed the work of the year, which included the distribution of literature, visits of nurses to homes of the poor, establishment of pasteurized milk depots, which it is computed have reduced infant mortality among the users from 14.5 to 4.5 per cent. In promoting sanatoria throughout Ireland much had been done. Two new institutions for prevention of consumption would soon be at work in Dublin. For one Mr. R. J. Collier had promised £1,000 a year for five years as a memorial of his father. For the other Mr. Arthur Ryan had placed a similar sum at their disposal for five years, which would enable a limited number of patients to be maintained in the hospital.

The report of the Hospital Saturday Fund shows receipts for last year of £30,662, as against £29,830 in the previous year. The management expenses were £2,422. The amount distributed to 213 institutions was £28,741, an advance of more than £1,000 above that of 1908.

The British Red Cross Society has made considerable progress of late. On Wednesday a Westminster City Division was inaugurated, when Sir F. Treves spoke at length on its aims, urging especially the importance of having only one organization in the country through which alone arrangements with the Admiralty and War Office must pass in time of war.

Edinburgh has lost by the death on the 15th inst. of Dr. John Smith a typical citizen. He graduated M.D in 1847 and practised medicine for a time, but eventually devoted himself to the dental branch, of which he became the chief exponent, the hospital of this department owing its foundation to him, as also did the Children's Hospital. He was surgeon-dentist to the late Queen Victoria and the Royal Infirmary and other hospitals—in fact, he held at one time or another almost all, if not quite all, posts of honor in his specialty, including the presidency of the Odontological, the Medico-Chirurgical, and the Harveian societies. His literary, artistic, and musical tastes were also remarkable. He was the author of many songs and verses which were very popular, a dramatized version of "Waverley," and some pantomimes. But his professional work was not neglected, as shown by his dental "handbook" and numerous contributions to societies and journals. His house was the rendezvous of a numerous circle of the leading literary and artistic celebrities of the academical city.

Dr. E. J. Munter, Medical Officer of Health for Gosport, died on the 13th inst. after a long illness, aged 60. A Glasgow student, he took the Faculty diploma in 1875 and added the Edinburgh College of Physicians in 1878. He was appointed Medical Officer of Health for Gosport in 1888 and has held a number of other offices there. He took a great interest in the volunteer and territorial services, in which he became Lieutenant-Colonel, and was commanding officer of the Southern Hospital.

Dr. Charles Hamilton Conolly, Medical Officer of Health for Wood Green, which office he held for twenty years, died on Tuesday, aged 56. He qualified in 1895-1896.

Dr. George W. Sidebotham, late Medical Officer of Health for Hyde, died on the 15th inst. A student of Owens College, he qualified in 1876-1877, was much interested in astronomy, served in the volunteers and became Lieutenant-Colonel in the territorials. He described a smallpox epidemic at Hyde in 1886 in the *Manchester Health Journal.*

Progress of Medical Science.

Boston Medical and Surgical Journal, April 28, 1910.

Blood Pressure in the Toxemias of Pregnancy.—The conclusions of R. M. Green are as follows: (1) The toxemias of pregnancy may be divided into a series of fairly distinct clinical groups. (2) In such of these groups as observed by the author the blood pressure bears a fairly constant relation to the other signs and is in general an index of the severity of the process. (3) Blood pressure alone, however, is not a reliable guide unless correlated with other signs. (4) Observations of blood pressure in conjunction with other clinical data may be of great value in determining prognosis and indications for treatment. (5) More extensive observations should be made on blood pressure in the forms of eclampsia described and in others not represented in the author's paper. (6) Such observations should be correlated with chemical examination of the nature of the eclamptic toxin.

Some Clinical Aspects of Pulmonary Embolism.—G. U. Sears presents a study of this condition as recorded in the clinical records of the Boston City Hospital. He finds that the most constant symptoms have been dyspnea, cough with bloody expectoration, and pain; but the suddenness of onset alone gives the first distinctive significance. The other two are so infrequent that their absence is of little importance. The discovery of physical signs of consolidation in the lungs may be of assistance in diagnosis, though a large infarction may lead to error by suggesting pneumonia. Differential diagnosis must be made from cardiac asthma, acute dilatation of the heart, angina pectoris, pneumonia and pleurisy, phthisis, bronchitis, and neuralgia. The characteristic points in this differentiation are passed in review by the author, who quotes illustrative clinical histories. Prompt medical treatment may tide over the crisis and give time for the establishment of a collateral circulation. Surgery has benefited a few cases. The chief reliance must be on prevention, and it may be that the pulmonary embolism may by the first manifestation calling the attention of the attendant to the fact that thrombosis has occurred in some peripheral vessel, but in conditions in which thrombosis may happen, as childbirth, abdominal operations, pelvic tumors, chlorosis, cancer, and other wasting diseases, the

occurrence of a steadily rising pulse not otherwise accounted for should lead to a suspicion that a thrombus was forming in some vein and measures adopted to prevent its separation.

Modern Dietetic Principles; Their Practical Application.—W. G. Thompson discusses this question, with special reference to typhoid fever, stomach ulcer, chronic nephritis, diabetes, tuberculosis, obesity, acute articular rheumatism, etc. He makes a plea for more accurate estimates on the caloric basis of food values by the general practitioner. Absolute accuracy can seldom be obtained outside of the hospital or laboratory, but sufficiently accurate data for clinical use may now easily be secured without special technical skill and without irksomeness for the patient. Tables of values and table scales have been devised. An empty dinner plate is set on the scales, a movable dial is turned so as to deduct the weight of the plate and before each article of food is added the dial is again turned to zero to give the exact weight of the food without the trouble of arithmetical calculation. In practice its use has shown itself to be perfectly simple and patients soon learn accuracy in its employment. The author says that the broad dietetic principles of the human race are directed by factors of environment, occupation, heredity, and individual experience, and are not to be prescribed by the isolated experiments of a few robust young subjects for a limited period. Most Americans consume more protein food than they really need, but the race as a whole is doing fairly well. Another sound principle of dietetics is not to continue the dietetic treatment of a local or special condition so long as to impair the health in other ways. For example, too rigid exclusion of meat may increase anemia; too narrow diet in ulcer of the stomach may lead to debility, and in some cases of diabetes the psychic depression produced by total abstention from saccharine and amylaceous foods may greatly aggravate all the symptoms.

New York Medical Journal, April 23, 1910.

The Statistics of Cancer.—This question is discussed by T. A. McGraw who says he feels justified in asserting that the United States statistics of cancer form no trustworthy basis for any statement *pro* or *con*, as to the alleged increasing prevalence of malignant disease. Men find what they look for and whatever calls attention to any disease will inevitably lead to an apparent increase in its prevalence. There can be no question that the exceeding attention paid by medical men to malignant disease during the last ten or fifteen years in every civilized country has been of great influence in causing the widespread opinion that it is increasing in relative frequency. Twenty years ago the great mass of the profession looked upon cancer and sarcoma as incurable diseases, and paid little attention to disorders which they regarded as hopeless. The instinct of the practitioner led him to refuse recognition to a malady which he could not successfully combat, and to hide from his patient, as long as possible, an evil which would plunge him into despair. What surgeon of that day cannot recall the many cases of advanced cancers of the breast and uterus which had been sent to him in their very last stages as cases of doubtful diagnosis. It required years of preaching and discussion to bring about a change of feeling and to inspire hope in the efficacy of early and thorough operations as a possible cure. Finally the resurrection of the old parasitic theory in a modified form confirmed the wavering belief of the profession in the local origin of malignant tumors, and induced a more general effort to make early diagnoses. As a result of this awakened interest there grew a conviction that cancer was much more frequent than had been believed, a conviction which became a certainty as operative surgery opened the abdomen to inspection and study. A curious effect of this change in point of view has been seen in the nature of diagnostic errors, a change which is due not only to greater attention but also to the recognition of injuries and irritations, as predisposing causes of malignant disease. When physicians became convinced that cancer of the uterus was due often to old lacerations, that of the breast to old injuries and inflammations, that of the lip to local irritations, and that of the stomach to chronic inflammations and ulcers, they began to see malignancy in every form of persistent irritation or tumefaction. This has been especially noticeable in tumefactions of the mammary gland. In former years the character of a malignant tumor was often not recognized before the occurrence of ulceration. Nowadays it is of frequent occurrence, for patients, suffering from fibrous tumors, fibroadenomata, cysts, or chronic inflammations, to come for operations, with a diagnosis from their family physician of cancer. These errors in diagnosis are probably rendered more numerous by the practice, advocated by many surgeons, of regarding every doubtful swelling as a cancer and of treating it accordingly.

Rectal Anesthesia.—J. H. Cunningham presents a review of the history of this method of anesthesia and the experiments which he and his associates have performed along this line. He commends the results which have been obtained in the Boston City Hospital during the last six or seven years. The employment of this method in diseases of the lungs, especially tuberculosis, abscesses, pneumonia, empyema, mediastinal abscesses, etc., has proved to be all that could be desired. Full details of his method must be read in the original paper, but we may quote his statement to the effect that the most satisfactory apparatus consists of a bottle, the body of which is 7½ inches in height, 5 inches being used for ether space, 2½ inches and the neck for vapor space. The diameter is 4 inches and the capacity of the ether space 29 ounces, so that a large amount of ether may be used without materially lowering the ether column. The efferent tube which leads to the bottom of the ether column ends in a bulb with several small perforations so that the air ascends in several small bubbles. The stopper and the connections should be tight. The bottle is placed in a water bath at a temperature of between 80° and 90° F. Ether boils at 98.6° F. It is desirable to keep the temperature below this point. By keeping the ether as warm as possible without boiling, the air forced in by the bulb is more easily saturated. If the operation is a long one it may be desirable to renew the temperature of the bath. We have employed all makes of ether and the results have been the same. The inexpensive ether has been quite as satisfactory as the most expensive. The efferent tube should be sufficiently long to allow moving the wash bottle away in case the operator wishes to change his position from one side of the table to the other. We have tried efferent tubes of varying lengths and have noticed no difference in the results; ether in no case being condensed in the efferent tube. The efferent tube should be of sufficient length to allow the etherizer to inspect the patient from head to foot still retaining the bulb in hand. We have not found it necessary to employ an "interceptor" as no ether is condensed in the tube. Experience has shown that the patient usually passes under the influence of the drug rapidly and with no sense of suffocation; that less ether is used not only in producing the narcosis, but also in maintaining it; that the stage of excitement is lessened or absent; that bronchial secretions are absent; that the ether recovery is more rapid, and that the disagreeable after-effects if inhalation ether narcosis is used are diminished or absent. This is especially true of vomiting. The author explains the theory of narcosis per rectum on the basis of the law of partial tension. A theory is referred to, first advanced by Vejux-Tyrode of Harvard, to the effect that a definite percentage of ether must be present in the entire circulation to produce complete surgical anesthesia. In human beings this amounts to a little under six volumes per centum. The rapidity with which complete narcosis results depends upon the rapidity with which the proportion of ether is brought up to nearly six volumes per centum. When ether is given by the lungs in the form of vapors it can only be administered in great dilution unless excretion be interfered with, and the proportion in the blood be raised above six volumes per centum, which would prove fatal by paralysis of the respiratory center in the medulla. On the other hand, when ether is administered by the rectum as a vapor, concentrated vapors may be given. Therefore, the chances for the rapidity of absorption and the raising to six volumes per centum will take place more rapidly while excretion may take place freely from the lungs.

Some Remarks on Flatulence.—This is a general paper by G. M. Niles who says that in his view a great proportion of stomach and intestinal flatus is swallowed atmospheric air—much greater than is usually credited to this source. This condition is designated aerophagia, and is generally found in nervous or hysterical persons. Incidentally it might be of interest to mention that this habit is not confined to the human race, but is occasionally acquired by horses, these equine freaks being called "stump suckers." Often the individual swallows air unconsciously but constantly, while the eructations are frequent, noisy, and sometimes so explosive that they reverberate almost like small artillery. An important point right here is the fact that in aerophagia the accumulation seems to bear little relation to the food ingested; neither is there much odor to the eructations or the gas

expelled from the anus. Little of this swallowed air, however, gets into the intestines, as most of it escapes back through the cardiac opening. It has been thought that the bulk of the intestinal gas made its way to the rectum, and was ejected therefrom, but it is asserted that, in healthy individuals, half or perhaps much more is absorbed into the blood, later on escaping through the respiratory tract. This accounts for the fact that, while normally there is at all times some fermentation going on in the intestinal tract, the gaseous tension remains about the same in the absence of either eructation or expulsion by the anus. After a general description of the symptoms the author lays down the diet and various remedial measures which have given him assistance in clinical work.

Journal of the American Medical Association, April 30, 1910.

Pleural Effusions.—A. J. Colton says that in cases of empyema in which the patient is desperately ill and septic it has seemed to him an heroic and shocking method to have an inch of rib dissected. Various forms of drainage have been used to avoid the necessity of resection, but all that he knows of have been failures. Rubber tubing is too flexible and soft when used alone, and soft tubes, besides failing to drain, frequently work loose and are lost in the pleural cavity, rendering necessary a still more serious operation. He has devised a tube, which he illustrates, which he thinks meets the needs. He has used it in a great many cases with perfect drainage and recovery of the patient. The method of its use is described. It is introduced into the seventh or eighth intercostal space in the midaxillary line, where the ribs are usually widest apart and the chest wall is thinnest. A linear incision is made one or two inches long, care being taken to avoid the intercostal artery by hugging the knife close to the superior surface of the rib. The opening in the pleural cavity is made simply large enough to admit the tube. If the tube is too long and injury feared to the opposite pleura, gauze can be wound around it as a guard to prevent its going in too far. After thorough pus evacuation, a loose dressing of gauze and a thick layer of absorbent cotton is laid over the tube to absorb the discharge, and is held in place by adhesive strips and a bandage. The dressing should be changed daily for a few days. The tubes should be made of silver in nests of three sizes, the diameter of tube as well as the length being varied to suit different cases. He summarizes his paper as follows: Effusions in the pleural cavity are not to be diagnosed solely by flatness on percussion; neither is the respiratory murmur always absent on auscultation, as is popularly believed. The most reliable means of diagnosing fluid and its character is by the aid of an aspirating needle, and this is not always to be relied on. The point which he wishes to bring out in this paper is the drainage of purulent cases by means of a tube without resection of a rib, whereby the operation is changed from one of a major type to a simple minor one, reducing very much the time required in doing it, as well as the danger accompanying it, thereby considerably lessening the mortality. In none of his cases did he attempt washing out the pleura, as he believes this is a dangerous procedure which should rarely be used. In all of his cases recovery has been rapid and without relapses.

Spastic Paralysis.—S. Kuh describes the symptoms and conditions of spastic paralysis, which may be merely a symptom of function neurosis or the result of an organic lesion. If the latter, it indicates an involvement of the pyramidal tract somewhere between the cortex of the brain and the anterior horns of the spinal cord. Spasticity and the associated exaggeration of the deep reflexes are both results of increased muscular tonus, the latter in turn being caused by the cutting off of the influences of regulation centers. These are not exactly located, though there is no doubt that one, and possibly the most important one, is in the cortex of the brain. Others are supposed to exist in the pons, the red nucleus, the spinal cord, the semicircular canals, and the cerebellum. It may appear only on voluntary movement as a slight stiffness, or it may cause intense contractures abolishing movement. Everything between these two is usually called spastic paresis or paralysis. We find that more or less weakness of muscles almost invariably accompanies their rigidity. If the lesion causing the palsy destroys the myelin sheath of the nerve but leaves at least some of the fibrillæ intact, what we call "intention tremor" is supposed to result. The syndrome from destruction of the pyramidal tract alone is seen in its purest form in three morbid conditions; in the later stages of cerebral hemiplegia, in the primary lateral sclerosis of Erb and Charcot, and in Little's disease. Senile spastic paralysis, resembling the Erb-Charcot malady in some cases, is due to arteriosclerotic changes within the cord. In some rare instances of hereditary or family spastic paralysis we have similar symptoms, and here too the microscope shows degenerative changes in the upper motor neuron. We find spastic paralysis in most cases of disseminated sclerosis, in various forms of myelitis, and in compression of the cord. It may also occur in general paresis. We have mixed forms in which it occurs as in the combined system disease and the characteristics of these conditions are described. In cerebral hemiplegia the paralysis is spastic. In ordinary apoplexy, however, there is usually a few days, rarely a week or more, when the paralyzed muscles are flaccid and then their tonus returns. This is especially the case with hemorrhage, embolism, or thrombosis. In tumor or abscess, encephalitis, etc., the spasticity is more apt to appear from the onset, especially if they involve an irritative lesion in the cortex. Functional and organic spastic paralysis may exist in the same case and the diagnosis be embarrassing. The patient's age, the condition of his cardiovascular system, of his kidneys, his heredity, the existence or absence of previous hysterical symptoms or stigmata are often of diagnostic value. Monoplegias of hysterical origin usually follow injury to the member, which could hardly occur with organic disease. The deep reflexes are almost invariably increased in organic disease, and facial paralysis is very common. True clonus does not occur in hysteria. Sensory disturbances are usually more profound in functional disease, and the abdominal reflexes are not abolished or lost in the latter. The deep tendon reflexes are not so significant as they may be affected in function as well as in organic cases, and the dragging of the leg in hysteria is very different from the semicircular swinging movement of the hemiplegic. Kuh does not attach the significance to the Babinski reflex that is often given it, as he is certain he has found it typical in several cases of hysterical paralysis. The influence of suggestion on the existing disability often clears the situation, but we must not forget that even organic paralysis is more or less influenced by excitements or mental depression. The electric reaction of degeneration, at least in the early stages, is, of course, conclusive evidence of organic disease.

Bilharziasis.—N. D. Brayton has studied the occurrence of bilharziasis in the Canal Zone. Until as late as 1904 the occurrence of this disease was not known in America, and its habitat was supposed to be almost exclusively African, although it had found a foothold to some extent in parts of Asia. He finds this it has been reported 104 times to the sanitary authorities of the Isthmus, chiefly in natives of the West India Islands, especially of the French islands. It has been suggested that its origin on this continent was in the importation of Hindoo laborers into British Guiana and Trinidad, but it must be remembered also that the blacks in this country came from Africa. In either case the disease can hardly have existed for a very long time on this continent, at the longest not over 200 years. Brayton describes the parasite and its methods of reproduction. Our knowledge of its life history is limited, but for part of its life it is a fresh-water organism, and it is likely that its intermediate host is a mussel, snail, fish, or fresh-water vegetable. It can live a long time in the human body. Its ova have been found as long as nine years after the patient had left the infected regions. The manner of infection is not well known, but it is presumed that the organism is introduced from fresh water by drinking, bathing, or exposure otherwise. Its period of incubation in the human being appears to be short. The portal vein is the principal habitat of the adult parasite, but young worms are also found in the liver, intestinal veins, the bladder wall, and the pelvic circulation generally in both sexes. Liver cirrhosis and gallstones may be produced by its presence and dangerous hemorrhage from the urinary organs. Cystitis and urethritis are common complications, and it is often the starting point of calculus. In the severer cases the entire syndrome of surgical kidney or surgical bladder may be produced. When the intestinal tract is involved the symptoms resemble those of tropical dysentery. Two cases are reported, one of which is of interest on account of the character of the ova found in the stools which were terminal spined, a character usually seen only in those found in the urine. Lateral spined ova, the characteristic type of the intestine, have also been found in the urine in one case observed. Whether this difference in eggs indicates a difference in species seems to be in dispute, though Manson inclines to this view. As regards prognosis and

treatment, the disease is rarely fatal, and on the Isthmus its discovery has been generally due to the routine examination of the stools. In case of moderate intensity appropriate general treatment is sufficient to cause amelioration, and in many cases the disease is self-terminating. Anthelmintics have no place in the treatment, and in urinary bilharziasis, except for grave complications, the disease should be left alone.

Gonorrhea.—J. H. Hurst reports a curious case of axillary glandular swelling which seemed to be connected with an eruption of pimples on the face and upper neck, the pus from which showed a mixed infection of staphylococci and gonococci. The infection could only be traced to a barber shop exposure. The swelling in the axilla later developed into an abscess, with abundant gonococcal pus.

Tabardillo.—H. T. Ricketts and R. M. Wilder state that they have found the organism of tabardillo (typhus fever) incapable of passing through a Berkefeld filter. For this reason they have been carefully investigating the blood of patients with the disease and have invariably found, on the fifth to the seventh day of the disease, a short bacillus which has roughly the morphology of those which belong to the "hemorrhagic septicemia group." On minute examination an unstained or faintly stained bar is seen to extend across the middle. Occasionally two organisms are seen end to end. Certain other bodies found may represent degeneration or involution forms of the same organism. They consist of two stained granules connected by an intermediate substance which is stained faintly blue or not at all. Frequently one of these granules or poles is larger than the other and stains a deep purple, while the smaller one takes a faint blue. They have also examined the dejecta and organs of a large series of lice, and have found polar-staining organisms only occasionally in normal lice, whereas they are present almost constantly in similar material from infected individuals. They describe the technique of their search for organisms; protozoa were not encountered. The authors discuss the significance of this organism as bearing on the question of the microbic etiology. From well-known analogies one might suspect the protozoan character of the germ, but they remark that we should keep an open mind of the subject. There are two reasons that favor a bacterial theory—the acute character and self-limitation of the disease and the immunity it affords, neither of which are characteristic features of protozoan disorders. Typhus, moreover, is an hemorrhagic septicemia from a clinical and experimental standpoint, and it has in this an analogy with plague and Rocky Mountain spotted fever which the authors are inclined to group with it as human hemorrhagic septicemias. The organism described has not been found susceptible of cultivation under ordinary conditions. While they say the evidence is not sufficient to claim for it an etiological rôle, yet they think it is sufficient, together with the theoretical evidence above offered, to be seriously considered and to justify further investigation.

The Lancet, April 26, 1910.

Acute Arthritis of Doubtful Origin.—G. B. Buchanan gives the histories of some thirteen cases of arthritis in which the origin was doubtful until some time had elapsed and he refers to the various starting points in cases of the disease which have been reported by others. Concerning young children, he says that they are very apt to get injured by tumbling about so that a traumatic origin can safely be assumed even if the history does not afford evidence of a definite accident. Nerve influence may be sufficient to induce a localized inflammation and it has been shown that arthritis may be induced after an injection of toxic bacteria, by cutting the nerve which supplies the joint. Treatment of these active forms of arthritis resolves itself into rest and the relief of pressure. The first hinders further preventable trauma and the second restricts the absorption into the general system and is carried out by the use of splints or extension. Further relief is secured by the aspiration which, in the milder cases, is all that is needed. Tubes are necessary for drainage in the pyogenic cases for although it is objected that in seropurulent conditions they are apt to induce fibrous thickening and subsequent ankylosis in the severe cases, this will take place anyway. If drainage cannot be properly maintained in this way, part of the joint should be resected to prevent pocketing of pus and this is especially called for in arthritis of the hip when the head of the femur often requires resection. Of the newer aids to therapeutics Bier's method and Wright's opsonic vaccination the author's own experiences have been at least disappointing. He prefers to express no opinion in regard to vaccine therapy until there is at the command of the profession more extensive collection of cases.

A New Method of Treating Acute Phthisis by the Alternate Use of Human and Bovine Tuberculin.—H. K. Crowe says that on general principles autoinoculations should have a greater effect in influencing the course of phthisis for good than artificial tuberculin, that is, regarding tuberculin merely as an agent which stimulates the system to produce antibodies; but tuberculin itself, if not at first, after repeated doses causes autoinoculation. It provides also an easy method of inducing autoinoculation in acute phthisis. Autoinoculations in this disease are dangerous if they be too prolonged in their effect, while the power to stop autoinoculation at will diminishes this danger. By using the T. R. and P. T. R. in an alternating fashion while the patient becomes sensitized to the one form, the power to prevent mischief is vested in the other, and on a continuance of inoculations of that other the inhibitory action is transferred to the former. For a full development of this inhibitory action hypersensibility should be developed, hence small doses should be used because an autoinoculation effect after the first dose or two is not desirable. The central nervous system may possibly play an important part in the processes of immunization.

Treatment of Graves' Disease with the Milk of Thyroidless Goats.—W. Edmunds refers to the later history of cases recorded by him one and two years ago, and adds the histories of several new cases. In a general way the condition of his cases has improved, but this has not always persisted. Improvement apparently affected the entire organism not being limited to any single organ or symptoms. The previous reports were published in the *Lancet*, issues of January 25, 1908, and April 10, 1910.

French and Italian Journals.

Presence of Diphtheritic Toxins Circulating in the Blood.—Gino Menabuoni has made careful investigations as to whether toxins of diphtheria can be found circulating in the blood of the patient after the throat infection has cleared up, and whether this is the cause of the late diphtheritic paralysis. His experiments were made upon rabbits, injecting the toxins, and examining the resulting gelatinous edema. He concludes that after a certain interval the toxins are no longer found in the circulation. Toxins were found from three to four days after the membrane disappeared from the throat; its presence is subordinate to the presence of the bacilli in the infective focus, living and virulant. As long as there is exudate we may expect to find the toxins in the blood. The paralytic phenomena are probably not to be attributed to circulating toxins. The period of true activity of these germs is very short, and they are most active during the first few hours after the infection. The toxins fix themselves slowly on the cells but quite stably. As a corollary we see the necessity of preventing this fixation very early in the disease by the use of antitoxin. The avidity of the toxins for the receptors of the antitoxin is greater than that for the receptors of the cells.—*Rivista di Clinica Pediatrica, January*, 1910.

Daltonism.—Alfonso Neuschuler defines Daltonism as a diminution in the chromatic sense, a dyscromatopsia, or partial or total achromatopsia. It is a diminution or loss of the chromatic sense. While absolute color-blindness for all colors is rare, a partial absence is not uncommon. It is more frequent in men than in women, on account of their more thorough education in colors. The total forms are generally bilateral, and associated with nystagmus and amblyopia. The most frequent forms of color-blindness are for red, for green, and for both of these colors. This condition may be congenital or acquired. In the congenital form the prognosis is absolutely bad. The secondary or acquired condition is dependent on general disturbances and symptomatic. There are various theories as to the causation of the congenital form, which the author recites. The symptomatology consists in alterations of perception for red and green, while the perception of blue and yellow is retained. In acquired Daltonism there may be atrophy of the optic nerve, or poisoning, as in alcoholic blindness. The use of santonin causes transitory disturbances of the color sense. The prognosis of this form is good.—*Il Policlinico, February 6, 1910.*

According to the statement of a Greek pastor of Lowell, Mass., 60 per cent of the large Greek population living in that city are afflicted with tuberculosis.

Book Reviews.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia. Assisted by H. R. M. Landis, M.D., Assistant Physician to the Out-Patient Medical Department of the Jefferson Medical College Hospital. December 1, 1909. Philadelphia and New York: Lea & Febiger.

The December number of this well-known review contains articles on: Diseases of the digestive tract and allied organs, the liver and pancreas, by D. L. Edsall; diseases of the kidneys, by J. R. Bradford; surgery of the extremities, tumors, surgery of joints, shock, anesthesia, and infections, by J. C. Bloodgood; genitourinary diseases, by W. T. Belfield; and practical therapeutic referendum, by H. R. M. Landis. The present instalment is of the same standard of excellence as its predecessors.

Compendium der Verband und Operationslehre. By Prof. Dr. Eduard Sonnenburg and Dr. Richard Mühsam. Second Edition, with 290 illustrations in the text. Part II., operations. Berlin: August Hirschwald, 1910.

In this, the second edition of the Sonnenburg's and Mühsam's "Compendium," the sections on general and special operative technic have been combined in a single volume, of which the contents have been largely rewritten and enlarged. Although most of the improvements on the older methods and the newer procedures are described, a few omissions have been observed. Thus in the description of transfusion the statement is made that the infusion of normal saline solution affords the only practical treatment in condition where an addition to the blood mass is indicated. No mention is made of the work of Crile and others with the transfusion by cannula of human blood—a process which seems to gain favor daily among surgeons. Aside from these and a few other, probably unintentional omissions, the book presents a condensed but very comprehensive manual of surgical operations.

The Prevention and Treatment of Abortion. By Frederick J. Taussig, A.B., M.D. Lecturer in Gynecology, Medical Department, Washington University; Obstetrician to the St. Louis Maternity Hospital; Gynecologist to the St. Louis Skin and Cancer Hospital; Fellow of the American Gynecological Society, and American Association of Anatomists. Fifty-nine Illustrations. St. Louis: C. V. Mosely Company, 1910.

The book here noted seems to afford the most practical and comprehensive manual on this important subject which has appeared in our language within recent years. The consideration given to this important topic by the textbooks is far too meager, and from the number of women who suffer from the complications attendant upon the premature expulsion of the ovum, it would appear that in such instances a knowledge of their treatment is very incomplete. The author of this book has undertaken to present to the general practitioner, in particular, the essential facts of this subject as we know them at present in a form which would serve as a guide to the variety of treatment demanded by the individual case. The first part of the book is devoted to the anatomy, pathology, etiology, and diagnosis of this condition as explanatory and introductory to the main portion on prevention and treatment. In the excellent chapter on the differential diagnosis of abortion, there is another factor which might have been considered, and that is the presence of an acute or subacute salpingitis. This condition may also give rise to uterine bleeding and localized pain of a kind simulating an incomplete abortion and the differential diagnosis should play an important rôle in a case of this kind.

Several chapters are devoted to a detailed consideration of the prevention of abortion, with particular reference to the necessity of more complete education and legislation regarding criminal abortion. In discussing the operative indications for abortions in general, Taussig believes that the best advice to be given to the general practitioner is to await developments in the absence of immediate danger and to operate only when complications ensue. Considering our present-day knowledge of the subject, this does not appear to be the best advice, and notwithstanding the fact that some, or perhaps many women, get well after abortion without operative interference, the majority, according to the author's own statement, certainly do not. If the general practitioner, so-called, is unable to clean out the uterus properly when necessary, the case should be turned over to some one who can do so. In concluding this brief comment on a most valuable book, reference must be made to the excellent manner in which it is printed and illustrated.

Age Incidence, Sex, and Comparative Frequency in Disease. By James Grant Andrew, Fellow of the Faculty of Physicians and Surgeons, Glasgow. London: Baillière, Lindall & Cox, 1909.

The writer of this book believes that data derived from one source sufficient to attempt a clinical classification of disease will be valuable to the diagnostician. Accordingly, he has taken the statistics of the Western Infirmary of Glasgow for a period of ten years, and has compiled them in such a way as to make them easy of reference. The book is therefore not one for general reading. The age, arranged in decades, at which any disease occurs is given, together with the sex and frequency. A complete index aids one to find quickly data relative to the occurrence of the diseases described.

A Textbook on the Practice of Gynecology. For practitioners and students. By William Easterly Ashton, M.D., LL.D.; Professor of Gynecology in the Medico-Chirurgical College of Philadelphia; Gynecologist to the Medico-Chirurgical Hospital, Philadelphia; formerly Lecturer on Gynecology in the Jefferson Medical College, Philadelphia; Fellow of the American Gynecological Society; one of the founders of the Congrès International de Gynécologie et d'Obstétrique; member of the American Medical Association, etc. Fourth edition, revised and enlarged, with 1058 new line drawings by John V. Alterder. Philadelphia and London: W. B. Saunders Company, 1909.

New matter has been added to the chapter on constipation, and the indications for the use of indoor exercises have been made to harmonize with modern ideas on the subject of defective body form in its relationship to abdominal and pelvic displacements. The equilibrium of the pelvic organs and the condition of the circulation depend largely upon the strength of the abdominal muscles, the capacity of the middle zone, and the prominence of the lumbar lordosis. So long as these three conditions are normal the uterus and the appendages maintain their position and there is no tendency to congestion unless pelvic lesions are present. When, however, the opposite conditions exist, indoor exercises are indicated, and, if properly used, will correct the physical deformities. In the chapter on the causes of diseases peculiar to women the effect of wearing corsets is considered from the standpoint of the abdominal wall as a factor in maintaining the balance of equilibrium of the organs of the abdomen and pelvis. The chapter on erysipelas of the vulva has been rewritten, and the local use of magnesium sulphate as devised by Dr. Henry Tucker is recommended; the local application of this agent has been used with such uniformly good results that he considers it a specific for this affection and other forms of inflammation. The operative management of suppuration of the pelvic connective tissue has been changed and special emphasis placed on the evacuation of pus by vaginal section. This route should always be selected because it is safer; it offers better advantages for irrigation and drainage; there is no danger of infecting the peritoneal cavity; and the operation is more quickly performed, which is a great advantage in patients weakened by sepsis. Alterations have been made in the chapter on ectopic gestation and the question of immediate *versus* deferred operation for intraabdominal hemorrhage due to tubal abortion or rupture thoroughly considered. Additions have been made to the treatment of cystitis, and tuberculosis of the genital organs has been fully revised. The pathology of shock has been rewritten and the views of recent experimenters carefully considered. Notwithstanding the fact that Crile's theory (which is that shock is an exhaustion of the vasomotor center) has been generally accepted by the surgical world, we are forced to the conclusion by the experimental work of Boise, Hendersen, and others that its true pathology is as yet undetermined. The Fowler-Murphy method for the treatment of diffuse suppurative peritonitis is now generally accepted by surgeons, and consists essentially of Fowler's position, pelvic drainage, and Murphy's drop-by-drop enteroclysis. This treatment is given in detail. The causes of movable kidney have been considered from the standpoint of defective body form. The treatment has been revised and special attention called to the importance of excluding gastroptosis before deciding on operative measures. A more modern and scientific exposition of the subject of gynecology has not been presented.

Jejunal and Gastrojejunal Ulcer Following Gastrojejunostomy. By Herbert J. Paterson, M.A., M.B., B.C.Cantab., F.R.C.S.Eng.; Assistant Surgeon to the London Temperance Hospital; formerly Hunterian Professor of Surgery and Pathology at the Royal College of Surgeons. London: John Bale, Sons and Danielsson, 1909.

This brochure is a reprint from the "Proceedings of the Royal Society of Medicine." It contains observations on jejunal and gastrojejunal ulcers following gastrojejunostomy. A full account of two cases occurring in the author's practice is given, and also an abstract of sixty-one other cases from the literature.

Physician's Pocket Account Book, and practical advice for professional success. By J. J. Taylor, M.D. Philadelphia, Pa. The Medical Council, 1909.

This book has about two hundred pages for accounts, with space for birth, death, and vaccination records. Suggestions for bills, collections, treatment of poisoning, etc., are included. The arrangement of the book is good and the busy practitioner ought to find it of great service in simplifying his bookkeeping, but the paper and binding should be better for a book that is destined for such constant handling.

A Textbook Upon the Pathogenic Bacteria, for Students of Medicine and Physicians. By Joseph McFarland, M.D.; Professor of Pathology and Bacteriology in the Medico-Chirurgical College, Philadelphia; Pathologist to the Philadelphia General Hospital and to the Medico-Chirurgical Hospital, Philadelphia; Director of the Laboratories of the Henry Phipps Institute; Fellow of the College of Physicians of Philadelphia, etc. With 211 Illustrations, a number of them in colors. Sixth Edition, Thoroughly Revised. Philadelphia and London: W. B. Saunders Company, 1909.

As the name implies, this book deals exclusively with the pathogenic bacteria. For the study of the nonpathogenic bacteria and the pathogenic protozoa, the student is referred to the works devoted to those subjects. Part One, "General Considerations," discusses infections; immunity; sterilization, and disinfection; bacteria, their biology, their cultivation, and the methods of observing them; bacteriology of the air, water, soil, and foods. Part Two, "Specific Diseases and Their Bacteria," is subdivided into The Phlogistic Diseases, The Toxemias, The Bacteriemias, and Unclassifiable Diseases. In considering the specific diseases and their bacteria, the author gives a description of the disease and its lesions. Each species of bacteria is very fully discussed, as regards its distribution, morphology, alteration, toxic products, and pathogenesis. Where antitoxins, vaccines, or serums have been discovered, the method of using them is described. In speaking of the use of tuberculin, in the diagnosis of tuberculosis, the various tests, with the exception of the Moro test, are mentioned, but their comparative values are not discussed. The illustrations are good, many of them being taken from standard textbooks. The book is well written, and contains an extensive bibliographical index. It is one that will be found very useful to the student and general practitioner.

Air and Health. By Ronald Campbell Macfie, M.A., M.B.C.M. Author of "Romance and Medicine," "Science, Matter, and Immortality," etc. New York: E. P. Dutton & Co., 1909.

For the student of hygiene and sanitation, as well as for those who wish a good reference work on these subjects, the author has written a serviceable book. The work seems sufficiently exhaustive for all practical purposes, and the subjects discussed are considered in a logical and clear order of sequence. One may venture the hope that the chapter on ventilation will be widely read, for this is a subject which is worthy of very careful attention, and is about the last thing to be considered by our modern architectural engineers. He thinks the limit of permissible impurity of carbon dioxide content is about 10 volumes in 10,000. He quotes the experiment of Dr. I. H. Hance at the Adirondack Cottage Sanatorium, where ten guinea pigs were inoculated with dust from one of the cottages in which tuberculosis patients had lived, five of which became tuberculous; this seems a sufficiently good argument in favor of the fact of infection through dried tuberculous sputum. The smoke problem in great cities he acknowledges is very difficult to control. In London, a certain Mr. Spence suggested some years ago that the smoke should be conducted by the sewers to a few enormous chimneys, where it could be completely burned, and where the sulphuric acid in the smoke would act as a disinfectant. Of course, such a scheme would cost too much to be of practical value. The last chapter considers the open-air treatment of consumption and open-air schools, and the author believes that when a nation realizes the importance of open-air education and puts it to use, the children thus taught will outstrip all their rivals in the race for life.

The Practical Medicine Series. Under the General Editorial Charge of Gustavus P. Head, M.D., Professor of Larynogology and Rhinology, Chicago Post-Graduate Medical School. Volume X, Nervous and Mental Diseases. Edited by Hugh T. Patrick, M.D.; Professor of Neurology in the Chicago Polyclinic; Clinical Professor of Nervous Diseases in the Northwestern University Medical School; Ex-President Chicago Neurological Society; and Charles L. Mix, A.M., M.D.; Professor of Physical Diagnosis in the Northwestern University Medical School; Ex-President Chicago Neurological Society. Chicago: The Year Book Publishers, 1909.

The first few pages deal with the symptomatology of nervous diseases in general. Then follow in order the discussion of the neurosis, diseases of the brain, meninges, and spinal cord; diseases of the peripheral nerves; miscellaneous nervous and mental diseases. This book, being a synopsis of the literature of the past year, is, like its predecessors of the series, of special value to the busy practitioner who wishes to keep abreast of the advancements in medicine but has not the time to thoroughly read the literature.

Visceral Surgery in Abstract. By Acheson Stewart, M.D., Junior Surgeon Mercy Hospital, Pittsburg, Pa. Pittsburg: Medical Abstract Publishing Company, 1909.

This is a small book that can conveniently be carried in the pocket. It covers briefly all the important facts in connection with the etiology, symptoms, diagnosis, and treatment of the various surgical conditions.

Arthrosteopedic Surgery (Extremities and Skeleton). By Stewart L. McCurdy, A.M., M.D.; Author of "Orthopedic Surgery," "Oral Surgery," "Anatomy in Abstract," "Emergencies in Abstract;" Orthopedic Surgeon to Columbia and Presbyterian Hospitals; Professor of Anatomy and Oral Surgery, Pittsburg Dental College, University of Pittsburg, Pittsburg, Pa. Pittsburg: Medical Abstract Publishing Company, 1909.

This book is of pocket size. It deals in a concise manner with all the important surgical conditions that are not included under the head of visceral surgery.

An Atlas of Dental Extractions, with Notes on the Causes and Relief of Dental Pain. By C. Edward Wales, M.R.C.S., L.R.C.P., L.D.S.; Assistant Dental Surgeon Kings College Hospital; Assistant Medical Officer (Education) London County Council; Late Dental Surgeon Victoria Hospital for Children, Chelsea, etc. Philadelphia: P. Blakiston's Sons & Co., 1909.

This book is a concise treatise on the relief of dental pains, either by means of local applications or in extreme cases by extraction. The first chapter considers the causes of dental pain and their treatment. The remainder of the book deals with extractions. It gives a description of the technique of extracting, with a limited number of selected forceps. There are eleven plates illustrating the application of the forceps to the different teeth, and showing the position of both patient and operator. The footnotes to each illustration describing the steps of the operation of extraction are excellent. This book will be found useful to medical men in a country practice or on board ship, where there are no dental surgeons.

The Operations of Aural Surgery. By C. Ernest West, F.R.C.S., and Sidney R. Scott, M.S., F.R.C.S., Surgeons to St. Bartholomew's Hospital, London. Philadelphia: P. Blakiston's Son & Co., 1909.

The authors attempt in this volume to describe all the chief surgical measures in otology, from incision of a furuncle to the operations for brain abscess, labyrinthine disease, and meningitis. They say that all the procedures recommended have been well tested and found of value, and that nothing is presented which is not the result of clinical experience. They believe that the acceptance of meningitis as a condition admitting of merely palliative treatment is discreditable to aural surgery, and they describe their method of dealing with this condition. The volume is well done, so far as it goes, but is scarcely written with that breadth of view or that exhaustiveness which would make it indispensable as a book of reference for the aural surgeon.

Society Reports.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

Eighth Triennial Session, Held at Washington, D. C., May 3, 4, and 5, 1910.

GENERAL SESSION, TUESDAY AFTERNOON, MAY 3.

(Special Report for the MEDICAL RECORD.)

THE PRESIDENT, DR. EDWARD L. TRUDEAU, IN THE CHAIR.

Symposium on Artificial Immunization.—The Formation of Antibodies.—Dr. LUDVIG HEKTOEN of Chicago presented this paper, which was read by the secretary. Dr. Hektoen stated that active immunization gave rise to the reaction products known as antibodies and to an increased sensitiveness to the primary immunizing substances. Any substance capable of inciting the formation of antibodies was an antigen. For two or three days after the injection of an antigen in a normal animal there was, as a rule, either no change in the antibody curve, or there might be a fall in the specific antibody if such were already present; at the end of this period of latency new antibody appeared; at first it increased rather rapidly and then somewhat more slowly until the maximum was reached, which in most cases seemed to take place about the tenth day; soon after this began gradual return to the normal standard. This was the third phase of the curve and it might last only a few days, several weeks, or even longer. Taking the curve as a whole, it represented the rise and fall of free antibodies in the blood, and one might regard it in any part of its course as representing the balance between production and loss of antibody. On this basis it was evident that in the second part of the curve the amount being produced exceeded the amount being lost, consequently antibody accumulated in the blood and lymph. When the acme was reached the production and loss were equal, but production soon fell and the curve gradually sank. Animals, including man, normally carried in the blood small amounts of a large number of antibodies. In many instances they possessed specific affinities for antigenic substances, and probably they were not essentially different from the corresponding immune bodies. The height and duration of the simple curve varied, depending on the kind and amount of antigen, the place of introduction, and largely also on the individual animal. In immunization with toxins and with bacteria the rule was to begin with rather small, harmless quantities and to reinject with increasing quantities, carefully graded to avoid severe reactions and prolonged depression of antibody production, at intervals of a few days for a considerable period. With increasing doses it seemed that most was attained when they were given at intervals of four and five days. The same bacterium or corpuscle might give rise to lysin, agglutinin, opsonin, and other specific bodies. In some cases the different bodies appeared to increase in the same proportion and to describe parallel curves, but in other cases this was not so. This asymmetry in the course of antibodies educed in the same animal for the same body suggested that we were dealing with distinct substances. Furthermore, that it would not be safe in all cases to conclude that because one antibody, like the opsonin, was high or low the other antibodies must also be high or low. It would seem that largely the same mechanisms produced all antibodies. Observations that had been made suggested that the lessened resistance to streptococcus and other infections of the acute eruptive diseases, notably smallpox and scarlet fever, and of tuberculosis, might depend in a measure on the inability of the body to respond freely to the stimulus of more than one antigen at a time. And the aggravation of the primary disease, *e.g.* tuberculosis, as secondary infection developed, might depend on depression in the manufacture of tuberculous antibodies by the antigen of the new infection, as illustrated by the suspension of the tuberculin reaction by an attack of measles. The antibodies were formed in the blood-making organs and given off to the blood or formed elsewhere and stored temporarily in these organs.

On the Relation of Anaphylaxis to Artificial Immunization.—Dr. FREDERICK P. GAY of Boston read this paper. He said that the condition of hypersusceptibility of anaphylaxis which might follow an initial injection of various toxic or nontoxic proteins had in the last few years attracted the merited attention of experimenters. This condition of anaphylaxis was experimentally demonstrable after a period of incubation, on reintroduction of the sensitizing protein, by a train of violent or fatal symptoms which did not occur in the normal individual. In such a manner, either by artificial inoculation, or without doubt in many instances by certain natural means of infection, an animal might become highly susceptible to intoxication with a substance which produced no effect under usual conditions (horse serum), or might be killed by a dose of bacteria or bacterial products which was under the amount that was fatal for the untreated animal. The condition of anaphylaxis was obviously related in some manner to conditions of increased resistance or immunity; either condition might occur following the introduction of a given antigenic substance and both depend on a similar incubation or reaction period. The fact that the two processes as demonstrated were apparently of diametrical opposed import to the host in no manner assured us that a nonfatal anaphylactic intoxication might not be of ultimate value. This latter view was, indeed, taken by many observers. It would at least be admitted by all that nothing approaching a final decision as to the actual relation of these two processes could at present be given.

Artificial Immunization in Nonbacterial Disease.—Dr. S. P. BEEBE of New York read this paper. He stated that a large portion of our knowledge concerning the processes of immunity and nearly all the practical applications of this knowledge had been concerned with infectious diseases. However, many of the theories which had made progress possible had been elaborated upon the basis of experiments with snake venoms, hemolytic reactions, and pure proteids, and this kind of laboratory experimentation had preceded, or been coordinate with, our advance in knowledge concerning the infections. He said that they had in the venom of poisonous snakes and in certain proteids of vegetable origin, such as ricin, examples of nonbacterial toxins; and the results obtained by the employment of these substances had been of great importance in the history of immunology. From a practical standpoint also such studies had been of value, and Calmette had perfected his methods of producing antivenin to such a degree that its therapeutic value was not to be doubted. Other animal toxins, such as those from the scorpion, from spiders, from the tarantula, heloderma, and from bees had been used as antigens to develop immune sera, and in a few instances such sera had been used therapeutically. Toxic substances of vegetable origin had been used as antigens for many experiments in immunity investigation, and in some instances notable additions to our theoretical and practical knowledge had been obtained. As was now well known, the injection of any alien proteid stimulated the formation of antibodies whose presence might be detected by one of several methods. It

seemed probable to the writer that he might do violence to no one's cherished belief in the infectious origin of tumors if he included in this discussion the question of immunity to cancer. At the present time the methods which appeared to be available for immunizing an animal with already growing tumors were as follows, it being understood that these methods were successful in only a certain percentage of cases: First, by repeated subsequent implantations of tumors, Gaylord and Clowes having shown that by this means the later plants grew for only a short time, the original tumor soon felt the effects of the developing immune forces and was completely absorbed. Gay had modified this procedure by obtaining complete absorption of the first tumor by the subsequent transplantation of only one graft, provided it was done before the development of metastases. Similar observations had been made by Van Dungern and Coca working with the transplantable sarcoma of hares. It would seem from the results of these experiments that a method of vaccination was a logical procedure in the treatment of malignant tumors, but it must be observed that efforts to accomplish the same results with tumor extracts, or with tumor cells killed by heat or chloroform or other physical means, had not served to stimulate the development of the immunity. Nothing short of the living tumor cells was capable of having such an effect. The interest which all cancer investigators had had in the experiments on cancer immunity had been greatly stimulated by the recent observations of Hodenpyl. He was fortunate in having under his observation a human patient with carcinoma who showed most remarkable spontaneous regression of a far-advanced tumor, the tumor being primary in the breast with extensive metastases in the liver. The regressive processes were accompanied by the production of chylous ascitic fluid. This fluid had been injected subcutaneously and intravenously in a considerable number of patients with very favorable therapeutic effects in many instances. In some cases there was at first complete absorption and apparent recovery, but during the last few weeks these cases had shown a renewal of the growth. It was, of course, impossible for us to say in what manner this fluid acted, but in view of the experimental work of the last few years the results did not seem surprising. Startling as had been some of the effects following injections of this fluid the procedure seemed to be a logical one, and, regardless of the ultimate outcome of the observations, they had at least served the purpose of awakening new interest and of giving a new lead in this most perplexing and difficult line of work.

Dr. J. George Adami called attention to the possibility that during the past score of years they had been directing their attention too exclusively to the specific antibodies and not sufficiently to those more basal phenomena which preceded the development of these specific antibodies, that was to the phenomena of nonspecific immunity. They had been too much accustomed to consider the individual case. If the body cells in general had the capacity to destroy, say, typhoid bacteria, they had been too apt to take this as an indication that the body cells naturally produced specific antityphoid bodies. There was absolutely no justification for this conclusion, no more than for concluding that the gastric juice could indifferently digest clams, planked shad, sweetbreads and calfsfoot gelatin. The first stage of bacterial antagonism in the system was nonspecific.

Dr. Alfred Stengel of Philadelphia said that he wished to speak of the practical or clinical aspect. Most of them, after all, were vitally interested in the practical side of all these matters of immunization. The laboratory worker would come up to a certain point, but the possibilities of untried results in our practical work would have to be studied and seen by practical clinicians. It was therefore important that they should be alive to that possibility. The clinician must keep close to the laboratory worker, and the latter, reciprocally, must keep close to the clinician for the inspiration or direction of his work.

Dr. Leo Loeb of Philadelphia said very interesting results had been obtained so far in experimental work on tumors, but the results had been very contradictory in many respects. They had never been able to produce experimentally by inoculation with tumor active sera with which they could cure cancer. On the other hand, there was no doubt from clinical and experimental data that under certain conditions antibodies were produced in the course of tumor growth. Why wasn't it possible for them to show experimentally in most cases the presence of such antibodies? He believed that the condition was similar to that prevailing in certain cases of internal secretion. In certain cases we could prove the presence of internal secretions by injections of the extracts of the organ producing that internal secretion, or by injecting the blood serum. In other cases in which we could be absolutely sure of the presence of an internal secretion we could not prove its presence by the injection of extracts of the organs or of the blood sera. It seemed to him that this conception might prove of use in immunity. Certain antibodies were produced continuously in very small quantities and very rapidly removed from the body, and that was probably the case in tumor growth, and they could not therefore make use of passive immunity, but, on the other hand, they had much better prospects for using active immunization in cancer growth, and he believed that in the near future quite marked progress would be made by that same means of immunization.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held March 21, 1910.

The President, Dr. Reynold Webb Wilcox, in the Chair.

Blotting Paper Moulds for Obtaining Crayons of Carbonic Acid Ice.—Dr. Sinclair Tousey showed this device which consisted in a hollow cylinder made by rolling several layers of blotting paper around a lead pencil or a glass vial, which was then removed. One end of the tube thus formed was tightly stoppered. The other end was placed firmly against the nozzle of the liquid carbonic acid tank, and wrapped around with adhesive plaster to make an air-tight joint. The carbonic acid cylinder employed was a small one, eighteen inches long and four inches in diameter, and containing five pounds of the liquefied gas. It was laid upon its side, with the lateral nozzle turned downward. The liquid should then be allowed to flow out into the porous paper tube. A portion of it immediately vaporized and escaped through the meshes of the paper, producing cold enough to freeze the remainder. The liquid should be allowed to flow very slowly, taking perhaps a minute to fill the tube. Turning it on full force would blow the tube off and waste a great deal of the liquid. When the mould was full of ice, the liquid would begin to spurt out around the adhesive plaster, and the flow should then be turned off. The adhesive plaster being unwrapped, the porous paper cylinder would be found to contain a crayon of carbonic acid, resembling very much the crayon used for writing on a black-board. The blotting paper might be unwrapped from one end of

the crayon, so as to expose the latter. The blotting paper was flexible enough and a sufficient non-conductor of heat to serve as a handle for the crayon, which must not be touched by the naked hand. Frozen carbonic acid, Dr. Tousey said, had been successfully used in treating port-wine stains, a type of nevus for which no other treatment was at all satisfactory. Other lesions for which it was excellent were lupus, condylomata, warts, moles, and epitheliomata.

Dr. William S. Gottheil said the employment of solid carbon dioxide in dermatotherapeutics was the most important remedial procedure that had appeared for many years. He had no hesitation in saying that more definite and lasting good could be accomplished with it than with all the elaborate radiotherapeutic and high frequency apparatus. Deformities and diseases that were formerly either untreatable, or manageable only with great difficulty and at much expense of time and labor, could now be handled with ease and confidence. Nevi of all varieties and of any extent, xanthomata, superficial malignant growths, tatooings, gunpowder stains, and many other deformities and new growths could be removed with a minimum of scarring, or even without any very apparent production of cicatrical tissue. It was a destructive agent that was anesthetic, so that no special measures to obviate pain were required; and one that was manageable in a way that was entirely different from other destructive agents. The entire thickness of the integument might be destroyed, or any layer of it alone, so that deep-seated and essentially untreatable conditions, such as large cavernous angiomata, might be covered with successive layers of delicate connective tissues by the cautious employment of the agent, until the deformity was relieved. The method of obtaining it that had been demonstrated by Dr. Tousey was one that the speaker said he had employed for more than two years, only that he made a larger mass, usually five or six inches long and one to two inches in diameter. Properly drawn, this mass was hard to brittleness, so that it could be cut into any desired shape. It should be almost translucent, and it could then be kept for hours. Dr. Gottheil said he had been receiving letters from physicians all over the country, requesting information as to the method of using the solid carbon dioxide, many of them wanting to use it on members of their own families or friends, and he would repeat here the warning that he had frequently given. The technique for getting the material and for employing it was of the greatest importance. Failure to get it in proper form, want of success in its use, or excessive and undesirable reaction were caused by lack of experience. It could be handled almost as an instrument of precision by those accustomed to its use, but it was well to know something about it before employing it on an important case.

Dr. Albert C. Geyser said that in one case of recurrent keloids where he had employed at one time the *x*-ray and at another the carbon dioxide, the former was practically painless, while the use of the latter was followed by such excessive pain that morphine had to be resorted to to control it.

What Do We Actually Know About Tuberculosis? The Wheat and the Chaff.

I. **Introductory: Some Open Questions in Tuberculosis.**—By Dr. Thomas E. Satterthwaite. (Will be published later.)

II. **The Crux of the Tuberculosis Problem.**—By Dr. Lawrence F. Flick of Philadelphia. (See page 830.)

III. **The Problems of Immunity in Tuberculosis.**—By Dr. Francis M. Pottenger of Los Angeles, Cal. (Will be published later.)

IV. **Phthisiophobia.**—By Dr. J. H. Lowman of Cleveland, Ohio. (See page 832.)

Dr. Beverley Robinson said that personally he was opposed to the expenditure of large sums of money from either public or private sources for the erection of sanatoria for the treatment of tuberculosis, for the simple reason that many such patients would be compelled to return and live in the same environment and under the same conditions in which the diseases was bred. Another objection to the sanatoria method of treatment was its limitations—only a few, a very few, could thus be taken care of, in spite of the enormous expense it entailed. In order to get at the root of the evil, the speaker said, we must get rid of the essential conditions that produced tuberculosis; the underlying, fundamental defects of living and environment and the lack of proper housing and sanitation, which were, after all had been said and done, the governing factors of the disease, rather than a few microbes. While the tubercle bacillus was the direct, exciting cause of pulmonary tuberculosis, it was only harmful under certain conditions; its development depended on the soil, and under favorable conditions of living, even the most susceptible individual was less apt to take the disease. Over thirty years ago the late Austin Flint showed that tuberculosis, like many other diseases, was self-limited, and that many recoveries took place under proper hygienic conditions. In addition to those that recovered, a certain proportion could be expected to improve, and finally, we knew there were some that would inevitably die, even under the most favorable surroundings and in spite of all treatment. Dr. Robinson said that thus far, the results of the sanatorium treatment of tuberculosis had not been particularly encouraging, and he believed that the benefits attached to it were neutralized, to some extent, at least, by the environment of the patient, and the mental attitude produced by his too close association with others similarly affected. In closing his remarks, the speaker said he was opposed to the treatment of cases of active tuberculosis in general hospitals. Regarding medication, he was firmly convinced that creosote, both internally and by inhalation, had a distinct curative effect in a certain number of cases of pulmonary tuberculosis.

Dr. Charles J. Hatfield of Philadelphia said he wished to enlarge upon one point of special interest that had been brought out in Dr. Flick's paper, namely, in reference to securing quarters for advanced cases of tuberculosis in general hospitals. In the general hospitals throughout the State of Pennsylvania, there were, broadly speaking, 2,000 vacant beds each year, exclusive of a certain proportion that must be kept ready for emergency cases. Throughout the State there are about 8,000 deaths from tuberculosis each year. It has been found that the three last months of the life of a tuberculous patient are the most dangerous from an infective point of view, because it was then usually that he is unable to take care of himself, and must be taken care of by some one. Among the 8,000 patients who die yearly in the State of Pennsylvania, there are many who are very poor, who cannot take care of themselves, and who are not properly taken care of by their relatives or friends. If they could be placed in some local, general hospital, and taken care of in a special ward set apart for that purpose, it would remove one of the chief sources of infection, and at the same time help solve the problem of what to do with these advanced cases of tuberculosis. Whereas many of these patients are disinclined to be transported far from home to an institution specially set apart for tuberculosis, very few of them probably would object to going to a local, general hospital. The handling of these patients in a general hospital would also serve as an effective argument against phthisiophobia. On the other hand, there is no good, scientific reason why, under proper precautions and with the aid of trained attendants, these patients could not be safely taken care of in any general hospital. In order to bring the matter to a practical test, Dr. Hatfield said, a number of petitions

were circulated and sent to the Governor, and the State Legislature was asked for an appropriation to defray the expenses of advanced cases of tuberculosis in general hospitals throughout the State, at a cost of $1 per day for each patient admitted. The Governor did not get an opportunity to act on the petition, as the bill referred to did not get further than the Committee on Appropriations. A communication on the subject was also sent to 137 general hospitals throughout the State. Of these, ten replied that they had no room for tuberculosis cases; fifteen had no way of isolating such patients; nine were undecided. Two hospitals consented to test the plan. From the re-remaining 101 institutions no replies were received.

Dr. L. Rosenberg of Bedford Station, N. Y., said he entirely agreed with Dr. Flick and Dr. Hatfield in regard to the absolute necessity of some sort of segregation of advanced cases of pulmonary tuberculosis, or their more careful home supervision. Unless this was done, he believed that the complete obliteration of tuberculosis in any civilized community was impossible. Some of the statements made by Dr. Pottenger in regard to immunity were perhaps too optimistic. While some degree of immunity was possibly conferred by a pre-existing tuberculosis in early life, it was not in accord with the speaker's observation that this was sufficient to protect the individual to the extent implied by Dr. Pottenger. On the other hand, he believed that certain races enjoyed more or less immunity, and that city dwellers were more immune to the disease than those who lived in the country. In a paper published several years ago, Dr. Woods Hutchinson claimed that the low mortality from tuberculosis among the Jews, as compared with that among the Irish and negroes living under similar conditions, was due to the fact that for centuries the Jew had been an urban dweller, and thus had acquired a certain degree of immunity. Dr. Rosenberg said he now agreed with Dr. Hutchinson, although at the time he was inclined to believe that the lesser mortality among the Jews was due to their more abstemious habits rather than to a racial immunity. The speaker expressed the hope that we would some day discover an artificial method of immunization against tuberculosis. He believed in the use of tuberculin in the treatment of tuberculosis, but at the same time he was not as optimistic as Dr. Pottenger in regard to it, neither as to its curative effects nor as to its power to prevent relapses. It was still a very empirical method of treatment and would remain so until we had a tuberculin, or some other cultural product of the tubercle bacillus, of known and standard strength.

Dr. Ira Van Gieson said he was strongly opposed to the tubercle bacillus being made the scapegoat of tuberculosis. While every reasonable precaution should be taken against the spread of the disease, there were evidences in many quarters of over-zealousness and even hysteria. By some, the tuberculous patient was regarded in the same light as a leper, and legislation had even been invoked to prevent these patients from passing through certain States. People acquired the disease by their own negligence, and then blamed the tubercle bacillus. Every man was the architect of his misfortunes and every man was the architect of his own tuberculosis. A man had no more right to get tuberculosis than he had to walk off the roof and break his neck, and among favorable surroundings and under right conditions of living the tubercle bacillus would probably be practically harmless. The idea of getting rid of tuberculosis by exterminating the tubercle bacilli was, in the present stage of our civilization, a Utopian one. They were as ubiquitous as snakes in Madagascar, and attempts to exterminate them always reminded Dr. Van Gieson of the story of a native of that far-off island who was found furiously attacking a group of snakes. When asked why he wasted his time killing them when there were so many more left he said that he did not care about the snakes, but that he objected to having them in his front parlor. Dr. Van Gieson said he was unalterably opposed to the use of tuberculin therapy. Under ordinary conditions, the human body was a poor habitat for the tubercle bacillus, and by injecting tuberculin, instead of helping the patient to throw off the infection, we merely added fuel to the fire and gave him so much less chance to recover. It was analogous to hitting a man with a club as a means of first aid to the injured.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Clinical Meeting, Held April 14, 1910.

Dr. Eli Long in the Chair.

A Case for Diagnosis.—Dr. Mary Sutton Macy presented a child, 14 months of age, who had been seen on the previous day for the first time. The baby had been spontaneously delivered. There was a tumor over the bridge of the nose which had existed since birth. When the child cried it became smaller. The tumor pulsated and a tentative diagnosis had been made of hernia of the frontal sinus, or a meningocele, or a pulsating angioma. The tumor was reducible by pressure.

Dr. Ward Bryant Hoag said that he had seen an exactly similar case at the New York Polyclinic. It had appeared in Dr. Kerley's service and they had concluded the tumor was a meningocele.

Dr. L. Pierce Clark said that he had seen but two or three of these cases at the Randall's Island institution. He was surprised that the meningocele disappeared in greater part when the child cried. The condition here was practically the same as in spina bifida and a similar operation of closing the communication with the cranial cavity might be undertaken. One should bear in mind that these cases did poorly under any form of surgical manipulation.

Dr. Henry W. Frauenthal believed this was a case of meningocele. The *x*-ray would aid them greatly in making a diagnosis.

A Cretin Six Months of Age.—Dr. Ward Bryant Hoag presented this patient. The labor had been difficult; not only was the delivery of the head difficult, but that of the shoulders as well. Instruments had been used. There was an interesting question as to whether the excessive traumatism of the neck and body had an influence in destroying the substance of the thyroid gland. When he first saw the child on March 28 it weighed eleven pounds and six ounces. The mother supposed that the child was a hopeless idiot and brought the baby to the hospital because of an umbilical hernia. He had coarse hair, a broad nose and a broad slit between the eyes; the mouth was characteristic of cretinism, but the tongue did not protrude from the mouth. There was the short condition of the bones. The broadened hands and shortened fingers were held in the characteristic position. The child apparently had no mentality. One-quarter of a grain of thyroid extract, which was equivalent to one and a quarter grains of the fresh gland, was given twice daily. At the end of one week the child nursed better and was warmer, although he had lost three-quarters of a pound in weight. One-quarter of a grain of thyroid extract was then administered three times a day and during the next week he gained one-half a pound. There had been a slow, but gradual improvement. So far as Dr. Hoag knew this was the youngest cretin ever reported.

Dr. Godfrey R. Pisek said that the picture was so typical that there was no doubt about this case being a true cretin. At this early time of life it was difficult to make a diagnosis between a cretin and a Mongolian idiot.

Dr. Eli Long said that the youngest cretin he had ever seen was eleven months old. The child was brought to the clinic because it never cried. When the photograph was taken the diagnosis was practically made. The oldest cretin he had ever seen was a man twenty-three years old. He had been to the hospital where sweet breads were ordered, but he had not been able to afford them. He was very phlegmatic and constipated; he slept nearly all the time. After taking thyroids he first became very thin. His teeth dropped out. He was unable to sleep. Then a marvelous change occurred for the better.

Dr. Charles Herrman recalled a case that he had recently seen in which the administration of thyroids was followed by falling out of the hair, which eventually grew again. The palms of the hands and the soles of the feet peeled as extensively as after an attack of severe scarlet fever. Emphasis should be laid upon early treatment in these cases as results were then much more favorable. These patients never attained a normal intelligence.

Dr. L. Pierce Clark said that the paramount interest in cretin therapy centered to-day in the effort toward successful thyroid transplantation. As arterial anastomosis was becoming more practical it seemed reasonable to look forward to a more hopeful future for these cases. It was a therapeutic aggravation to rely upon thyroid feeding for a number of years and then upon its withdrawal to see the patient relapse and become worse than he was at first. It had not been sufficiently impressed on the clinical mind that cretinism *per se* had but little or nothing to do with idiocy as ordinarily understood. No special therapy could improve the mental outlook of an idiot. The type here shown might more properly be called cretinoid in as much as it lacked the intensity of coarseness and stupidity of the endemic cretinism of Switzerland.

Cases of Head Nodding in Colored Children.—Dr. Charles Herrman presented five children treated in Dr. LaFetra's service at the Vanderbilt Clinic. One boy had been treated when six months old and the condition had disappeared. He was now four years old and the trouble had reappeared two months ago. It was unusual to see the condition in a child of this age. The most interesting point in these cases was the etiology. Rickets was supposed to play an important part, but practically all the colored children brought to Vanderbilt Clinic were affected with this disease. Rickets was not an essential etiological factor. Eruption of teeth was considered by some to be a factor in causation, more marked if dentition was difficult and the children were restless and slept badly. Few of the cases gave a clear history of a fall so that if traumatism occurred it was probably the result of incoordination as part of the disease already existing. Dr Radnitz some years ago attributed the condition to the effort the child made to fix objects but dimly seen in a dark room. Some years ago Dr. Herrman had investigated twenty cases and found but one-half of them lived in dark rooms. Therefore this could not be the sole cause. The most plausible theory seemed to be that the condition was caused by the long continued rhythmic kick in comparative darkness. Dr. Herrman was inclined to believe that the head movements with nystagmus in infants was a coordination neurosis to which certain children were predisposed. A certain stage of development in the nervous system was an essential factor. The nystagmus was often unilateral, even if bilateral it was usually more marked in one eye. This was difficult to explain if it was due simply to fatigue of the eye muscles. The children had a peculiar way of "cocking the head," holding it to one side and looking out of the corners of the eyes, and this was so characteristic that it might almost be considered pathognomonic. Errors of refraction and astigmatism were not present, and vision was normal. Bromides had little or no effect. The children should live out of doors.

Dr. L. Pierce Clark said that in as much as nodding spasm of the type presented occurred only in infancy and all cases recovered the real cause should be looked for in a retarded anatomic development in the bulb mechanism of coordination of head and eye movement. Its frequent association with other disorders of development helped on this hypothesis. The partial recurrence of the head movement in the eldest boy might be caused by fright. He looked upon it as a choreiform disorder induced by a congenitally weak coordination mechanism. It would be interesting to note whether infants once afflicted with nodding spasm developed chorea in later life.

A Case of Endocarditis Acquired at Sixteen Months of Age.—Dr. Ward Bryant Hoag presented this case, a girl eight years of age, whose birth was normal. She was considered a normal child up to the age of fourteen months. At this time she had been fed indiscretely and was very ill from the age of sixteen to twenty months. She was very short of breath, had moist râles, a certain amount of edema of the lungs and could scarcely walk across the floor. She was put to bed and confined there for a number of weeks. When allowed to be up her activities were carefully supervised and she improved greatly. Her fingers were not clubbed and she was not at present suffering from any shortness of breath. A loud thrill was heard over the heart. There was but little cardiac hypertrophy, the apex being very near the normal point.

Dr. Roland G. Freeman believed that this was a case of congenital heart disease which had only become manifest when the child became ill.

Dr. William P. Northrup said there was no doubt in his mind but that the case was one of congenital heart disease. He had made autopsies upon nine similar cases, three of which had been under observation at the Foundling Hospital. In each case there was narrowing of the pulmonary orifice with defective septum ventriculorum.

Friedreich's Ataxia: Two Cases.—Dr. Edward Livingston Hunt presented two patients, who were sisters. Their ages were eleven and three and one-half years. The history of the pregnancy and labor was absolutely normal in each case. There was no history of alcoholism, tuberculosis, or syphilis. The older child was late in learning to walk and had walked with difficulty since the age of five years. There were no knee jerks, but a lateral curvature of the spine existed. She had marked choreiform movements, but not nystagmus. The younger child began to have difficulty in walking a few months ago; this was the only symptom present. The unusual feature in this case was the early age, two and one-half years, at which she developed ataxia. The mentality of both children was very good. The older child also had clubbed feet with a marked prominence of the instep. Dr. Hunt said that there had been only about 200 such cases reported.

Dr. L. Pierce Clark said that the chief interest to him in the subject under discussion was that they were now in a position to refute the theory propounded by Oppenheim and his school that Friedrich's ataxia was an hereditary, luetic affection. The Wassermann and Noguchi blood tests in these cases were entirely negative. Dr. Clark referred to the theory of Edniger and Gowers which best explained the disorder here as in muscular dystrophies, where blood tests for hereditary lues were also negative. This theory maintained that certain muscles groups, nerve tracts, and ganglia had not only a defective development, but also met with an untimely death.

Dr. Richard B. Kruna believed that it would be reasonable to attempt some forms of exercise in these cases, in fact a reeducation.

Dr. Henry W. Frauenthal thought that this instruction should be given with the child in front of a mirror; they should be taught to concentrate their minds on the work they were doing.

Dr. Hunt said that the prognosis in these cases was not good, such patients usually dying before they reached the age of twenty-five years.

A Case of Gummatous Infiltration of the Meninges.—Dr. Godfrey R. Pisek said that this patient, a girl of six years, had been born prematurely and weighed three and one-half pounds at birth. She had a younger brother who was said to be in good health. With the exception of pneumonia and pertussis she had had no serious illnesses until the present one. About one year ago she had a convulsion, prior to which the mother had noticed that the child was deteriorating both mentally and physically. The fact was elicited from the mother that about three weeks after the birth of the child there had been scaling of the palms of the hands and the soles of the feet, which promptly disappeared under treatment. The mother learned that the father had a luetic history and was treated during her second pregnancy with the result that she gave birth to a healthy, robust boy. Physical examination of the patient showed a fairly well developed girl of six years, with unimpoverished nutrition, but with marked cyanosis of the hands and feet, the skin of the feet being dry and atrophic. When in the erect posture she assumed a leaning position from the hips. She could stoop and walk alone, but preferred help. In the sitting posture she had a relaxed spine. She also had inguinal adenitis. The left median incisor tooth was notched and loose and the lower medium incisors were notched. There was general caries of the teeth. The heart sounds were normal; the liver was one inch beneath the right costal margin; the spleen not palpable; a spasticity of the lower extremities, exaggerated knee jerks, and Kernig's sign were present. There was some hyperesthesia over the whole body. There were no anesthetic zones found. The language was repetitional and somewhat incoherent. The eyes showed a peppery granular appearance around the macular region and a pale disc. This was an descending atrophy of the optic nerve due to degeneration compression. A tentative diagnosis of gumma of the base of the brain was made upon clinical symptoms as at the time neither father nor mother admitted leutic infection. The Noguchi modification of the Wassermann reaction was made and was negative. The question of the relation of the mother to the condition was interesting. The Noguchi reaction was negative for the father, but positive for the mother. Thomsen and Boas, who had examined a large number of cases, had concluded that a positive Wassermann reaction in the mother lessened the possibility of the child's being born sound. Latent syphilis might give a faintly positive reaction in the child or it might entirely fail during the first month. The mothers who bore syphilitic children were themselves to be looked upon as syphilitic if their blood gave a positive Wassermann reaction. Dr. Pisek reviewed the work of Knoepfelmacher and concluded that it would not be at all unexpected to find that 40 per cent. of mothers, whether they had symptoms or not, failed to show complement fixation. While it was too soon to draw any absolute conclusions serious doubt was thrown on the Colles law, and it might be fair to claim that it would be only a matter of time before the incorrectness of the law would be established. At present it seemed highly probable that the mothers of children with hereditary syphilis were syphilitic also.

Dr. William P. Northrup said that he was not sure that this was a case of gummatous infiltration of the meninges. It might be a case of proliferation of the connective tissue. He had seen many cases with a thickened dura and pia but with no gummatous infiltration.

Cases of Intestinal Infantilism of Herter.—Dr. Roland G. Freeman referred to five cases reported by Dr. Christian S. Herter in 1908 in which the symptoms were arrested development of the body, marked abdominal distension, often with dilation of the abdominal veins over the upper part of the adbomen. There was usually very marked fatigue and some anemia. There was a tendency to looseness of the bowels with occasional attacks of diarrhea, often with fatty stools, even though there might be but little fat in the food. Theses cases were liable to have an excessive appetite and thirst and increased secretion of the urine. Herter found an absence of the ordinary intestinal flora of the intestines of young children. The organisms present were Gram-positive, the prevailing organism being the *Bacillus bifidus* of Tissier, the *Bacillus acidophilus*, and the *Bacillus infantilis*. The *Bacillus coli* and the *Bacillus lactis acrogenes* were infrequently found during the active stage of this disorder. The urine showed a rise in the ethereal sulphates, a pronounced indicanuria, and an excessive phenol together with the presence of aromatic oxyacids. Herter found gelatine particularly useful in increasing the weight in these cases. Dr. Freeman had recently seen three cases of this condition. The first case had been under his care for eight months. She was three and one-half years of age and greatly debilitated. No food had been found which would agree with her until about a month ago when she began taking buttermilk. She had gained two pounds in weight and there was an improvement in her general condition. Examination of her urine and feces showed the characteristic condition described by Herter. The administration of intestinal antiseptics had had no influence on the bacteria of the intestines. The second case was a child nineteen months of age; she also showed the classical symptoms and there were also some colon bacilli present in the feces. The child had not gained on any modification of milk that had been tried. She did best on a preparation of dried skimmed milk to which a moderate amount of fat was added in the form of cream. The third case was a child seventeen months old who had an attack of vomiting diarrhea and fever last July. She had not done well since that time and similar attacks had followed at intervals. Many different foods had been tried and a wet nurse had been secured, but the child did not gain in weight. This case approached that type of intestinal infantilism described by Herter, but was not entirely characteristic. The bifidus was present in the feces as well as the coli communis and some cocci.

A Case of Spastic Paraplegia Treated by Resection of Posterior Nerve Roots.—Dr. John J. Moorehead presented this patient, a boy, seven years old. There was difficulty in learning the child's early history. However, it appeared that the boy had been well until he was two years of age, although he had never walked. When he entered the hospital he had a typical spastic condition which was most marked in the lower extremities, especially on the left side. There was the characteristic irritability of the reflexes, very marked knee jerk, ankle clonus, and Babinski's sign. A laminectomy was performed following the technique laid down by Dr. Taylor. Because of the little space between the transverse processes it was found impossible to expose a sufficient amount of the cord to do a hemilaminectomy and they had had to resort to a bilateral laminectomy. Digitations of the second, third, and fourth lumbar posterior roots, and three upper right lumbar roots were divided. After the operation there was a rise of temperature and rapid respiration which aroused fears lest pneumonia might develop. Four days after the operation the temperature was 101° and a satisfactory convalesence followed. The spasticity became markedly lessened within three days after the operation; the reflexes had disappeared absolutely and had not returned. The general tone and nutrition of the lower extremities had been very much improved and the boy was in a position for further orthopedic and educational means of treatment.

Dr. Godfrey R. Pisek said that when the boy entered

the hospital he knew that he was a good subject for operation as the spastic paraplegia was associated with a good mental condition. The spasticity had been very marked; the boy was able to walk only on his toes holding onto the furniture.

Dr. L. Pierce Clark thought that Dr. Moorehead was to be congratulated upon the excellent clinical results in this case. Orthopedic training could now be employed with great advantage. He advised a further resection of half of the dorsal nerve roots of the first and second sacral in a year from the first operation. His own series of operated cases were making excellent progress under physical training and he would present them to the Society again in the fall.

A Congenital Freak.—Dr. Henry W. Frauenthal presented a child with congenital clubbed feet and hands, a congenital dislocation of the hip on one side, and a knee which was at right angles to the normal axis.

New Signs of Meningitis from French Authors, with Illustrations.—Dr. William P. Northrup spoke of the new signs of which he had read in French journals and their application which he had employed in three cases. He illustrated his remarks with pictures, called "identical reflexes" and "contralateral reflexes."

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of May 7, 1910:

	Cases	Deaths
Tuberculosis Pulmonalis	663	166
Diptheria	406	40
Measles	1,311	24
Scarlet Fever	584	29
Smallpox	1	—
Varicella	135	—
Typhoid Fever	27	8
Whooping Cough	99	10
Cerebrospinal Meningitis	8	6
Malarial Fever	—	—
Totals	3,174	283

Tuberculosis Sanatoria in Sweden.—A significant phase of the campaign against tuberculosis in Sweden is the establishment, by various industrial concerns, of sanatoria for tuberculous workmen from their own factories. The Vulcan Match Company, the Ljusne-Voxne Timber Company, the Sandviken Hardware Company, the Eriksson Telephone Company and the Stora Kopparsberg Company are among those who maintain such institutions, each accommodating from fifteen to thirty patients. At these sanatoria the workmen are received free, and their families may be admitted for a small charge.

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended May 6, 1910.

THE SCAPHOID SCAPULA.

A FREQUENT ANOMALY IN DEVELOPMENT OF HEREDITARY, CLINICAL, AND ANATOMICAL SIGNIFICANCE.*

BY WILLIAM W. GRAVES, M.D.,

ST. LOUIS, MO.

ASSISTANT PROFESSOR IN NEUROLOGY IN THE ST. LOUIS UNIVERSITY SCHOOL OF MEDICINE.

WE have been taught to think of the vertebral border of the scapula in man as having a more or less convex outline. It is thus described and represented in text books on human anatomy, and common observation establishes this fact. In apes, monkeys, quadrupeds, and, indeed, throughout the entire range of vertebrata, the vertebral border of the scapula, is, as a rule, more or less convex. We see, therefore, that comparative anatomy lends support to the idea that the vertebral border of the scapula, under normal circumstances, in man should be, as we have been taught to believe, more or less convex. But scapulæ having more or less concave vertebral borders, are by no means rare in man. Indeed, such scapulæ are relatively frequent. Now, since throughout the vertebrata the vertebral border of the scapula is more or less convex, a more or less concave border occurring either in man or the lower animals must be anomalous. Furthermore, such a vertebral border must be an anomaly in development, a something inherent with the individual, and cannot be a reversion, since more or less concavity of the vertebral borders predominates neither in man nor other vertebrates. The vertebral border, sometimes called the base of the scapula in man, is that border adjacent to the vertebral column extending between the superior and inferior angles of the bone; but, for the purposes of this communication, only that portion of the border extending from the mergence with the spine of the scapula to a variable point along this border and usually to a point about opposite the process for the attachment of the teres major muscle will be considered as the vertebral border. It is along this part of the vertebral border that a more or less distinct concavity may be made out with relative frequency in the living subject, and a scapula presenting such a concavity, I desire here to designate the scaphoid scapula (Fig. 1).

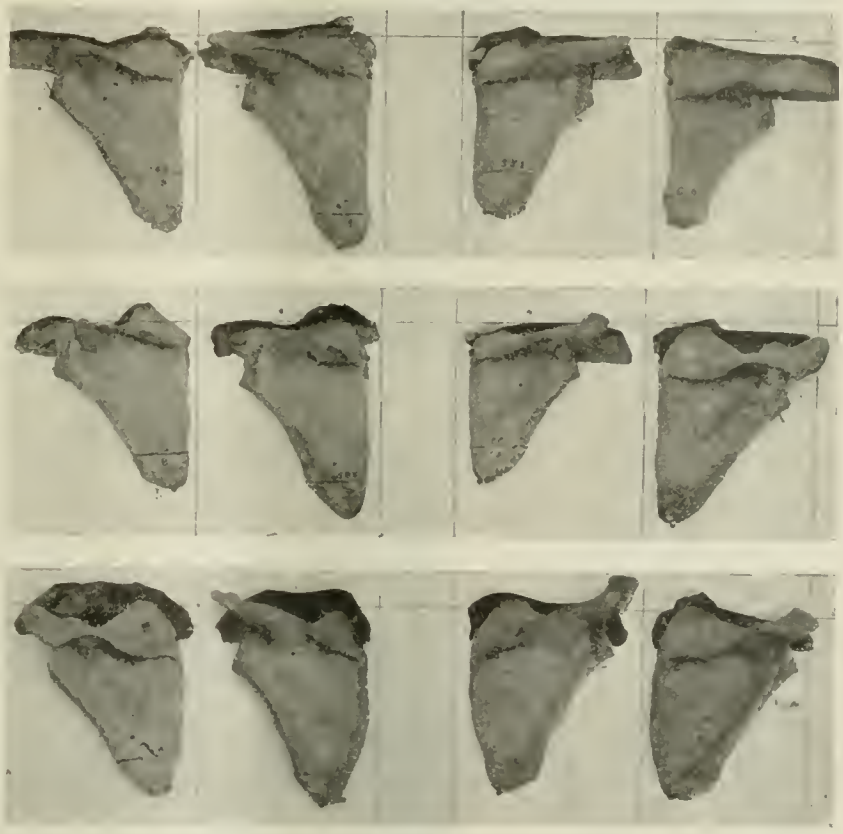

FIG. 1.—The upper row shows scapulæ of the scaphoid type, having more or less concave vertebral borders; the middle row shows scapulæ having more or less straight vertebral borders, all of the scaphoid type; the lower row presents scapulæ whose vertebral borders are more or less convex, average scapulæ, the dominant racial type.

Observation I.—On September 18, 1906, while making a routine physical examination in the neurological clinic of the St. Louis University School of Medicine of a seven-year-old boy, a victim of major and minor seizures, I was impressed with the peculiar development of the vertebral borders of his shoulder blades. Each was distinctly concave from the mergence of the spine of the scapula with the vertebral border to a point slightly above the inferior angle, and these borders with the inferior angles stood out prominently, winglike. The vertebral borders were abnormally far apart, and, instead of slanting downward and outward, as do shoulder blades in the average individual, their course was quite parallel with the vertebral axis. The boy's neck was longer than the average, his shoulders were hanging, drooped downward and

*Presented to the St. Louis Medical Society in general session, February 5, 1910.

forward, and the right shoulder was lower than the left. The chest was well formed, though shallow, and it was somewhat narrowed at the lower costosternal junction. The claviculæ took a distinctly horizontal course, the abdomen about its lower one-half was unduly prominent, and, as he stood before me, his general attitude was one of extreme sluggishness (Fig. 2). He was much under size for

Fig. 2.—Front and back view of a boy, seven years old, epileptic, with scaphoid scapulæ.

his age, and his muscle development was defective, without evidences of atrophy. He was able to assume normal attitudes, to elevate and approximate his shoulder blades in a normal manner and to execute all movements with coarse strength proportion to his muscle development. His head was large, rather bulging along the plane of the frontal and parietal eminences. The auricles were prominent and somewhat defective, his nose was rather short, with poorly developed nostrils. His lips were separated and an examination of his nasopharynx disclosed adenoids. His second toes were much longer than the great toes, and there was slight webbing between the second and third, and third and fourth toes of both feet.

An examination of the mother, age 39, showed a similar type of physical development, and the vertebral borders of her scapulæ were even more markedly concave than those of the patient. Subsequently the other children in this family, a boy of 5, a girl of 3, and the father, 43 years of age, were examined. The father presented an average physical development, and the vertebral borders of his scapulæ were distinctly convex, but those of the younger children were as concave as those of the older brother. The younger brother's physical development was somewhat better than that of the older, though in him it was much less than that of the average boy, and in features and general development he resembled his older brother and mother. The girl's neck was relatively shorter than that of either brother, and she resembled her father more than she did her mother. Her general development was defective and her attitudes were sluggish. This brief description of the patient, his younger brother and sister, and of his mother will serve to illustrate a certain type of individuals—a very common type, indeed—met with in every branch of society in both child and adult life, and in individuals presenting this type of development the scaphoid scapula will be frequently found.

Since this, my first observation of the scaphoid scapula, I have noted it many times in the course of routine physical examinations, and in only a few instances have I found it well marked in individuals even approaching average physical development. Thus far I have always found it associated with other signs of deviation from the average. To enumerate these here would be but to repeat the long list of heretofore recognized anatomical physiological, psychic, and psychoneurotic stigmata. While even genius may occasionally be found in an individual of defective development, "Mens sana in corpore sano" is the ideal in human development, and that which we all recognize in the average individual approaches this ideal. The scaphoid scapula may be found even in a man of genius, but its natural habitat is in the deviate.

I have said that the scaphoid scapula is relatively frequent. Let me illustrate: Through the courtesy of Dr. R. P. Scholz, I recently had the privilege of studying in a preliminary way a group of ten public school children, all suffering from adenoids, all one or two years behind the average in school work, all showing defective physical development, under size, sluggish attitudes, etc., etc., and in every one I found the scaphoid scapula well marked. Through the courtesy of the attending physician, Dr. J. R. Clemens, and the Sister Superior of St. Joseph's Orphan Asylum,

Fig. 3.—A group of defective boys from St. Joseph's Orphan Asylum, all showing arteriosclerosis, palpable glands, etc., etc., and scaphoid scapulæ, and other anomalies in development.

I have begun the study of fifty-eight boys and their immediate relatives. This study is far from completion, and will serve the purpose of some future communication. These boys range in age from five to fourteen years. Eleven of these are reported by the Sisters as average in their school work. Ten of the average boys show the scaphoid

scapula. All of these are under size, most of them show other decided physical defects and have sluggish attitudes. Three are mouth breathers and two have nocturnal incontinence. Forty-seven of the boys, out of a total number of 58, are reported by the Sisters to be much behind in their grades; 40 out of 47, or about 85 per cent., show the scaphoid scapula, and 7, or 15 per cent., show convex vertebral borders; 27, or about 58 per cent., are mouth breathers; and 8, or 17 per cent., are bed-wetters. All are under size, show other anomalies in development, other clinical signs, and every one of them would be recognized at a glance as a deviate from the average (Figs. 3-4).

I shall not at this time offer further evidence upon the frequency of the scaphoid scapula in the living subject, but will merely say that my observations, confined almost exclusively to private and dispensary work, warrant the prediction that further studies of backward and defective children, studies of inmates of epileptic homes and colonies, asylums for the insane, of penitentiaries, and of deviates in general, will establish the relative frequency of the occurrence of this anomaly. The scaphoid scapula occurs less frequently and usually to a much less degree in individuals who on superficial examination pass for average individuals—even in such of seeming excellent mental and physical endowments. But when found in such individuals a closer study of their mental and physical states will not fail to disclose other physical anomalies alone or in combination with mental tendencies differing from those of average individuals. I have observed it in successful business men, even in captains of industry, in prominent preachers, in excellent lawyers, in capable physicians, in educators, in inventors, artists, and artisans; indeed, among members of what we call our best society who are leading useful and successful lives. Remembering what is said tonight, should any member of this society later discover that he is the possessor of the scaphoid scapula, let him take comfort in the fact that he is not alone.

FIG. 4.—A rear view of defective boys from St. Joseph's Orphan Asylum.

Immediately following my first observations of the scaphoid scapula, a search of the literature at my command failed to disclose any reference to the anomaly here described, and conversation with several well posted anatomists indicated that their ideas had been in accordance with the teachings of text books on anatomy, that the vertebral borders of the human scapulæ are more or less convex. It was not until the actual preparation of this paper was begun, in looking up some references given me by Professor R. J. Terry, of Washington University, I was led to two articles, one by St. George Mivart (The Appendicular Skeleton of the Primates, *Phil. Trans.*, Vol. 157, 1867, p. 304), the other by Thomas Dwight (The Range of Variation of the Human Shoulder Blade, *Amer. Nat.*, 1887), that the slightest reference bearing upon this anomaly was found. Under the heading, "Exceptional Forms," St. George Mivart says: "The vertebral margin is generally more or less convex, but sometimes in man, the gorilla and orang, ateles and chrysothryx, it presents a sigmoid curve. Sometimes it is nearly straight, as in the Indris; sometimes it is very strongly convex as in Perodicticus." Thomas Dwight, in speaking of the variations of the vertebral border, states: "The most common form of scapula presents a line slightly curved at the lower part and then straight as far as the root of the spine, from which point it inclines slightly forward till it ends at the upper angle. The forward inclination of the upper part, though varying in degree, is, so far as I know, constant, but the rest of the line varies much. Sometimes it is almost straight, sometimes the whole border of the bone is convex, sometimes the border below the spine is concave." He illustrates the variations of the vertebral border with a figure of the tracings from several bones, and he figures several complete scapulæ, one of which I should unhesitatingly call a scaphoid scapula. This variation in the vertebral borders mentioned by both Mivart and Dwight was noted by them in dry bones and was considered and described by them as a variation within the normal; but the main thesis of this paper is, that the scaphoid scapula is an anomaly in development, originating in the progeny from some abnormal circumstance operating in the parents; is thereafter transmitted from parent to child and so on through several generations; and, unless the abnormal circumstance again becomes operative in the descendants, the scaphoid scapula finally disappears and the racial type again becomes dominant.

Dry Bones.—Following my first observations of the scaphoid scapula, I was for a long time on a quiet hunt for a dead specimen, but it was not until the summer of 1909, a short time after mentioning my quest to Dr. V. P. Blair, that he brought me three typical scaphoid scapulæ, having found them among a lot of scapulae in the anatomical department of Washington University. It seemed desirable to make a study of these, and, furthermore, to inspect a lot of scapulæ with a view to determining the relative frequency of the scaphoid scapula among dead bones. Prof. R. J. Terry kindly placed at the

disposal of Dr. Blair and myself the dry scapulæ of the anatomical department of Washington University. These scapulæ had been accumulated during the course of years from bodies studied in the anatomical department and consisted of 165 bones. Among these were found five fetal and seven child scapulæ, the remaining number being from adults. A much smaller, but similar, group consisting of 33 scapulæ, all from adults, in the Anatomical Department of the St. Louis University School of Medicine was kindly placed at our disposal by Prof. A. C. Eycleshymer—making a total of 198 bones. A general survey of these scapulæ readily suggested their classification into three divisions: (1) Scapulæ having vertebral bodies more or less convex; (2) scapulae having vertebral borders more or less straight; (3) scapulæ having vertebral borders more or less concave (Fig. 1); 121, or about 61 per cent., were more or less convex; 51, or 26 per cent., had more or less straight vertebral borders; 26, or 13 per cent., showed concave vertebral borders. It must be remembered that these bones came from individuals, many of whom had doubtless been unfortunate derelicts—deviates, if you please—and their bodies had in consequence found a resting place in the dissecting room.

A closer inspection of these bones showed that almost all of those we had classified as straight were really more or less concave, so that from an anatomical point of view, a simpler division would be: (1) Scapulæ having more or less convex vertebral borders; (2) scapulæ having more or less concave vertebral borders. For certain purposes, however, as I shall later show, it is desirable to adhere to our first classification—an arbitrary classification which I had long employed in my clinical studies. But, adopting the anatomical classification for the moment, we should have in the scapulæ studied in reference to their vertebral borders, 61 per cent. more or less convex and 39 per cent. more or less concave.

As one might well imagine, there are all gradations within certain limits in the degree of concavity as well as in the degree of convexity in the vertebral borders of human scapulæ. The gradations in the vertebral border between the average, or convex, and the straight, and between the straight and the concave are so minute that a consideration of the outline alone would leave one in doubt at times as to the classification of a particular scapula, even in the dry bones, but this is especially true in the living subject.

Of the fetal and child scapulæ, four had vertebral borders more or less concave, one more or less straight, and seven more or less convex. It must be remembered, however, that in the fetal and child scapulæ, the vertebral border of the dry bone represents only its osseous development, the cartilaginous portion of the border having been lost. About 80 scapulæ from the Medical Department of the Washington University have been subjected to further study by me. In these studies I have been able to show that scapulæ having straight and concave vertebral borders are very nearly related, indeed, belong to a distinct type, which I shall hereafter designate the scaphoid type, since scapulæ of this type further differ from those having convex vertebral borders in the following particulars: First, the mean scapular index of the scaphoid type is 2.3 less than the average or convex type; second, that the scaphoid type of scapulæ differs from average scapulæ in the direction taken by their vertebral borders when these are compared with a straight line, and that the vertebral border more nearly parallels in the scaphoid type the long scapular axis; third, that the spine in the scaphoid type, as a rule, forms more nearly a right angle with the long scapular axis than does the spine of the average scapula; fourth, that the anterior and posterior lips and intermediary surface of the vertebral border in the scaphoid type of scapulæ are much less developed than in the average type, and that the greater the concavity of the vertebral border of the scapula, the less marked will be the lips and the intermediary surface; fifth, that the tuberosities varying both in size and number, frequently found along the vertebral borders, which I shall hereafter call vertebral border buds, are much more common in the scaphoid than in the average type of scapulæ. These essential differences, based upon my studies of infantile, child, adult, and skeletal bones, and in the living subject, seem to me to entitle the scaphoid type to a distinct anatomical classification.*

Let us for the moment turn our attention to the embryo and fetal forms of scapulæ. A consideration of these should lay the foundation for the hereditary nature of the scaphoid scapula. I have already partly accomplished this in indicating its relative frequency in certain living types and in the study of the family in which my first observations were made. A study of the embryo forms should go a long way toward determining the origin of the scaphoid scapula, and perhaps give us a clue to the solution of the problem of its causation. I am greatly indebted to Professor Eycleshymer for his kindness in turning over to me a part of his collection of embryos and fetuses. Of those in which the scapular form could be made out through the skin, I found 22 specimens. Of these 14 had convex and 8 had concave vertebral borders. I have subjected several of each type to a fine dissection, laying bare the greater portion of the scapulæ, especially freeing their spines and their vertebral borders. Through the kindness of Dr. W. H. Foster, of the Anatomical Department of the St. Louis University, the scapulæ of three of Professor Eycleshymer's monster forms have been laid bare and I have similarly dissected two fetuses, each in about the seventh month of development, which were kindly turned over to me on January 14, 1910, by Dr. Carl Fisch. In my studies, comprising nine embryo, two fetal, and three monster forms, I have noted the general condition of each, the contour of each vertebral border, compared one with the other, compared the size and shape of one scapula with another in the same fetus, measured the length of the long scapular axis, and when possible, simply by noting the transparency of each scapular form, have attempted to determine the degree and form of its ossification. My studies of the scapulæ of embryo, fetal, and monster forms justify, it seems to me, the following conclusions:

1. As early as the end of the sixth week in development, the human cartilaginous scapula has acquired that form which differentiates it from all other forms, and which in its essential particulars it maintains throughout its further development. Even the vertebral border buds were discernible in one specimen, measuring only V. B. 24 mm.

2. The vertebral border of the ossifying plate parallels with striking accuracy the contour of the cartilaginous vertebral border; where this is convex,

*My studies in detail of dry scapulæ and of embryo, fetal and monster forms will be published elsewhere.

it is convex; where this is concave, it is concave; where it is partly convex and partly concave, it, too, is the same; in one specimen the buds on the cartilaginous vertebral borders have their counterpart opposite, on the margin of the ossifying plate and in a more distinctly scaphoid type of vertebral border there is entire absence of lips and intermediary surface—just as we have found in similar specimens in the dry bones.

3. Early embryo forms of scapulæ are but the prototypes in miniature of the later fetal, infantile, child, and adult forms.

4. In the same subject having scapulæ of the scaphoid type, decided differences in the size and form of the scapulæ and specific differences in the contour of the vertebral borders are common. In my studies of scapulæ in living subjects I have been deeply impressed with the relative frequency of decided differences in size and form and specific differences in contour of vertebral borders and with the presence of vertebral border buds in those individuals having the scaphoid type. May not these features so frequently found in this type be indications of Nature's efforts either to maintain, or to return to, the dominant—the racial type?

Beginning with the recognition of the scaphoid type of scapulæ in child and adult life, I have shown the same forms in dry bones and traced them back to the sixth week in embryo life. It is, therefore, reasonable to suppose that a histological study of embryo forms of the average and scaphoid type of scapulæ would show either some microscopical differences in structure, or some vascular changes, or both, and I have begun such a study which will serve the purpose of some future communication. Having indicated the frequency of the scaphoid scapula in the living, dry, and embryo forms, and having learned in my first observations that a mother and all of her children had the same type of scapula, the offering of further evidence at this time of its hereditary nature, it seems to me, would be superfluous. My studies in its hereditary ramifications are, indeed, thus far mainly fragmentary. Any one who has attempted to examine personally all the living members of a family will appreciate the difficulties in such investigation. I have, nevertheless, been able to do this in 22, and in many families in a fragmentary way in my studies of the scaphoid scapula in its hereditary and clinical bearings, and I have formulated a few hypotheses based upon such investigations; these are as yet merely tentative. They may be confirmed or completely upset by further investigation; but, in order that those who may become interested in the study of the hereditary, pathological, and clinical significance of the scaphoid scapula, it seems to me to be proper at this time to set them down as working hypotheses. Not only are these hypotheses based upon my studies of the scaphoid scapula in its hereditary and clinical bearings, but they are here given as possible exemplifications of the main thesis mentioned in the beginning, which I shall here repeat:

Thesis.—The scaphoid scapula is an anomaly in development originating in the progeny from some abnormal circumstance operating in the parents; is thereafter transmitted from parent to child and so on through several generations; and, unless the abnormal circumstance again becomes operative in the descendants, the scaphoid scapula finally disappears and the racial type again becomes dominant.

Hypothesis I. Since scapulæ having more or less convex vertebral borders have been shown to represent the racial type of scapulæ, we should expect under normal circumstances that the children of parents having this type of scapulæ should have a similar type.

Hypothesis II. From one or both parents having scaphoid scapulæ, we should expect, under normal circumstances, in their progeny: (*a*) If only one has it, the children to show it less marked than the parent having it; (*b*) if both parents have the scaphoid scapula, we should expect their children to have it more marked than either parent, or at least to be as well marked as the parent showing it to the least degree.

Hypothesis III. Both parents having average scapulæ, we should expect under abnormal circumstances their children to show scapulæ of the scaphoid type, the degree in each child from the oldest to the youngest depending upon either the remoteness from or the activity of the abnormal circumstance producing it, and as a rule the youngest child should show the scaphoid scapula to a less marked degree than the oldest.

Hypothesis IV. Where only one parent has the scaphoid scapula, we should expect, under abnormal circumstances, all of the children to show it to a greater degree than the parent having it, and, all things being equal, the youngest child should show it to a less marked degree than the oldest.

Hypothesis V. Where both parents have scaphoid scapulæ, we should expect, under abnormal circumstances, all of their children to show the same type, but to a greater degree than either parent, although depending upon the remoteness from or the activity of the abnormal circumstance, the youngest child may show it less than the oldest, but equal to that parent having it the least.

What is the certain abnormal circumstance at work in the production of scapulæ essentially differing in so many particulars from the average type of the human race, the scaphoid scapulæ. From the day of my first observations, this question has occupied my mind. I came very early to the conclusion that no known or assumed circumstance in the life of the individual after his birth could give him a scaphoid scapula, such as I was constantly seeing in my practice, and that it must be a hereditary or congenital circumstance at work. If a hereditary or a congenital one, it must be in the very early development of the individual, either transmitted to him from his parent or parents or originating in consequence of some disturbing factor in his early development, and the validity of these assumptions has been, I believe, practically established in my studies of living, dry, and early forms. Its origin could not be explained by any known or assumed local *in utero* factor heretofore believed to be at work in the production of monsters or other gross anomalies, because I early found it occurred in whole families, and was present in a varying degree in a very large percentage of our population.

Observing that, when the scaphoid scapula was found to a rather marked degree, it was almost invariably associated with other anomalies in development, either physical or psychical, or both, and that its natural habitat was in the deviate—in those individuals who frequently show blighted physical and mental development—I have thought of it merely as one manifestation of a blight affecting the whole organism; and, since I could not for a long time find any clue bearing definitely upon its origin, I have thought of the underlying abnormal circumstance as an X-blight.

Searching for the nature of the X-blight in my studies of individuals having scaphoid scapulæ, the product of parents under Hypotheses III, IV and V, those hypotheses supposing the working of a certain abnormal circumstance, I have found in them, in addition to the associated general conditions and other anomalies in development, certain clinical signs, first and foremost of which is the relative frequency of arterial changes—sclerotic changes, which we all recognize as keeping pace with advancing years after the fortieth year of life. But in individuals of such parentage these arterial changes occur much earlier than in average individuals, in some discernible by the ordinary methods of clinical investigation as early as the fourth year of life, and in older individuals a degree of sclerosis out of all proportion to their years. In such individuals I have also found with great frequency an abnormal degree of lymph gland palpability. Associated with arterial and lymph gland changes in these individuals will be found histories of frequent catarrhal affections developing in early infancy and childhood and persisting for years, and, as already pointed out in my studies of defective children, the relative frequency of adenoids and of nocturnal incontinence.

I have given some attention in my search to those diseases, which Sir William Gowers (Lectures on Diseases of the Nervous System, Second Series) a few years ago classified as abiotrophies, meaning thereby "Diseases from Defect of Life," as pertaining to the whole individual or one or more of his organs, and in which he traced either a hereditary influence or a pathogenesis due to "failure in vitality." Among those due to hereditary, abiotic influences, he refers to early baldness or grayness of the hair, the various forms of muscular dystrophies, certain early and late degenerations of the nervous system, hereditary optic atrophy, Friedreich's disease, the scleroses; and of those due to failure in vitality, the forms of neuritis incident to metallic poisoning, and the later manifestations of syphilis, such as tabes and general paresis. In such abiotrophies, the scaphoid scapula, other anomalies, and arterial changes will be frequently found associated in the same individual. It is not my purpose, however, to trace the ramifications of the scaphoid scapula in general and special pathology, but merely to indicate its relative frequency in several abnormal states and to show that it is associated with other signs of blighted growth and with pathological changes readily discernible by the ordinary clinical methods. If I have thus far accomplished this, even to a slight degree, I have, it seems to me, established its clinical importance and laid the foundation for a determination of its origin.

Having indicated its frequent association with other anomalies in development and with various pathological states, may not the one clinical fact so frequently met with in many of these lead us to the ultimate determination of the cause or causes underlying the origin of the scaphoid scapula? And this clinical fact is the occurrence before the time of vasculosclerotic changes in many of those having the scaphoid scapula and to a greater degree in them than is commonly found in average individuals. Of the various causes, any one of which may so operate as to produce arterial changes in the individual, alcohol and metallic poisons are considered preeminent; but, so far as I know, no one of these causes alone so affects the individual as to cause the transmission of even a tendency to arterial degenerations in his offspring. Furthermore, a consideration of the conditions with which the scaphoid scapula is frequently found to be associated, its occurrence in such a large percentage of our population and in all branches of society should readily exclude any one of such factors as being the underlying cause of the scaphoid scapula. There is but one disease known to me which permeates all branches of society, which causes vasculosclerotic changes in the individual and otherwise so affects his entire organism that he may transmit either the same disease or a blight to his offspring, as well as the tendency to vasculosclerotic changes—and that disease is syphilis!

Syphilis is preeminently a vascular disease. Its whole pathology centers about its vascular manifestation. Whether the *Spirochæta pallida* so affects the vessels in the growing embryo as to bring about a general blight, of which the scaphoid scapula may be but one manifestation, or whether this and other manifestations are but the result of its toxic products, I do not know; but that there is a strong connection between the occurrence of the scaphoid scapula in the offspring and syphilis in either one or both parents or in their ascendants, I shall be able to demonstrate to you to-night.

That there may be other causes, which may so operate as to affect the nutrition or the development of the growing embryo and thus bring about the scaphoid scapula and other associated anomalies in development, seems possible, but I have searched for these in vain, though my search has been brief when compared with its importance—perhaps others may be more successful. If further investigation should establish this connection, the presence of the scaphoid scapula may serve as a key to more than one medical mystery; but, before we can admit syphilis as even one of the factors in its causation, we must be able to show the connection in more ways than one. A single sign of any morbid state is practically valueless unless associated with other signs; and fortunately for us, other signs are always present if we will but search for them. With the use of modern refinements in clinical investigations, with the use of laboratory methods merely to confirm and control clinical deductions, with patient study of the individuals of families rather than the histories of individuals of families on the part of many workers, the ultimate cause or causes as well as the hereditary, clinical, and pathological significance of the scaphoid scapula may be readily determined.

Alone and unassisted by the rank and file of the medical profession the apparent and intricate problems intimately associated with the scaphoid scapula might remain long unsolved. These considerations have prompted me to lay before you the results of my mainly fragmentary studies formulated in Hypotheses III, IV, and V bearing upon these problems. In order that I may better indicate to your minds a possible connection between the scaphoid scapula and syphilis, let me call your attention to some of the known, but not always appreciated, facts which from the accumulated study of syphilis may be considered as established, and furthermore, to some personal observations bearing on this connection.

Of the very great per cent. of our population who contract syphilis, only a few suffer from lues cerebri, lues cerebrospinalis, tabes, and general paresis. Nevertheless, tabes and syphilis of the nervous system (tabes and general paralysis) is believed by many observers to be becoming more frequent in our population, the latter making up an increasing

percentage of the inmates of our hospitals for the insane.

It is a matter of common observation that the malignant forms of syphilis, particularly as affecting the skin and bones, are becoming yearly less frequent. My personal observations indicate that

Fig. 5.—Two "little old men" from St. Joseph's Orphan Asylum with sabered tibiæ, marked arteriosclerosis, palpable glands, scaphoid scapulæ, and other anomalies in development.

the malignant forms of acquired syphilis are relatively infrequent in individuals having scaphoid scapulæ, and that in those suffering from tabes, general paresis, and syphilis of the nervous system the scaphoid scapula is frequently found.

It is a matter of common observation that those who suffer from syphilis of the nervous system, tabes, and general paresis are, as a rule, free from decided evidence of a former luetic infection as pertaining to the bones, skin, and mucous surfaces; but that they almost invariably show vasculosclerotic changes beyond their years is not sufficiently recognized.

May not the infrequency of malignant syphilis indicate that our population is acquiring a relative immunity from such forms because of the general syphilization of the race; and may it not be that what we have gained in the infrequency of skin and bone syphilis, we have lost in the relative frequency of its more distal forms as affecting the other structures of the body and especially the nervous system; may not the presence of the scaphoid scapula in individuals suffering from the more distal forms of syphilis be an indication of its origin as well as of the individual's acquired relative immunity, the latter having been transmitted to him either from his parents, or through them from his more remote ancestors?

If it be accepted that the scaphoid scapula is found in a large proportion of our population, and especially in the type known as the deviate; if it is also frequently found in pathological development, in monsters, etc., etc.; if, furthermore, it is frequently present in the abiotrophies, in syphilis affecting the nervous system, tabes, and general paresis; if in these conditions one clinical fact (vasculosclerotic changes) supported by other clinical and by pathological findings can be traced in association with the scaphoid scapula even more or less completely—do not these facts, at least in some instances, point to a common origin, and in such instances to a strong connection between the scaphoid scapula and syphilis?

Thus far I have purposely avoided any direct reference to the manifestations of syphilis in the offspring of syphilitic parentage, but it is in the careful study of such individuals in connection with like study in the parents that we may hope to definitely show this connection, if it really exists. It is upon the evidence afforded by such studies that the final proof that syphilis is an etiological factor in the genetics of the scaphoid scapula must rest. This study must not only apply to the individual but it must be a comparative one with every member of his generation as well as an account of the illnesses and deaths therein, and, if abortions have occurred, the pathological and bacteriological study of the products of these. A study of his parents both clinically and by every known laboratory method which may give additional information and a comparative study of his uncles, aunts, cousins, grandparents, and as far back as his ancestry may be traced, and then his entire family as far as possible must be compared with other families having similar opportunities in life.

I have made use of the word blight in characterizing the scaphoid scapula and many individuals in whom it is found and in thinking of the various manifestations of syphilis, we may sum them up and characterize them by the one word—blight. Blighted characterizes the individual who has sustained a luetic infection. He remains thereafter a

Fig. 6.—Rear view of the two "little old men," shown in Fig. 5.

blighted individual, one of lowered resistance, a subject of slight and at times of marked degenerative changes, and under stress and strain ten, twenty, thirty, forty, and fifty years after his infection active manifestations of this insiduous enemy of the human race may appear. No one can say when an

individual is cured of his infection and it seems to me that the word blight is expressive of the early and late effects of luetic infection, and that as a rule individuals who have had such must be considered blighted individuals.

A study of such individuals and their progeny demonstrates the effects of this blight in the vast majority of cases. Blighted is the one characteristic of syphilitic progeny. "Taint" and "tainted" are words commonly used to characterize syphilitic offspring, but they are ambiguous and indefinite. I need but remind you of the "little old man" type so frequently seen among syphilitic progeny to show you why the words blight and blighted are preferable to taint and tainted in characterizing the progeny of syphilitic parentage (Figs. 5-6-7-8). The effects as well as the degree of this blight in syphilitic offspring will dpend upon the activity of the blight in the parents, and as a rule both will be more marked the nearer the occurrence of a conception to the time of the infection of the parents. If early during the greatest activity of the blight as in the first year, repeated abortions occur; if somewhat later, full term pregnancies, but the product may show active manifestations of syphilis; if still later, apparently healthy children may be born, but in many of these, and as a rule the oldest the most, the youngest the least, will show evidence of a general blight (Hypotheses III, IV, and V). Even if apparently healthy children have been born owing to an awakening of the virus from some stress or strain in the parent, premature births again occur, or a child may be born showing marked evidence of congenital lues. In their later development, children of syphilitic parentage show the blight in many ways which we need not here particularize; nor is it necessary before this audience to enter into the clinical manifestations of congenital lues, but I will merely add that those cases which we classify as congenital and hereditary show early vasculosclerotic changes, blighted physical and mental growth—at times the one, at times the other, and frequently both —resulting in retrograde types when compared with their immediate relatives and ancestors and the average members of the community.

I am well aware that some of the statements just made may seem radical, even exaggerated, and some may seem not in accord with the generally accepted views concerning the effects of syphilis in the offspring, and I freely admit that these are wholly at variance with my own former views; but I have lived long enough to see some of the end effects of syphilis in children of syphilitic parentage, the progeny of those where I had personally observed the course of the disease in the father, had treated him energetically, and finally, after three, four, or five years, consented to his marriage. In attempting to trace the ramifications of the scaphoid scapula, I have studied the wives and progeny of those fathers I had cured (?) and in no instance have I found a child equal to his forebears or failed to find some evidence of the syphilitic blight in the mother.

To him, who will continue to be blinded by the "glare of thereapeutic triumphs" in the treatment of acquired syphilis, I would say search! Search the parents and search the offspring for the subtle and blighting manifestations of syphilis and he will find ample evidence in support of the views here expressed, and I may add he will find evidence in support of Hypotheses III, IV, and V. But the blighting effects of syphilis do not cease with the first and second generations; it is often manifested in the third and fourth—the difference in the later generations being merely one of degree. Among these will be found many deviates, weaklings, distrophies, and other anomalies, and frequently the scaphoid scapula in a varying degree. In the blighted progeny of the third and fourth generations, also among those of the secend generation, whose advent into the world occurred at a time remote from the infection of the parents or when the infecting agent was dormant in the parents, will be found many of the types referred to early in this communication who pass as average individuals, yet who differ essentially from them in mental or physical endowments and frequently in both.

Time precludes my giving here the detailed clinical notes on individuals and families bearing upon the connection between syphilis and the scaphoid scapula in the second and later generations. The hypotheses set down above are based upon clinical investigations from which this connection appeared evident. I shall give illustrations of one or more of these in the presentation of patients; but what seems to me to be even more important upon this occasion is the offering of some suggestions bearing upon the recognition of the effects of a former syphilitic infection by modern methods of investigation and to indicate the assistance which may be derived from pathological, biological, and bacteriological sources in determining the connection between the scaphoid scapula and syphilis.

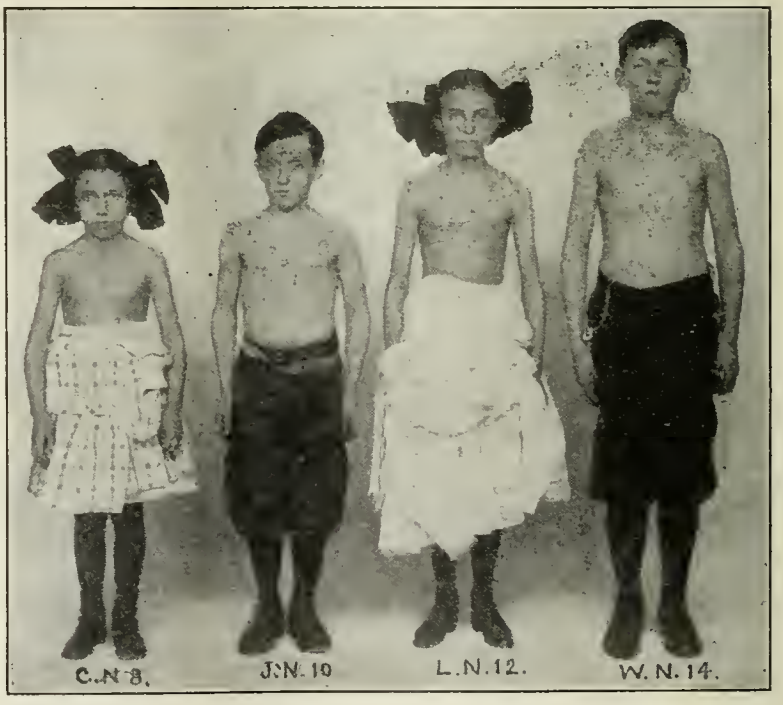

Fig. 7.—Four out of five heredosyphilitics in one family. Father now a victim of lues cerebrospinalis; mother of a distal form of lues; infection occurred in father four years before marriage; all of the children have palpable radials, enlarged glands, defective physical and mental development, and scaphoid scapulæ; both parents show convex vertebral borders.

I have, it seems to me, thus far sufficiently emphasized the blighting influence of a syphilitic infection upon the whole individual and its similar effects in the progeny of such to the second, third, and fourth generations. But it is to the recognition of the more subtle manifestations of syphilis in any one of these generations that we must now briefly direct our attention. Since we have been able to trace vasculosclerotic changes as a sort of connecting thread between the syphilitic and his progeny, our ability to recognize these is of prime importance in establishing one cause of the scaphoid scapula. So constant are these that even by the ordinary methods of clinical investigation they will rarely be missed if diligently sought for in syphilitic parents after the second or third year of infection or in their progeny after the tenth year of life.

As an aid to the usual methods in detecting these changes, let me call your attention to the Czapski binocular corneal microscope as recently modified by our own Dr. W. H. Luedde, with which we may readily see the blood coursing through the conjunctival vessels, and when present, the thickening, crinkling, and aneurysmal dilatations of their walls. He was kind enough to demonstrate this instrument to me just five days ago, and I immediately elicited his cooperation in the study of a few cases of syphilitics and their progeny in which I had by ordinary clinical methods, among other findings, been able to find evidence of vascular sclerotic changes. In order that Dr. Luedde might be wholly free from any influence in his studies, he was requested to make no further examination of these individuals than of their conjunctival vessels, and he did not until he came here to-night know anything whatever about the possible connection between syphilis and the scaphoid scapula. He will indicate his findings in connection with the cases which I shall presently present and these cases are to serve as a nucleus for our further joint study of early vascular changes in syphilitics and their progeny. The use of this instrument in the hands of the profession is destined to play an important part in determining one or more causes of the scaphoid scapula and in the determination of early vascular sclerotic changes from whatever source. Like other instruments, it is to be hoped that it will be used merely to extend our powers of observation, and not, as is so frequently done with instruments of precision, to render diagnoses easy.

FIG. 8.—Rear view of four out of five heredosyphilitics in one family, shown in Fig. 7.

Almost, if not quite, as constant as the cardiovascular manifestations of syphilis in the parents and in the offspring are such as may be detected by a careful examination of the nervous system, comprising as it does a consideration of the entire individual and particularly his mental, motor, sensory, and reflex functions. Intimate and inseparable in any examination, whether for the manifestations of syphilis or otherwise, is the search for such information as may be elicited by a thorough ocular examination. Syphilitics and their progeny will rarely pass through an examination of the nervous system, including the ocular examination, without revealing some of the more subtle and blighting manifestations of this disease. Finally, in our effort to determine one or more causes of the scaphoid scapula, we should not fail to use biological and laboratory methods to control our clinical findings and deductions. I have so used them in these studies and am greatly indebted to Dr. J. W. Marchildon for his working out in many instances, without knowing until to-night the significance of the Wassermann reaction in the blood and spinal fluid in the genetics of the scaphoid scapula. In order that his Wassermann reactions might be controlled, as well as for the purpose of getting further information, whether confirmatory or negative, of previous clinical deductions, I have made the punctures and subjected the fluid to the Nonne-Appelt test and a lymphocyte count per cubic mm. Our joint researches along this line will be continued and the findings up to the present time will be indicated later in the evening.

All known facts in pathology bearing upon the recognition of syphilis should be brought to bear in the study of those individuals coming to section having scaphoid scapulæ and especially upon the products of abortion from whatever source. Included in this will be the search for the *Spirochæta pallida* and the determination of the vertebral borders of the scapulæ in those embryos sufficiently advanced to permit of such determination, and when possible an attempt should be made to correlate the pathological and bacteriological findings with clinical data.

Realizing the value of such information in attempting to determine one possible cause of the scaphoid scapula, I recently requested Dr. Carl Fisch, without mentioning the object of my search, to permit me to examine any fetal forms in which he had beyond any question found the *Spirochæta pallida*. The study of the scapulæ in these fetuses show them to belong to the scaphoid type.

No. 13, according to the record of Dr. Fisch, was the product of a syphilitic mother presenting active secondary manifestations in December, 1907. No.

14 was turned over to him by Dr. L. C. McElwee and it was from a mother in whom he strongly suspected a syphilitic infection, though neither in the mother nor the father did he find active manifestations of the disease. Through the courtesy of Dr. McElwee, I became acquainted with the parents of No. 14 and learned that another miscarriage had occurred in about the sixth month in the year following the birth of No. 14 and that one year later the mother had given birth to an apparently healthy child.

I have made a superficial examination of this child, now six months old, and of its parents, each 35 years of age. The child has scapulæ of the scaphoid type to a much greater degree than the father, whose right scapula is concave in the upper two-thirds of its vertebral border, also in the left slightly concave just opposite its trapezial surface, but below these points the vertebral borders are generally convex. The mother has average convex scapulæ and an examination of her half-sister shows the same type. The father weighs about 175, the mother 115 lbs. Both show pupillary changes and very marked arteriosclerosis, especially the father. It was not possible to make a more complete examination of the parents and they have thus far refused to permit the Wassermann reaction and other tests. The present attending physician, Dr. M. J. Lippe, informs me that he found unmistakable evidence of lues in the baby six weeks after its birth and that he has seen the results of specific treatment not only in the child but in both parents. The child has many anomalies in development, but it is well nourished and might easily pass for an average baby.*

Mr. President and gentlemen, I must now bring this communication to a close, and in so doing deliver to you and through you to the medical profession the results of my studies, extending over a period of about three and a half years, bearing upon the ramifications of the scaphoid scapula. The statements made to you to-night, are, in every particular, based upon definite clinical and other data subject to your verification by the ordinary methods of investigation. I do not now draw definite conclusions; definite conclusions should not even be suggested by any one man in the many weighty problems which appear to be intimately associated with the scaphoid scapula. That there is a strong connection between syphilis and the scaphoid scapula I have, it seems to me, in more ways than one demonstrated beyond all question or doubt; but my findings must need be verified by others before such a connection can be considered an established fact. The verification of my findings must rest with the medical profession; and, if those of its members becoming interested in the ramifications of the scaphoid scapula will follow where it leads them, we shall, undoubtedly, in the course of time be able to definitely determine the connection between the scaphoid scapula and syphilis, if it really exists; and if so, its clinical significance, its diagnostic worth, and its bearings in both general and special pathology.

I have indicated the manner of further research—the manner thus far followed by me as far as possible in these studies, and what our joint studies may ultimately bring forth patient work and time must determine. But this we now know and appreciate: as physicians we need more light in many dark problems. We need it to-day as we did forty years ago when our own John T. Hodgen uttered these immortal words: "Should voices from the dead come to us, the cry would be—more light, more knowledge for our profession."

Metropolitan Building.

*Nine individuals were presented, representing five families, and over one hundred lantern slides shown, representing approximately 150 families, in which the scaphoid scapulæ existed in the progeny, associated with early vascular sclerotic changes, other signs, and other anomalies. Dr. Luedde's studies had been made in five of these families, comprising fourteen individuals ranging in age from three to forty years, and in each of these he had found sclerotic changes in the conjunctival vessels.

HYGIENIC PRINCIPLES OF VENTILATION.*

By W. A. EVANS, M.S., M.D.,

CHICAGO, ILL.

COMMISSIONER OF HEALTH, CHICAGO.

I DEAL especially with the sanitary side of ventilation. Good air is the most important problem before health departments. Sewage engineering has "made good." It has saved thousands of lives and added to the sum total of human happiness. It has approached the subject in a comprehensive way, from the health standpoint, as well as the engineering and mechanical. Sewage disposal, both in and out of the house, is causing less than 400 deaths a year in Chicago, a city of two and a quarter million people.

Is this true of ventilating engineering? It is not, and it will not be so long as lung diseases are responsible for one-third the total deaths. In round figures Chicago loses 10,000 people a year from these diseases. Man consumes solid food, liquid food or water, and gaseous food—air. Ten thousand deaths a year from bad meat, or bad milk, or bad water, would produce a world-wide scandal. Yet we accept 10,000 deaths from bad air with complacency, and a landlord, a manufacturer, a storekeeper, a head of a house, will have an easy conscience if he can think that he did not kill any more than his share. Of course, that conscience should not allow him to sleep until he takes no human life by bad air through any sin of omission or commission.

This campaign for better air must take many directions. There must be open bodies of water for purposes of purifying. Trees and other vegetation must be made to keep pace in growth and spread with the growth of population, because an equilibrium between animal and vegetable life must be maintained. There must be antismoke campaigns, dust campaigns, spitting campaigns, fog campaigns, fumes campaigns. But our special subject to-day is inside air.

Ideal ventilation is that in which the body is placed in the sunlight with a moderate wind blowing directly over it. Such conditions are seldom possible in crowded cities. But under all circumstances we should approximate the ideal as much as possible. The factors which are harmful in bad air fall into two groups: (*a*) quick acting; (*b*) slow acting.

The agencies resulting in the quick-acting harmfulness of bad air I would name in the order of

*A contribution to a symposium on ventilation. The article forms one of a series, to be published as follows: 1. Outside Air, Hygienically Considered. 2. Harm of Smoke. 3. Hygienic Principles of Ventilation. 4. Mechanical Principles of Ventilation. 5. Ventilation as Applied to (*a*) Street Cars; (*b*) Factories and Workshops; (*c*) Assembly Rooms; (*d*) Offices; (*e*) Living Rooms, Bedrooms, Flats; (*f*) Kitchens and Bakeries; (*g*) Hospitals.

their importance as follows: (1) bacteria; (2) dust; (3) temperature; (4) humidity; (5) odors; (6) CO; (7) organic matters; (8) CO_2. The resulting diseases are consumption, pneumonia, bronchitis, colds, influenza, cerebrospinal meningitis, anterior poliomyelitis, smallpox, diphtheria, and scarlet fever; all of these are infections which are air borne; the gas poisonings, also air borne. Of these influenza, colds, bronchitis, cerebrospinal meningitis, anterior poliomyelitis can be carried some distance by the air; smallpox not so far, while consumption, pneumonia, diphtheria, scarlet fever, and gas poisoning extend only a few feet.

The slow-acting harmful agents I would also name in the order of their importance: (1) heat; (2) humidity; (3) organic matter; (4) CO_2; (5) odors; (6) bacteria; (7) dust; (8) CO. The diseases caused by these are anemias, headaches, drowsiness, constipation, and the slow group following in the wake of these. This group is of additional consequence in that they at times determine infections.

We will discuss the harmful agents in expired air. Bacterial content overshadows every other item, in the first group—quick-acting—and the first group overshadows the second group. All other factors, except dust, are of minor importance. The most of these are the bacteria of pneumonia, consumption, and ordinary colds. Bacteria do not follow the laws of *diffusion* or *dilution* that pertain to gases. Not being of exactly the same gravity as air they do not follow exactly the same laws of *currents* as does air. Furthermore, insofar as they cause disease, the laws of dissemination are still further confused by the incoming of the incidence of contact with a susceptible man.

Let us illustrate: Two gases of differing specific gravity will not separate if left stagnant, but they will diffuse to an even mixture. This is not true of liquids or solids. Bacteria will settle out of quiet air. The law of diffusion of gases will not apply to the bacteria suspended in that gas.

Furthermore, if you have 10 per cent. CO_2 in air and then add an equal volume of air free from CO_2, in a few minutes you have 5 per cent. CO_2 in all parts of the gas chambers. If you have a chamber of air holding 1,000 bacteria to the cubic foot and you now add an equal quantity of air holding no bacteria, you do not get a homogeneous mixture of air holding 500 bacteria to the cubic foot. The laws of dilution do not accurately apply.

Air responds very accurately and promptly to differences in density due to differences in temperature. Bacteria do not, and any bacterial movement is due to forces outside of the passive bacteria. And, finally, 1,000 tubercle bacilli where no man is breathing are far less harmful than one within the breathing zone.

A fair percentage of men who have had pneumonia harbor pneumococci in their mouths. A small percentage of men who have not had pneumonia also harbor them. We will say that such a man runs for a car. He reaches it and stands panting and maybe sputtering. Into the same breathing zone comes a susceptible man who has just overeaten or overdrunk. What there is near the ceiling or under the seat certainly has nothing to do with this case.

The same physical laws govern dust as govern bacteria. As bacterial particles are smaller than dust particles they "lift" more easily and "settle out" less easily. The physical laws governing the dissemination of dust are not the same as the laws of dilution and diffusion of gases. Another very important hygienic law in dust should not be lost sight of. Individual bacteria differ in etiological importance. Different strains differ in etiological importance, and, of course, different kinds also differ. Just so different dusts also differ, inorganic dusts being more harmful than organic; sharp-edged dusts more harmful than rounded dust; metal and stone dust more harmful than wood and coal; dust from old hats and old clothes being more harmful than that from flour.

This introduces a hygienic factor in ventilation quite apart from the laws of gas diffusion and dilution. I think that we can assume that there will be denial of the importance of room dust in determining infections. The dust originating in a room is of more importance in causing disease than the dust brought into a room from the outside, principally because bacterial life does not long persist in outside atmospheric conditions.

Temperature, aside from its relation to comfort, is of some importance in the health side of ventilation. The mechanics of temperature and ventilation can not be separated. Therefore, it will be more extensively discussed in a paper on that subject. Nor is it of the same consequence in the air-borne infections that it is in the second group. In a warm room there will be some increase in bacterial multiplication as compared with a cold room, yet this is negligible. The relation of temperature is practically, therefore, limited to its relation in determining infections, and here it is of considerable consequence. If the ambient air is so cold or so warm that the body does not adjust itself to it, then infection is liable to result. Brisk cold applied to the body as a whole stimulates compensation. If this is too long continued, there will be a partial break in compensation, or there will be an overwhipping of the forces of compensation and infection may occur. If the chilling is limited to a portion of the body there may not be stimulus to compensation and infection may result. More important, however, in causing infection is overheating. Air issuing from the mouth and nostrils at 97° is almost instantaneously cooled to 90° or below, according to temperature and wind movement. If, then, the ambient air is 80° or over, the expired air hangs around the head to be rebreathed. The bacterial flora of the breathing zone is increased by a high temperature.

As to humidity: I am of the opinion that a dry house air is not so harmful to health as has been held. The uncomfortable feeling, say of apartment air, is due to the air being too warm for comfort rather than too dry. Humidifiers and sprinklers for moistening the incoming air are, as the French say, *"inutiles."*

Odors do not exactly comply with the laws of diffusion and dilution. In so far as most of them are gaseous, they diffuse like gases. But that which counts is not the presence of an odor but its appreciation. We will say that a certain room is offensive to 100 people who enter. To dilute that air with an equal quantity of fresh air does not mean that only 50 of those people will appreciate it or that those who smell it will object one-half as much. Odors, then, do not conform to physical laws exactly as do gases.

Air which is offensive may not be harmful. For example: Analysis of the Chicago Public Library

air does not show an excessive amount of CO_2. Anemometer measurements show a good air supply. Yet there is great complaint of offensive odors. The room is used by large numbers of people, many of whom have dirty bodies and dirty clothes. Odorous air may be beneficial if it leads to better ventilation.

The other factors are negligible.

We see, then, that of the eight harmful factors in air concerned in infections, three are not governed by the physical law which is made the basis of ventilation. Two are somewhat more governed by them, and those three which do not conform closely are least important.

In the second group—the bodily conditions due to bad air (anemia, drowsiness, headache, lassitude, etc.)—we find that the responsible factors in some instances diffuse as to gases, in others they do not. The two most important, heat and humidity, do not diffuse exactly as gases do. Excretory organic gases, CO_2 and CO, being gases follow the laws of gases; odors do in part and in part do not; dust and bacteria do not.

In the conditions which follow bad ventilation long continued, the most important factor, as Pflügge and his pupils have shown, is high temperature. This temperature does not do harm in the open or anywhere where there is a free circulation of air. For example: It is not harmful in engine rooms where there is air in plenty because the fires demand it. If the temperature of the room is above 70° F. and the circulation of air is not free, harm is done because the excrementitious expired air does not rise out of the breathing zone, but hangs around the head to be breathed in again. The pause between expiration and inspiration is but a second, and in this period diffusion does not accomplish much. Add to this a failure to rise because the outside air is about as warm as the expired air; on top of this pile a system of downward ventilation, and the expired air is buttressed right in the breathing zone and the air which goes into the lungs is nearly as foul as that which came out.

Humidity is sometimes of much consequence. The high humidities of certain trades are certainly harmful. This is partially due to the relation of water content, to temperature, and partly due to other factors. The low relative humidities of overheated rooms dry mucous membranes and thus are harmful.

Gaseous organic matter and carbon dioxide are poisons slow acting, mild, and inconsequential in any dose liable to be contained in a single inspiration; yet in total quantity inspired in a 24-hour intake of air, liable to be of much harm.

Odors, except such as are due to gaseous organic matter, are scarcely of consequence.

Bacteria and dust, while of more consequence in determining infections, are also factors in subinfections, which are of varying harmfulness.

Under ordinary circumstances carbon monoxide is made in such small quantities and is so rapidly diffused that its inherent toxicity is ineffective for harm.

While discussing the chronic conditions due to bad ventilation, I want to add that no system which entirely does away with a free blowing of air at some time during the day can be followed with impunity. A blowing out with changing the air content oftener than six times an hour reduces the bacterial content. It revivifies the air in a way that cannot be explained on the basis of the known chemical ingredients of air. The individual is much better off who stays in a current of moving air. The capacity for taking colds from drafts, the cringing from the inconvenience of drafts, all of this has been acquired. It is not natural to man or any other animal.

I read in Bergey's "Hygiene" as follows: "In a hospital or other place for the sick the windows should be so placed that the air should blow across the bed. There must be perflation." In this I concur, but to it I would add that to keep well is as important as to get well, and a well man is as much entitled to protection from sewer air as is a sick man. By sewer air I do not now mean the air of street or house sewers, but the air from the breathing apparatus, the most deadly of all sewers, as shown by the death returns.

The highest regard for health demands unhousing. One of the earlier disease experiences was with typhoid, erysipelas, and sepsis, during the Civil War. It was then discovered that the percentage of recoveries in unhoused hospital cases was greater than in those seemingly more fortunate cases that got into more elaborate hospitals. This lesson was apparently forgotten, for year by year hospitals grew snugger, their walls tighter, the opening of windows less prominent, and the legend, "so many feet of air washed and tempered," came more and more to the front.

Then came the open air treatment of tuberculosis. In such a camp it was found that temperature dropped almost at once. Secretion lessened, the patient improved, but the pulse remained rapid and the lung did not improve with the same rapidity as the drop in temperature. Then it was thought that the free blowing air was good for tuberculosis but better for the sepsis entering into the case of consumption (I trust that the above sentence will not be construed as meaning that a pure tubercular process is not fever producing). Then pneumonia was found more amenable to draughty air, if you please, than tuberculosis. Nobody has yet found a disease which has a lower death rate with air washed, tempered, and ladled out than it has in the free-blowing open air.

Society does not allow of unhousing in a certain sense. It is contrary to the laws of providence, of thrift, of economic production, of economic living. It would put an end to all community life. The remedy would be more expensive than the disease. The need is for regulated housing—housing in which the prime consideration is health through good air. Such housing is much less expensive than disease. From this consideration there naturally flows a discussion of methods.

The object of this paper is to lay down certain hygienic laws as a basis for the mechanical principles of treatment. The treatment will be wrong unless the mechanical principles are right. And the mechanical principles will be wrong unless the hygienic principles are right. The present almost universally wrong ventilation installations are wrong partially because of wrong mechanical principles but mostly because of wrong hygienic principles.

The following is my estimate of the basic hygienic principles of ventilation:

1. Attention must be concentrated on the breathing zones of the habitually occupied portions of the

room. This in the average room means a space of from 4 feet above the floor level to 6½ feet above it.

2. In this zone there must be the greatest possible effort to prevent (*a*) stagnation, and, (*b*) dilution.

3. Dead zones and corner eddies must be encouraged as settling places for bacteria. In them there must be the smallest possible air movement. Such spaces must be cleaned daily with moist methods. Therefore, they must be readily accessible for cleaning purposes. Such zones must be unoccupied. If such nooks are occupied, *e. g.* a working desk is placed therein, conducting ducts with air inlets must be made to open into them. Ventilation of such crannies by dilution is a myth.

4. The breathing zone must be occupied by an even up-current of air, moving at the rate of at least 60 feet a minute from multiple floor inlets to multiple ceiling outlets. If the natural upward flow is met by a down flow of air, the expired air is buttressed right in the head zone and does its maximum harm.

5. The ventilating air in mechanical systems should never enter the room at more than 40 degrees below body temperature; 30 degrees below is better still. Where men are working hard, a high temperature, say 70°, is required on account of the chilling of perspiration. Where men are very still and sluggish, a room temperature of 68° to 70° is required. Where men are mildly active, 60° to 65° is better.

6. The air must be protected from dust—both the introduction of dust from the outside and the dissemination of dust produced inside.

7. It is of great importance that the relative humidity of the inside air should not be materially greater than that of the outside air. It is of some importance that it should not be more than 10 degrees less than the outside air.

8. The volume of air per quiet person per hour should be around 500 cubic feet, varying with the directness of removal of the polluted air.

9. The arrangement of the ventilation must be such that the windows can be opened and the room blown out at least once in each 24 hours.

10. Recirculation of air is not to be tolerated.

11. The air must be below 6 parts per 10,000 in CO_2, and low in dust and bacterial content.

THE LOCAL HOSPITAL-SANATORIUM AS ONE OF THE MOST IMPORTANT PHASES IN THE ANTITUBERCULOSIS CRUSADE.*

By S. ADOLPHUS KNOPF, M.D.,

PROFESSOR OF PHTHISIOTHERAPY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ASSOCIATE DIRECTOR OF THE CLINIC FOR PULMONARY DISEASES OF THE HEALTH DEPARTMENT; ATTENDING PHYSICIAN TO THE RIVERSIDE HOSPITAL-SANATORIUM FOR THE CONSUMPTIVE POOR OF THE CITY OF NEW YORK.

JUST about nine years ago I was privileged to address the Laennec Society of Johns Hopkins Hospital on "The Value of Local Sanatoria in the Combat of Tuberculosis." It was then quite a novelty to have anything done locally in the line of antituberculosis work. The majority of workers, and there were not any too many in those days, still adhered to the idea that it was necessary to have sanatoria, if not in certain States with a climatic reputation, at least in mountainous regions as far as possible removed from habitations.

The definition of a local sanatorium which I gave in the just mentioned address holds good to-day, at least for the type of institution I have in mind and which, if I am not mistaken, is also in the minds of those who are now so devoted to the work of caring for consumptives in local institutions.

Such an institution is not a sanitarium, or health resort, nor an ordinary hospital or home. Such a sanatorium is not like a general hospital, inasmuch as it treats only patients suffering from tuberculous diseases, and the equipment of the institution is particularly suited to the open-air, hygienic, and dietetic treatment of consumptives. A sanatorium for the treatment of consumptives is not a home managed by the gentle hand of a minister, Sister of Charity, or matron, but an institution where patients are treated, not kept. There the trained physician not only carries out the most approved hygienic and dietetic treatment of tuberculosis, but infection of other persons through the ignorance or carelessness of patients is made impossible by the proper training of the invalids and constant medical supervision on the part of the physician and his assistants. To make the distinction between a home and such a local sanatorium still clearer, I may say that a properly conducted sanatorium for consumptives is not a danger to the neighborhood, but a blessing. In the German villages Goerbersdorf and Falkenstein, where sanatoria for consumptives have been in operation for over thirty years, the mortality from tuberculosis has actually decreased one-third among the villagers since the establishment of the institutions. The reduction in the mortality from tuberculosis among the villagers is to be explained by their imitation, voluntary or unconscious, of the cleanliness and sanitary precautions practised in the institutions in their midst.

Since I made these statements, nine years ago, the fact concerning the benefit of local tuberculosis sanatoria to the neighborhood have been verified by experience with such institutions as were established during or shortly before that period in or near American villages or towns.

To have any tuberculosis institution removed far enough from congested districts is as good a policy to-day as it ever was, but I believe we have changed our views as to the necessity of establishing of sanatoria at long distances from large centers of population. We now know that pure air is after all the most essential requisite, and wherever we can find it constantly we are reasonably sure to obtain good results in the treatment of tuberculosis. We have also learned to realize that when the patient is treated near his home, where he can frequently be seen by his relatives and friends, the element of nostalgia, which is often such a grave hindrance to recovery, is practically done away with.

It is the Committee on the Prevention of Tuberculosis of the New York State Charities Aid Association which has realized, perhaps more than any other of the various tuberculosis activities of this country, that the care of tuberculous patients in institutions should not be limited to the early and curable cases, but should also include advanced cases, particularly when these latter are more or less destitute and living in unsanitary environments.

The criticism has been made, and I have heard it even from medical circles, that it was a waste of money to bother with the hopelessly ill; that institutional treatment should be reserved for the curable

*Prepared for reading before the antituberculosis meeting at Albany on March 19, 1910. Because of an unavoidable delay the author did not reach Albany in time to read his communication.

cases, who could again be made breadwinners and useful citizens. Those who made these criticisms are not even right from the utilitarian point of view, much less from the humanitarian aspect of the problem. One who has had any experience at all with tuberculosis as a physician or as a social worker will know that the consumptive, no matter in what stage of the disease, if he is untrained and uncared for, constitutes a great menace in his workshop and in his home. But unfortunately, even when he is trained in the prevention of the disease, particularly in the careful disposal of his sputum or bacilliferous droplets during the so-called dry cough, at night when he sleeps he will cough and expel his small drops of saliva containing the tuberculous germs. If he has his own bed, which is not by any means always the case, he has rarely his own room. More frequently several beds are closely crowded together in a small tenement house bedroom, and the tuberculous spray infection may suffice to render gradually every one of the sleepers tuberculous. These tuberculous droplets are at times even more dangerous than the dried pulverized sputum, for in the moist state the bacilli retain their virulence, while in the dried tuberculous spittle the infectiousness of the germs is comparatively lessened. It must be evident that if the patient is confined all the time to his bed, the danger of his constituting a center of infection in a crowded bedroom, often without light and air, is very great.

Such a patient, because he is not taken care of at the right time and in the right place, costs a good deal more in the end, and not infrequently additional lives are sacrificed through his condition and environments. This is my answer from the utilitarian point of view to the statement that it is a useless expenditure to take care of the seemingly hopeless cases.

And now a word as to the humane aspect of caring for the more advanced and seemingly hopeless cases. Our present knowledge of phthisiology does not in my opinion enable us as yet to definitely state which case is absolutely curable and which case is absolutely incurable, or which case can or can not be improved sufficiently to constitute at least an economic cure.*

Institutional treatment for the consumptive poor has up to this date proved the most efficacious and successful, and if it was only for humanitarian reasons we should give to all the consumptive poor, in all stages of the disease, the sanatorium-hospital treatment. I use this hyphenated word sanatorium-hospital, or hospital-sanatorium, advisedly. A somewhat extensive experience with consumptives, particularly among the poorer classes, has taught me that they have of late years learned to know the difference between the words hospital for consumptives and sanatorium for consumptives. They have themselves come to the conclusion that a hospital means a place for consumptives to die, a sanatorium a place where they get well. Let us give our consumptive poor, no longer in the incipient or early stages, the same hope and comfort which we give to the well-to-do, who are received in many private sanatoria even in the more advanced stages, as long as they are able to pay. If we must make a distinction, let us call the institutions for the consumptive poor hospital-sanatoria. Let us receive there all cases and give them the best of care. We thus add the element of hope to all the other cura-consumptive poor, in all stages of the disease; inasmuch as we can take care of all cases among the consumptive poor, in all stages of the disease; inasmuch as we can increase their chances for recovery in these hospital-sanatoria by proper scientific and humane treatment, with a view of curing the curable and rendering comfortable and even happy the incurable, insomuch will we fulfill our duties to our fellowmen and come nearer to the object of our present labors, "no more uncared-for tuberculous in New York State in 1915."

16 West Ninety-fifth Street.

*By economic cure is to be understood a condition in which the disease has been sufficiently arrested to allow the trained patient to take up some occupation whereby he can earn his livelihood without aggravating the relatively quiescent stage of his disease.

THE RECOGNITION OF DEMENTIA PRECOX.

By S. P. GOODHART, M.D.,

NEW YORK.

The attention of students of mental phenomena has been directed within very recent years to that fascinating domain of normal and abnormal psychology in which occur the peculiar variations and perversions of psychic life incidental to the developmental periods. An understanding of the physiological variations of mental activity, as well as its pathological manifestations, is of great importance to the general practitioner of medicine. He it is who is first consulted, and upon him falls the burden of early opinion. It is often upon the acuteness of his vision for recognition of the aberrant mental types that the future of the individual and his relation and obligation to society depend.

Whether or not the term dementia precox is well chosen as nomenclature is not of concern to us here, further than to remind you that not all of the cases pass to ultimate dementia; nor is the term precox to be understood as indicating the presence of the disease in very early life only. Its manifestations may occur as late as at forty years.

By the term dementia precox, as now accepted, is understood essentially the three forms of insanity peculiar to the developmental periods of life. These have been divided into the three types hebephrenia, catatonia, and dementia paranoides. While the dividing line of each is not sharply defined, and all are possessed of certain elements in common, yet each has features of distinction. Particular interest attaches itself to the juvenile insanities for the physician, the sociologist, and the pedagogue. No other form of mental illness presents such opportunity for discriminating care and prophylaxis.

The pubescent and adolescent periods, vital in the effect of subtle changes upon the developing economy, are fraught with the gravest dangers. At these transitional periods, the deeply fixed forces of heredity and the modifying influences of environment play out their active parts. We see the awakening of formerly quiescent nerve forces, and the variations in the intellectual and emotional sphere; the development of religious, moral and ethical feelings, sexual impulses, ambitions, and an awakening interest in human institutions and forms. It is the formative, the plastic period, its finality representing the basis of the personality, a form made or marred in the melting pot of the composite energies.

The variations of psychic life at this time are so kaleidoscopic, so bizarre, that we are sometimes amazed to observe how perilously near the ill-de-

fined dividing line of normal from abnormal mental life these individuals come. Indeed, the vagaries of the adolescent period, in its struggle for proper balance, are almost identical clinically with various forms of true psychosis, and the discrimination is sometimes difficult, and always important. Every family physician should be familiar with these modifications.

Since the form of dementia precox termed hebephrenia counts among its victims many young people of unusual mental endowments, and often with no strain of heredity to warn us, it behooves us to recognize at once the initial signs that mean varying degrees of intellectual dethronement or decay.

We must not forget that while the term dementia precox, as a generally accepted name, is comparatively recent, the essential features of the juvenile forms of insanity have long been recognized. Over thirty years ago the term was used by several critical observers to designate those cases which ended in partial or complete dementia, and this criterion, the tendency of the disease phases toward ultimate mental deterioration, remains to-day. You will observe I have elected to speak of the recognition rather than the diagnosis, and for the reason that for the general practitioner cognizance of the nature, rather than the quality or type of the mental disease, is essential.

The evolution of this form of psychosis particularly is often gradual, and from the initial symptoms to development may require weeks or months. The initial or premonitory stages may be almost identical with the functional neuroses, particularly neurasthenia and psychasthenia. The individuals from whose ranks the milder forms of dementia precox are recruited are of the so-called neurasthenoid type. In many instances the gradual development of the psychasthenic into a condition of absolute incapacity marks the beginning of a progressive process of mental deterioration. It is most important that such cases as *maladie de doute*—that is, the condition of mental perversion characterized by fears, inertia, and indecision should not be mistaken for dementia precox. The apparent identity is further suggested since in both there is the mental distress, internal conflict, with indecision, hesitation in ideation or thought sequence. These borderland cases suggest the true psychosis, but have a far more favorable outcome; they do not terminate in dementia. Neurasthenia and psychasthenia may be differentiated from dementia precox if one will bear in mind the cardinal stigmata of the former, headache, muscular asthenia, rachialgia, gastrointestinal disturbances, along with resulting dyspeptic symptoms, insomnia, and cerebral depression.

As now conceived, the forms of insanity of early life are classed as hebephrenic, catatonic, and paranoid types of dementia precox. The fundamental element is, as the term implies, a tendency to ultimate mental decay. The psychological feature is a disproportion between the ideation and emotional effect, and this is a true clinical distinction. The stage of absolute dementia is by no means always reached. The premonitory symptoms are much the same in all three forms, and one hardly can tell at once which type will be assumed; indeed, the characteristics of one form may be present in some degree in all.

The onset is, as a rule, gradual, and the indefinite neurasthenoid symptoms coming on at this period of life, in individuals predisposed, should awaken suspicion. I say predisposed, by which I mean that there really is a type of individual who already in early life suggests the predestined hebephrenic. He is often of the artistic temperament, shows departures from the normal in character and in affective tone and eccentricities of manner, neologisms in speech—that is, the introduction of newly-coined words, peculiarities of word-extravagance in writing, a tendency to mix and use unnecessary words—a veritable word salad—in talking. Characteristic changes in demeanor are observed in the hebephrenic "type" of individual early in life. Among these is an unfitness, an inadaptability to simple situations and experiences. There is an unreasonable reserve and unapproachability, due in large measure to defect in critical faculty and simple discernment—what might, in spite of the apparent paradox, be spoken of as defect in instinctive judgment. This implies an *original* or congenital error, and so I would consider it. It would be otherwise difficult to explain the ultimely mental crepitude sometimes seen to follow precocious intellectual attainment. Nevertheless, we rarely see in those having the mental stigmata of dementia precox real constructive faculties, qualities of true and productive science workers; they are rather of the type given to pursuits not requiring the power of outward discrimination and judgment. Naturally, one must exercise discrimination, and not thrust into the hebephrenic class those who, in the evolutionary periods, react unduly to slight or trying experiences; their upheavals may be only temporary and their poise soon regained. Among the early symptoms of onset is a gradual enfeeblement of the power of voluntary attention; apathy, mistaken at times for simple depression; neurasthenoid symptoms, headache, drowsiness, capricious moods. I have seen several cases of brain tumor, especially of the frontal lobes, in which the psychic symptoms strongly suggested dementia precox, and only the changes in the optic discs made a positive diagnosis possible. There is a lack of spontaneous animation and a rapid dissipation of the powers of attention and concentration.

A characteristic and early feature is the disparity between memory and judgment, and in the lack of emotional reaction. Memory suffers far less than the apperceptive powers. New acquisitions are with difficulty attained. I am now speaking of the hebephrenic, the simplest type. All three forms show disturbances of judgment, memory, will, affecting the powers of attention and concentration. Later we may see mutism—stubborn silence; negativism—a senseless resistance to every external influence. For instance, if these patients are told to flex the arm, or attempt by the operator is made to flex the patient's arm, the opposing muscles will become rigid and an attempt to extend the arm will be made, or *vice versa;* there is verbigeration, that is, the senseless repetition of words or phrases, fixed attitudes, and stupor and catalepsy; all of these may be found in all three forms of dementia precox, but when present in hebephrenia, deprive it of its purity of class. Any of them may be wanting, and simple mental deterioration alone may supervene, preceded by mild neurasthenic symptoms.

Of particular interest to the general practitioner are the milder forms of hebephrenia. Here we find recruits from all strata of society; its victims may be found in every social plane. Among these we meet with those who have become mild offenders against the ethical code, whose perversion is often rather intellectual defect than moral obliquity, those

presenting varying deviations from the standard of normal; again we see most flagrant departures that make removal from society imperative. In this class of precocious dements we find many so-called victims of an unkind fate or circumstance, those who have repeatedly permitted splendid opportunities to pass by unnoticed, those whose early years were full of promise, but whose energies and ambitions seem to have become suddenly blunted. In them, want of concentration, dissipation of attention, perversion of judgment and loss of emotional reaction are conspicuous. These persons fall back into very simple occupations. They often are cognizant of the cloud upon their intellects, but do not appreciate their affliction. One may often hear the complaints of family and friends who misinterpret the changes in intellect, and particularly the want of emotion or feeling reaction.

Another feature is the moral obliquity or obtuseness, in some cases followed sooner or later by an acute mental storm. Many errors in early diagnosis have been made, and injustice and unhappiness resulted from the failure to grasp the import of these initial manifestations. The period of peculiar indifference to surroundings and progressive apathy may develop into one of profound hebetude; or, again, after several periods of mental storms, these patients fall back to a certain lowered level, but continue to keep abreast of simple activities and occupations.

Characteristic of the hebephrenic type is the lack of emotional poise, a want of balance between what may be termed the affectivity and the intellect. These patients show obtuseness of moral feeling quite in contrast to their education. A more or less sudden apathy, diminishing concentrative power, mild fading of intellectual activity, all these to the keen observer point to the coming crisis. The mild types of hebephrenia never may come under the care of the alienist, and among these are many highly gifted in youth, showing unusual aptitude for music or art, who more or less suddenly cease to progress in their intellectual activities. There are none of the physical stigmata of ears, palate, facial and cranial asymmetry seen in all grades of the imbecile class.

In estimating the qualities that constitute the predisposed and the active hebephemic form of dementia precox we must not lose sight of the fact that some of the peculiarities and abnormal symptoms seen in the pubescent and adolescent periods are but the efforts toward the attainment of balance, and soon disappear as the economy develops. With these mild aberrations we are all familiar.

A more active type of this hebephrenic form is seen in cases beginning with headache, vertigo, insomnia, and mental depression, soon followed by a period of excitement. There develops immediately after acute neurasthenic symptoms a peculiar loquacity, irritability, eccentricity of dress and demeanor. From indecision and dullness of mental action these cases pass suddenly into states of maniacal outburst, soon to fall again into profound apathy. About 17 per cent. of the hebephrenic type of dementia precox partially recover after one or two mental storms, and about 75 per cent. are said to go on to terminal dementia; only about 8 per cent. recover. These figures are approximate, and opinions as to recovery vary.

The characteristic mutism, verbigeration, uncontrollable unprovoked laughter, fixed attitudes, stereotyped movements, stupor, and catalepsy occur rarely in the hebephrenic, but are common to the catatonic form. In the latter the motor phenomena mentioned, together with a peculiar stiffness and awkwardness of the muscles, catatonic stupor, or excitement, give character to this form. Here again transitory vague neurotic symptoms may precede by weeks or months the first acute outbreak. Here mild transitory delusions, based upon auditory and visual hallucinations, may end in the final dementia.

The third type is that known as dementia paranoids, and its distinguishing feature is the delusion. It is the most unfavorable as to recovery. In these cases we observe some of the most atrocious acts of violence, homicidal and suicidal, and the sudden impulsiveness of the acts often suggests the epileptic furor. The likeness is further suggested because in dementia precox we sometimes observe convulsive seizures. A large percentage of juvenile criminals belong to this class. Its forensic import has scarcely been appreciated. I recall several cases of homicidal acts, the result of auditory hallucinations, seen at the Tombs here in New York, in youthful precox cases. Examination showed the characteristic psychological disorders of attention, and emotional anesthesia. These cases differ from the systematized delusional forms of true paranoia. They do not pass through the successive stages of true paranoia, and the delusions are based upon the auditory and visual hallucinations as a rule.

The physical symptoms of dementia precox possess no special features. The reflexes are invariably exaggerated. The pupils are found uniformly dilated. Peltz speaks of the frequent occurrence of characteristic changes in the iris, irregularly in its periphery, shifting from one quadrant to another. He further says that the normal pupillary unrest is absent in precox. This I can confirm. The so-called orbicularis reaction of the pupil is far more difficult to elicit than in normal beings. Choreiform and convulsive movements, vasomotor disturbances, hyperidrosis, and cyanosis, etc., are seen in the catatonic form.

Clark and Tyson have described changes in the optic discs in dementia precox. I have seen several cases in which dilated veins and disc changes occurred and were variable in their intensity at different examinations. The clinical value of these disc changes, if they can be established, is manifestly considerable.

I would again urge the physician in the practice of general medicine to give some attention to a study of the mild forms of psychosis common to the developmental periods. Some knowledge of normal and abnormal psychology of these periods is not only of scientific interest, but of great practical advantage.

We are really but in the dawn of our understanding, though our advance has been rapid and the impulse to progress is accumulating in force. The incipient stages of the mild types cannot be entirely relegated to the care of the specialist.

34 West Eighty-seventh Street.

Tubercle Bacilli in Dust.—In order to show that spitting on the sidewalks is dangerous to health, an investigation has been made by Dr. John Robertson, Medical Health Officer of Birmingham, England, which shows that 7 per cent. of the "spits" collected in public places contained tubercle bacilli. On the other hand the dust collected from the floors of the cottages of the Adirondack Cottage Sanatorium has been found to be free of tuberculosis germs, showing that a careful consumptive is not dangerous.

A CASE OF TABES AND MUSCULAR ATROPHY.

By EDWARD LIVINGSTON HUNT, M.D.,

NEW YORK.

INSTRUCTOR IN NEUROLOGY, COLUMBIA UNIVERSITY, N. Y. CITY; ATTENDING NEUROLOGIST, N. Y. CITY HOME FOR THE AGED; NEUROLOGIST TO WORKHOUSE AND PENITENTIARY HOSPITALS; SENIOR ATTENDING NEUROLOGIST, HOSPITAL FOR NERVOUS DISEASES; FORMERLY ASSISTANT VANDERBILT CLINIC, MEMBER N. Y. ACADEMY OF MEDICINE.

The combination of tabes and muscular atrophy occurring in the same patient is of sufficiently uncommon experience to warrant the report of such a case. There have been in all, so far reported, nine cases: Wagner, 2; Collins, 2; V. Ufen, 1; Trolly, 1; Chrétien and Thomas, 2; Goldscheider, 1. These Dr. Collins has collected and reported in a monograph on the subject in the *Journal of Nervous and Mental Diseases.*

It must be borne in mind that some degree of atrophy occurs in from fifteen to twenty per cent. of all the cases of tabes, but the nature of this tabetic atrophy differs somewhat from the real muscular atrophy. As Collins says, "the clinical characteristic features are: (1) Slow progression, (2) absence of fibrillary twitchings, and (3) absence of R. D. The most common location is the peroneal region." On the other hand the clinical characteristic features of pure muscular atrophy are: (1) presence of fibrillary twitchings, (2) a diminished reaction to both faradism and galvanism, and (3) a location in the upper, rather than in the lower, extremities.

The case which I now report shows, I think, a sufficient number of the classical features of pure muscular atrophy along with the classic signs of tabes to warrant its being classed as a case of tabes and muscular atrophy. Gowers says that muscular atrophy is an occasional complication of tabes; he lays special stress upon the fact that in this combination the atrophy is to be found especially frequently in the tongue. This, however, was not found to be present in my case.

H. S., aged forty-four, married, the father of thirteen children. He was by occupation a piano-tuner and maker. As an infant he had measles, scarlet fever, and diphtheria. In infancy he suffered from a hernia. When about ten years of age he fell four stories, striking on his back, but not sufficiently hard to cause unconsciousness. At eleven he developed blood poisoning; at twelve, pneumonia. The question of a specific lesion remains somewhat obscure but the probability is that at the age of twenty-eight he did contract syphilis.

The present illness dates back about six years. After great exposure to snow, which was followed by sleeping in a cold room, he complained of pain in his left side, which was followed by numbness. Previous to this he had had for some time shooting pains in the legs. Three years later he was again drenched while working in the rain and at this time noticed that he no longer had any great control over his left foot.

Now he complains of muscular weakness in the neck and back and inability to use his arms well. The hands are numb and he has great difficulty in dressing and buttoning his clothes. He has difficulty in passing his water.

The patient is very poorly nourished and greatly emaciated. There is marked wasting of the muscles of the right hand and right shoulder. Both scapulæ are shrunken. The neck muscles are atrophied and the head hangs well forward. There is some atrophy of the left hand and arm.

In both arms and fingers there is marked ataxia; he cannot approximate the hands with any degree of accuracy. The voice is weak. The eyes show nothing except that he sees double. There is a squeezing sensation around the waist. He has the Romberg symptom. The gait is so very ataxic that he requires the use of a stick to get about. There are no sensory changes beyond slight anesthesia along both hands and the right shoulder. The knee jerks are absent. There is a constant tendency for the water to run away. From time to time he is addicted to shooting pains in the legs.

There is no nystagmus but the pupils are typical Argyll-Robertson. There is no Babinski and no ankle clonus. Fibrillary twitchings are frequent in the legs. The plantar reflex is present. The wasting of the muscles is present in the interossei of both hands, the right hypothenar eminence is wasted, and the face shows atrophy.

Here, then, is a patient who shows Argyll-Robertson pupils, loss of knee-jerks, presence of the Romberg sign, and great ataxia in all the extremities. At the same time, he shows a progressive muscular atrophy beginning in the hands and extending to the neck and scapular muscles—an atrophy which evinces fibrillary twitchings and a diminished electrical response. It is an atrophy which has advanced with considerable rapidity. Another feature of the atrophy is that it involves not the legs, but the arms, and that it has steadily progressed from the interossei of the hands to the scapular muscles and the face.

A CASE OF ALKAPTONURIA.

By CLIFFORD MITCHELL, M.D.,

CHICAGO, ILL.

While determining chlorides in a certain sample of urine by the indirect method of Volhard as modified by Luetke, the writer was struck by the indefiniteness of the end reaction which in this process is usually sharp and satisfactory. This led to closer study of the specimen, with the result that alkapton (homogentisic acid) was found in it. The patient presented the following history: C. N., age 46, born in Germany of parents probably related, but not near relatives. His mother died of typhoid fever, and an uncle died of diabetes mellitus. The family history was otherwise unimportant. At the age of 24 he had typhoid fever, at 38 a severe attack of what he termed colic, lasting 12 hours. At 44 he had another similar attack lasting nearly a week. For the last six weeks he has been constipated, without appetite, and has had some elevation of temperature (102 degrees maximum). He is subject to business worry, has been a heavy smoker, and until lately a beer drinker. Six or seven years ago his application for life insurance was not accepted, but he was told to stop beer drinking, and to try again. On second trial he was accepted. Three years afterwards he applied for more insurance and was accepted, but was told that there was something "unusual" in his urine. He himself was afraid that the condition was diabetes mellitus.

Analysis of the urine made by the writer, December 30, 1909, showed in addition to the alkapton bodies a marked indican reaction, but otherwise nothing noteworthy.

The diagnosis made was gastrointestinal toxemia from worry, faulty dietary and habits. He was told to pay no attention to the "unusual" condition of his urine, but to look after his digestion and general health. One month later he returned and reported feeling "perfectly well." Examination of the urine showed the condition of alkaptonuria to be the same as before.

The presence of the alkapton bodies (homogentisic acid and uroleucic acid) in the urine is an anomaly of metabolism rarely encountered in this country, only four cases having been reported up to 1902. The condition may be congenital and occur in the offspring of consanguineous marriages. Alkaptonuria, though it may occur in disease, is not inconsistent with health. The principal alkapton body is homogentisic acid (hydroquinonacetic acid), which is apparently derived from tyrosin. The opinion has been expressed of late that this acid is a normal intermediary product in the destruction of tyrosin and phenyl-alanin, that its formation represents an oxidation which precedes the breaking up of the benzene ring, and that its appearance in the urine is an expression of metabolic insufficiency which renders the destruction of the benzene ring impossible. A. E. Garrod has described the condition in his little volume, "Inborn Errors of Metabolism" (Oxford Medical Publications), along with albinism, cystinuria, and pentosuria.

The clinical importance of alkaptonuria is as follows: 1. The liability of the individual to be rejected for life insurance, since the alkapton bodies affect some of the sugar tests (see below). 2. The liability of the individual for this same reason to be treated for diabetes mellitus with unnecessary restriction of diet and needless worry about his condition. 3. The liability of the individual in any event to worry in case the condition be not properly identified but vaguely described to him as "unusual."

When the matter was explained to the patient in question, and he was told that he neither had diabetes mellitus nor serious urinary disease, he exclaimed, "Doctor, you have removed a heavy load of worry from my mind."

Inasmuch as the text books on urine analysis familiar to the general practitioner give but little specific information regarding alkapton urine, the writer takes this opportunity to describe with some minuteness the appearance, properties, and reaction of the urine in the case above referred to. It is possible that the condition is more common than supposed and that cases of it are not identified by us as often as they should be in the hurry of everyday practice, the assumption being that "a trace of sugar" is present.

Physical Characteristics: The urine was darker than normal even when freshly voided, but the color did not correspond closely to anything on Vogel's Color Scale. On standing exposed to the air, it gradually darkened from above downwards until finally it was almost black, looking like molasses. On addition of an alkali such as ammonia, even in small amount, the urine darkened in a few minutes.

Qualitative Tests: The tests for albumin with heat and acetic acid, heat and nitric acid, cold nitric acid (by contact) with H. Le Roy Thompson's apparatus, and acetic acid with potassium ferrocyanide, were all negative. It occurred to the writer to float Goodman and Stern's phosphotungstic acid solution upon the urine, with the result that a precipitate in the form of a whitish ring soon turning slaty-gray was obtained. A number of normal urines were similarly tested, all of which gave the whitish precipitate in form of a ring, but without the slaty-gray color on standing.

In testing for sugar much that was interesting developed as follows: Four c.c. of Haines' solution were boiled and the alkapton urine added drop by drop with boiling after each drop; as soon as the first drop of urine struck the boiling reagent, the latter immediately darkened throughout its upper third. After four or five drops had been added, the entire liquid darkened, and when the sixth drop was added, a yellowish precipitate suddenly formed, which turned somewhat reddish in a few moments. On repeating the experiment, the same precipitate formed when the sixth drop was added. Five c.c. of Fehling's solution were next boiled, and the urine added drop by drop as before. The same darkening of the fluid was noticed as in the case of Haines' solution, but it required 22 drops to produce the yellowish precipitate. Ten c.c. of the alkapton urine were next boiled several minutes with Nylander's bismuth test reagent. No change was observed, *i.e.* no darkening. Ten c.c. of the urine were then placed in an Einhorn saccharimeter with one gramme of condensed yeast and allowed to stand at room temperature for 24 hours. No perceptible evolution of gas took place. The alkapton urine was tested for acetone bodies with the nitroprussiate test as suggested by Kelly—no reaction characteristic of acetone was obtained. On standing the green reaction characteristic of creatinin was considerably modified, being darker and more opaque than usual.

The behavior with ferric chloride solutions was characteristic of homogentisic acid. When to 5 c.c. of alkapton urine a 20 per cent. solution of ferric chloride (not synthetic) was added drop by drop, a dark green color was noticed just as the drop of reagent struck the urine, which immediately disappeared and left a slaty-gray precipitate of phosphates in its place. The same happened when a 5 per cent. solution of ferric chloride was used.

When Ehrlich's diazo reaction was sought for in this alkapton urine, an interesting result was observed. Ammonia being floated upon the sulphanilic acid-nitrite-urine mixture a double ring was obtained; below, a yellowish white ring of deposited phosphates, and just above it a slender wavy dark-brown ring due to the action of the alkali upon the alkapton bodies. The slender brown ring soon disappeared. On gently shaking the mixture, the upper portion was gradually darkened by the ammonia.

In testing for indican the original method of Jaffé as modified by Stokvis gave no blue color. A whitish emulsion of chloroform and interfering substances sank to the bottom of the tube. In order to remove these interfering substances, three methods were used, viz., first, that of Daland of Philadelphia, who avoids the formation of an emulsion by pouring slowly and repeatedly from one tube to another without shaking; second, that of the writer in precipitating the interfering substances with neutral acetate of lead added in different amounts so as to avoid excess; and third, the method of Obermeyer as modified by Askenstedt of Louisville, who washes the chloroform emulsion with water. All three methods showed indican in excess. It would appear, therefore, that the alkapton bodies

do not interfere with the oxidation of indoxyl to indigo blue.

Quantitative Tests: The acidity of the specimens examined was normal and the ordinary method of titration with decinormal sodium hydroxide agreed with Folin's method in which potassium oxalate is added to the urine with shaking. Phenolphthalein is reddened by sodium hydroxide in such urine apparently as in the case of normal urines, although the end reaction is not perhaps quite so sharp as usual. Nothing of special interest was observed in the quantitative determination of urea by the Doremus instrument with the hypobromite solution nor in that of phosphoric anhydride with uranium nitrate. In the quantitative determination of uric acid by the Folin method of titration with permanganate, the usual pink color of the permanganate was affected, at first being much more brownish than in the case of normal urines. In the determination of chlorides by the Volhard-Luetke method much difficulty was encountered, and it was during this process that the writer's attention was first directed to the peculiar features of this urine. In using the Luetke method the chlorides are indirectly determined by titration of the excess of silver nitrate in the silver-urine mixture by means of a solution of ammonium sulphocyanate. The end reaction is extremely sharp, but in the alkapton urine the end reaction was faint and indefinite until what was obviously an excess of the reagent was added.

Special Test for Alkapton: The most striking way in which to demonstrate the presence of alkapton was found by the writer to be the following:

The urine in small amount (1 c.c.) was carefully floated on 5-10 c.c. of a solution of sodium hypobromite (NaBrO) the same as used for determining urea with the Doremus instrument. Brown foam appeared on the surface of the mixture, and a dense brown band of color below the foam. Normal urines give a white foam and little or no color below the foam.

Summary: Urine containing the alkapton bodies shows the following features:

1. It darkens gradually on exposure to the air from above downwards. The upper portion of a given sample may appear black as molasses while the rest of the liquid is only slightly affected. Finally the entire body of fluid turns a dark brown or black. Addition of ammonia or other alkali hastens the change. Addition of hydrochloric acid removes the dark color.

2. If carefully floated in a test tube on the alkaline hypobromite solution used for the estimation of urea, it causes a brownish or brown-streaked foam to rise and a dense brown color band is seen below the foam.

3. Added drop by drop to boiling Haines' or Fehling's solutions, darkening immediately occurs and ultimately a yellowish red precipitate, simulating the presence of glucose.

4. With the bismuth and fermentation tests results are negative.

5. It gives a dark brown ring in Ehrlich's diazo test.

6. It interferes to a certain extent with the determination of uric acid with permanganate and renders the end reaction doubtful in the Volhard-Luetke indirect method of determining chlorides in the urine.

7. It does not appear to affect the nitroprussiate test for acetone nor the usual tests for indican.

8. A characteristic test depending on the presence of homogentisic acid is the dark green color on addition of ferric chloride, which color immediately disappears.

EXAMINATION OF DUODENAL JUICE OBTAINED BY THE GROSS DUODENAL TUBE.

By F. VON OEFELE, M.D.,

NEW YORK.

Some time ago, when I was working in the new Research Laboratory of the Roosevelt Hospital (Dr. Lyle), I received from Dr. M. Gross a quantity of duodenal juice for chemical examination. I hope I shall have an opportunity of continuing these examinations on a larger scale in my own laboratory, which will probably result in obtaining greater clearness in regard to the function of the duodenum in both normal and pathological conditions. The results so far obtained, however, seem important and interesting enough to warrant this short report.

All previous experiments on this subject, to which I can find any reference in the literature, differ from present results in two points: (1) the local source from which the juice was obtained, and (2) the method of obtaining it. Former investigators procured direct pancreatic juice, bile, or juice from the lower parts of the intestines; and as these juices were obtained through a fistula, involving an artificial traumatism, the condition of the individual operated on was not normal. A third point might be added, in that these juices were mostly taken from animals, and not from man. By the method introduced by Dr. M. Gross, naturally normal and naturally pathological duodenal juice of the living man can be procured without any artificial lesion, which explains that there cannot be any previous literature on this point. This is not the place, however, to describe the method in detail, especially as the same has already been published; but the present article may be regarded as supplementing the one referred to, because it shows the importance of the method, and gives rise to the hope that in time it will be more and more improved and become as important in the domain of clinical medicine as is the examination of the gastric contents at the present time.

Although, as I stated, there is no literature available on the subject in its present aspect, it will always be necessary to compare the results obtained from duodenal juice with those [redacted] pancreatic juice, bile, or juice taken from the jejunum and ileum, and to this literature I shall refer at the proper time.

First Examination.—A 1 per cent. solution of Kahlbaum's soluble starch was prepared with distilled water, and 10 c.c. of this solution were put into 5 test tubes each. To the first test tube 1 drop of duodenal juice was added, 3 drops were added to the second tube, 9 drops to the third, 27 drops to the fourth, and 81 drops to the fifth tube. The duodenal juice was freshly obtained, and filtered. The tubes were numbered and placed simultaneously in an incubator registering physiological human temperature. After 4 minutes the tubes were removed and placed in an ice box, thus interrupting any further fermentative action.

From the contents of tube No. 5, 2 c.c. were separately taken and titrated with a centinormal iodine

solution. With the addition of the first drop the iodine color disappeared, the liquid remaining colorless. With the second drop the iodine color changed to a faint pink; with the third drop the color turned slightly violet, but still was more pink than violet. With 0.4 c.c. of centinormal iodine solution the mixture of red and blue assumed a more pronounced bluish tint than would a solution of ferrichloride and carbolic acid. In 0.8 c.c. of centinormal iodine solution the color remains unchanged.

This initial titration proves that the starch was digested, and that achroodextrin, erythrodextrin, and amylodextrin were present. I wish here to recall that achroodextrin has the highest, erythrodextrin the second, amylodextrin the third, and amylum the lowest affinity for iodine. From the text books this is not quite apparent; in fact, the statements made relating thereto in any published books are distinctly wrong. The facts are as follows: If iodine is gradually added to a mixture of achroodextrin, erythrodextrin, amylodextrin, and soluble starch, the liquid remains colorless up to the time that the achroodextrin is completely saturated with iodine. After that it turns pink and remains so until all the erythrodextrin is saturated. A further excess of iodine changes the color to violet, and later, when the amylodextrin is saturated, a further excess of iodine turns the color in the presence of soluble starch to sky-blue, while in the presence of insoluble starch a blue-black powder is precipitated to the bottom.

The digestion of starch takes place in the opposite order. The first regular digestive product of starch is amylodextrin, after which will follow erythrodextrin, achroodextrin, maltose, and dextrose, in the order named. Starch, amylodextrin, erythrodextrin, and achroodextrin are no single chemical bodies, but are composed of a large number of chemical substances. For this reason it is sufficient to put maltose and dextrose together and determine in one figure of percentage their copper-reducing power. Considering that normal, pure saliva changes in one minute 24 per cent. of soaked starch to reducing sugar, the determination of made sugar should also be added as a comparative and conclusive measure of the action of duodenal juice in the first instance. In each of five dishes 5 c.c. of Fehling's alkaline and 5 c.c. of Fehling's copper solution were mixed and boiled. To the boiling mixture were added 5 c.c. of the samples, as above described, and the boiling continued for further four minutes. The precipitate of copper hemioxide was separated, purified as usual, balanced by weight, and calculated as sugar. The duodenal juice transformed in four minutes, in concentrations of: 0.5 per cent.—7.5 per cent. of the starch originally present in the sugar; 1.5 per cent—15 per cent. of the starch originally present in the sugar; 4.5 per cent.—22 per cent. of the starch originally present in the sugar; 13.5 per cent.—29.5 per cent. of the starch originally present in the sugar; 40.5 per cent.—22 per cent. of the starch originally present in the sugar.

These results show that in the lowest concentrations the saccharifying power of this duodenal juice was very quickly increased. Afterwards it increased more slowly, reached the optimum at about 13.5 per cent. and decreased in higher concentrations, so that 40.5 per cent. gave exactly the same result as 4.5 per cent. The true optimum was not exactly observed, because in this very first examination only one test was made between 4.5 and 40.5 per cent. concentrations. The optimum may thus be lower or higher than 13.5 per cent.

With the same sample of duodenal juice the fat splitting capacity was tested, and Gruetzner's emulsion of olive oil and gum arabic was employed for this purpose. In each of 5 test tubes 10 c.c. of emulsion were placed and neutralized to a violet color by the addition of a small quantity of litmus solution. Tests were made with 1, 3, 9, and 27 drops of duodenal juice, also a blind test. In the incubator with physiological temperature there was no change whatever in the first minutes and hours, while after 24 hours the solution of the blind test remained violet, and the other four samples turned an identical red color. This proves that a fat-splitting ferment was present, producing free fatty acids. But a quantitative examination of the fat-splitting forces of the different concentrations of duodenal juice was not made, and this is reserved for examinations at a later time.

Second Examination.—Four days later I received from Dr. Gross another test sample of duodenal juice taken from another person. I prepared the same solution of Kahlbaum's soluble starch, from which I made two blind samples and six others to which this juice was added. The juice, having first been pased through a Chamberlain filter, became an almost clear, strongly green liquid. To the contents of tube No. 1 was added 0.01 c.c. of juice in 10 c.c. of a 1 per cent. starch solution, 0.03 c.c. to No. 2, 0.09 c.c. to No 3, 0.27 c.c. to No. 4, 0.81 c.c. to No. 5, and 2.43 c.c. to No. 6. The eight test tubes were placed in the incubator for four minutes at a temperature of 40° C and afterwards put into the ice box for twenty-four hours.

Now 2 c. c. of each sample were separately tested by centinormal, aqueous iodine solution. The two blind samples assumed by the addition of one drop a strongly blue color, resembling methylene blue. The same color resulted in 2 c.c. of Nos. 1, 2, and 3 by the addition of one drop of this iodine solution. This would prove that in these three samples the amount of achroodextrin, erythrodextrin, and emylodextrin produced was insufficient to entirely absorb the free iodine contained in one drop of centinormal solution. But this result may partly be due to the sticky condition of the liquid and to the consequent difficulty in mixing it. After the reaction had taken place, the samples were kept in the ice box for another twenty-four hours, but a further effect of the amylolytic ferment was not obtained. But now No. 1 was blue like methylene, No. 2 very pale bluish violet, No. 3 pale and medium violet. Therefore, a small amount of achroodextrin and erythrodextrin was present in both, but a little more erythrodextrin in No. 3. In No. 4 one drop of iodine solution was immediately decolorized; with the second drop the color changed to blue like methylene. After a stay of twenty-four hours in the ice box this blue liquid was nearly completely decolorized, showing only a pale reddish violet. This proves that No. 4 contained more achroodextrin and also more erythrodextrin than No. 3, but only a very small amount of amylodextrin. The first and second drops of the iodine solution were at once decolorized by 2 c.c. of the contents of No. 5. The third drop turned the color to bluish violet, but this color disappeared after five minutes and did not return after twenty-four hours' stay in the ice box. The first three drops of iodine solution were decolorized by 2 c.c. of No. 6, and

changed with the fourth drop for a short time to a red color which disappeared after two minutes. The same result was obtained by the fifth and sixth drops. With eleven drops an intense violet color of a few minutes' duration was produced. Now these 2 c.c. were diluted to 10 c.c. by the addition of distilled water, and after five minutes the solution was nearly colorless, showing a very pale pink tint.

Now I proceeded to the determination of sugar in the same manner as in the first test. The duodenal juice transformed in four minutes, in concentrations of—

0.1 per cent.—2.0 per cent. of the starch originally present in the sugar; 0.3 per cent.—3.2 per cent. of the starch originally present in the sugar; 0.9 per cent.—7.0 per cent. of the starch originally present in the sugar; 2.7 per cent.—16.0 per cent. of the starch originally present in the sugar; 8.1 per cent.—5.6 per cent. of the starch originally present in the sugar; 24.3 per cent.—1.0 per cent. of the starch originally present in the sugar; 0.0 per cent.—0.0 per cent. of the starch originally present in the sugar.

A comparison of the determination of sugar with the tests of the various dextrines by iodine shows that the highest concentration of duodenal juice produced the highest amount of the earliest starch-splitting products of carbohydrates. The greater the splitting capacity, the sooner was the optimum reached, after which a decrease set in. The optimum at the lowest concentration attained sugar production with a little more or less than 2.7 per cent. in the second case, and with a little more or less than 13.5 per cent. in the first case.

Third Examination.—One day later I received from Dr. Gross a third sample of duodenal juice taken from a third patient. The total quantity of this sample was 18 c.c., color greenish yellow, appearance feebly opalescent and turbid. In the first and second tests the juice had been filtered, but being very anxious to make a change in this respect, I did not filter the third sample. The specific gravity was 1,009. I have noticed that Demont, Turby, Manning, H. Hamburger, Heckma, and Nagano have made examinations of human intestinal (not duodenal) juice, in which the specific gravity was stated to have been 1,007. This corresponds very well with my own figure, because from the pylorus to the valvula Bauhini the amount of water increases and therefore the specific gravity decreases.

Of this duodenal juice 6 c.c. were used to determine the total solids and ash. The total solids amounted to 1.32 per cent. and the ash to 0.73 per cent. of the fresh liquid. The ash had an intensely yellow color, and a solution of the ash by hydrochloric acid was also yellow. These findings likewise correspond with the figures of earlier investigators, but my figures very nearly reach the top of those previously reported.

I also made a third amylolytic examination with artificial limits between the different groups of dextrin. I determined sugar by reduced copper hemioxide. In three experiments, after filtration, a greenish second reduction of copper was obtained and calculated as a second group. This second reduction was produced by a very viscous matter, which with iodine turned into reddish brown; this made the other color reaction of iodine very difficult and partly impossible. In this case I also determined the amount of starch which was not changed by the amylolytic ferment.

Duod. Juice, Per Cent.	Unchang. Starch, Per Cent.	Erythrodextrin, Meas'd by Iodine Titrat, Iodine Units	Achroodextrin, Meas'd by Iodine Titrat, Iodine Units	Produced Sugar, Per Cent.	Greenish Reducing Mucilagenous Matt'r Per Cent.
0.1	70	Absent	15	1	Absent
0.3	35	10	20	3	5.5
0.9	20	25	20	10	20.4
2.7	15	25	30	13	2.9
4.0	20	50	25	13.3	Absent
6.0	20	60	25	17.6	"
8.1	20	85	30	30.4	"
24.3	25	75	80	12 5	"

These figures recapitulate more precisely those shown in the first two examinations. The strength of duodenal juice was not the same, and as the physiological and pathological conditions in these three case were different, the results are not absolutely, but only relatively alike; it would be rash, therefore, to draw too far reaching conclusions from the same. But it will be seen that there is a possibility of obtaining more exact findings in regard to the duodenal digestion in different physiological and pathological conditions; and there is also a possibility of working out a satisfactory method of examination. After a short time it should be possible, therefore, to make examinations of the duodenal contents which will admit of conclusions valuable alike to physicians and patients, such as are now possible in the examination of gastric contents.

ABRAMS' METHOD IN THE TREATMENT OF ANEURYSM OF THE THORACIC AORTA.

By L. ST. JOHN HELY, M.D.,

MADERA, CAL.

Dr. Albert Abrams of San Francisco first directed attention* to a novel method of treating this intractable affection, which he has since elaborated in his recent book.† He reports fourteen cases of aneurysm of the thoracic and abdominal aorta which he has apparently cured, although he qualifies his results by stating that he has not the hardihood to regard his method as curative, for time alone is the decisive factor. A conservative estimate of the results, however, prompt him to say that, as a palliative method, it surpasses any in simplicity and rapidity of action which has yet been introduced to the profession.

Abrams claims that the subsidiary center of the vasoconstrictor nerves of the aorta is located in the spinal cord in proximity to the spinous process of the seventh cervical vertebra and that by stimulation of the center in question by concussion, the normal as well as the abnormal aorta may be brought to contraction. Ample evidence is furnished of the latter fact in his work on spondylotherapy. The method, in brief, which he suggests in the treatment of aortic aneurysm, consists in concussion of the spinous process of the seventh cervical vertebra. He deprecates the employment of the conventional vibrating apparatus. The vibratory apparatus which the physician must employ is one giving the percussion stroke. All other motions, such as oscillations, shaking, and friction interfere with results. In the

*Medical Record, July 3, 1909.

†Spondylotherapy, 1910. Philopolis Press, San Francisco.

absence of a suitable apparatus, a pleximeter (a strip of linoleum or thick rubber) and a hammer, to the end of which is fixed a piece of hard rubber, are employed. The pleximeter is applied to the seventh cervical spine and is struck a series of rapid and moderate blows by the hammer. The daily *séances,* according to results, may last from five to fifteen minutes, but during the *séance* the treatment must be interrupted from time to time to avoid irritation of the skin.

The results of Abrams' method are usually immediate, great relief following a few *séances.* When the writer first encountered the monograph of the latter on the subject, he was rather skeptical, although Abrams anticipates such criticism in his book by observing that any merit attached to his method may be obscured by its simplicity.

The writer presents the following history of a patient suffering from aneurysm of the thoracic aorta who was treated by the "concussion-method" of Abrams:

J. A., age 46 years; weight, 185 pounds; a blacksmith and a moderate drinker, had no previous history of illness beyond the diseases of childhood. On the sixth of November, 1909, the patient first noticed a small projection in the region of the first rib about the size of a dime. A peculiar burning sensation corresponding to the latter point was likewise noted but the patient gave it no serious consideration until December 19 of that year, when while assisting in lifting a wagon he experienced a choking feeling and the miniature projection attained an enormous size. The patient then sought medical counsel and the diagnosis of a thoracic aneurysm was definitely established. At this time the following subjective and objective symptoms were noted:

Pronounced cyanosis which was universal, cardiac palpitation, choking, and dyspnea upon the slightest exertion, and an almost incessant cough. At night the patient could find a modicum of relief only in one position, viz., propped at an angle of 45° on the right side, and even then the coughing and choking would awaken him every hour. I regarded his condition as absolutely hopeless and so informed his friends. Having at this time read of the method of Abrams, I employed it first on January 21, 1910. Concussion treatment of the seventh cervical vertebral spine was executed daily for fifteen minutes from the latter date until March 5, 1910, when treatment was discontinued.

The second night following the concussion the patient rested well, and after the fourth treatment there was an absolute evanescence of all symptoms. In the language of the patient, "I can now sleep in any position and like a baby; in fact, as natural as any one. I do not cough nor suffocate any more, and, aside from the tumor on the chest, I would not know that there was anything at all the matter with me."

The aneurysmal tumor when first examined projected considerably and measured about 2½ inches in diameter at the base. At the end of the first week's treatment the tumor was reduced about 25 per cent., but there was no apparent further diminution in size when treatment was discontinued. It was impossible for me to continue treatment, as the patient insisted that he was well and further treatment was unnecessary. The results in this case were, however, immediate and corresponded in the main with the results obtained in the cases reported by Dr. Abrams.

IN MEMORIAM.*

DR. ANDREW H. SMITH.

By BEVERLEY ROBINSON, M.D.,

NEW YORK.

To those members of the Climatological Association who knew Dr. Andrew H. Smith well, words of praise and high appreciation were almost needless. But even to them it may be well to say a word of hope and cheer; to the younger and aspiring ones a timely word to show a brave and loyal soul to imitate and follow were also well. My dear old friend Andrew was good, kind, conscientious, full of real religious zeal in well-doing, and that was the sort of fear of God that animated him. He worked hard and uprightly and relieved many a bed of sickness or of death of its sharp suffering and dread. In my two only severe illnesses in New York, Andrew was near me and most serviceable. He helped save my life in diphtheria; he relieved me magically, almost, by his clear insight into medicine, when I was worn out with the pain and distress of acutely inflamed tonsils, due doubtless to scarlatinal infection, not otherwise evident. Whenever Andrew spoke, or wrote on medical, or other subjects, his words were words of wisdom. He always battled most bravely and singly for conscience' sake and to those who listened and trusted he guided to better doing and higher living. Nor did the serious side of his nature prevent his sharing mirth and jollity, and many a good story he told and enjoyed. But he had no use for ribaldry, profanity, or things or thoughts of bad alloy.

To medical literature his contributions were many and of very high excellence. His acumen was keen and he was ever most suggestive. At once he was practical and also, in a sense idealistic, and by the latter word I mean there was always an undercurrent of well thought out judgments, which might seem theoretical to some, but were based upon wide knowledge of much that had been acquired by master minds in different directions.

Andrew's war record is bright and fair as that of many, thank God, of the bravest and best, who did yeoman's service in our Civil War as surgeons at the front. His life struggle in the beginning was hard and difficult, but he knew that it was meant to be so to those who strive manfully for the right. In his later years he was prosperous, but, alas, he was shadowed for a time with grave symptoms of disease.

His final few weeks of life were weeks of great suffering despite all that devoted skill and affection could do for him. It was my enviable lot to see him several times before he died, and when I say enviable it is not because I did not suffer keenly from witnessing distress which I could not relieve, but because one likes to do one's best to be useful to the good and the true of the world. The Climatological Association has lost a member and associate, who, with his unsullied record, shines brightly as an example to us all.

*Read at the annual meeting of the American Climatological Association, held in Washington, May 3, 4, and 5, 1910.

Tuberculosis in Bulgaria.—Efforts are being made in Bulgaria to abolish the numerous monasteries and convents of the Greek Catholic Church and to use their buildings and revenues for the establishment and maintenance of tuberculosis sanatoria. King Ferdinand has given 100,000 francs for the erection of a national sanatorium. The death rate from tuberculosis in Bulgaria is very high, being 31 for every 10,000 living.

MEDICAL RECORD.

MEDICINE AS A PROFESSION.

WHEN making choice of a profession, various matters must be taken into consideration. If a youth be ambitious of material welfare or of great power, perhaps, medicine would be the last profession to choose. Politically, the medical man, as a rule, is a cipher and he seldom amasses great riches, as riches are accounted nowadays. The profession of law offers far more opportunities both for making money and for rising to political eminence than does the medical profession, while for gaining honor and glory, the army and the navy, even in these piping days of peace, hold out more hopes. However, on the whole, regarded from the standpoint of obtaining a fair livelihood, the medical profession is equal to any of the others and in some respects is superior.

In *Science*, April 22, 1910, is published a lecture delivered by Prof. Harold Williams to the students of Tufts College, in which the author emphasizes the importance and value of a college education and points out that Huxley's definition of a liberal education is supplied by good class colleges to those who are able and willing to avail themselves of the advantages offered. Further he draws attention to Gibbons' dictum on the question of education, namely, that "everyone has two educations, one which he receives from others, and one, more important, which he gives himself." Self education must not be neglected. It may be taken for granted, however, that a college education is more or less essential for those desiring to take up medicine. At least, if not essential, a liberal education is a most valuable foundation upon which to build the medical superstructure.

Prof. Williams is of the opinion that it is well to choose a profession as early as possible in a college career, for the somewhat obvious reason that an early decision will enable one to select a curriculum of study in line with the profession chosen. A warning is given against too great idealizing of the medical profession in the minds of its would-be followers. It is to be doubted whether this warning is needed. High ideals never did a person harm, albeit he may and probably will be brought to earth rather roughly. If one is fated never to reach the heights, it is better to have dreamt that one has reached them than always to have remained below. Imagination is an asset not to be despised by the clear-sighted scientific man. Still there are but few members of the medical profession who will become famous, and the great majority will belong to the rank and file and will live and die as humble practitioners. What then are the privileges attaching to this class? Are they commensurate with the time, labor, and money expended in obtaining the right to practise? There are many advantages in being a medical man and to one who is so from choice, and is not a round peg in a square hole, these more than counterbalance the drawbacks. Socially, the life is pleasant, the physician is thrown into contact with all sorts and conditions of men, and, as Prof. Williams says, "such environment is enormously stimulating to his intellectual life." Moreover, the practice of medicine has a broadening influence on a man, in a higher degree than the practice of any other profession or trade. The fact must be borne in mind that the medical profession itself has widened greatly in scope during recent years. Medicine *per se* is not adhered to as in times gone by. Nowadays, there is almost as much preventive medicine followed as curative or remedial. Public health problems absorb a considerable amount of the attention of present-day practitioners, and the research worker is in evidence, and becoming more so in all parts of the civilized and uncivilized world. Thus when a youth enters the medical profession under existing conditions, he has a wide choice as to which branch he should pursue and is not bound down, as used to be the case, by certain well defined rules as to practice. Again medicine is the most cosmopolitan of all the professions. Scientific medicine, like pure science, knows no artificial boundaries. The medical student is equally at home in the schools of Paris, Berlin, London, and New York, and the graduate in medicine, were there no local laws preventing him, would be competent to practise in any part of the world.

As to the preliminary course of training for the medical profession Prof. Williams has some well defined views. He is a stickler for biology and thinks that each collegian who contemplates entering the profession should place biology in the first rank of preparatory studies. Biology is of great use, over and above its intrinsic value, in teaching medical students methods of study, "it is like studying the map of a city before we explore the city." Next in his estimation comes physics, third chemistry, fourth Latin, fifth advanced English, sixth and seventh German and French, eighth and ninth economics and sociology, tenth and eleventh drawing and painting and shorthand writing, and lastly public speaking. The student who before he commences in earnest the study of medicine, takes the advice of the Tufts' professor as to his preliminary training will certainly not lay himself open to the charge that he has not endeavored first to prepare himself for his life work by a liberal education. A serious omission in this list of necessary studies, however, is that of Greek. No physician who is not more or less familiar with this foundation of scientific nomenclature can ever really understand the language of his profession. There is no

reason that the medical man should not be cultured, indeed the day of the blunt almost boorish physician is past, and as a college education tends to culture, the advice to store one's mind with knowledge prior to studying medicine is sound from all points of view.

A high standard of medical education is certainly to be strongly advocated and such an education to be really effective should be uniform throughout the country. By these means, the status of the entire profession will be raised, undue competition will be checked, and all concerned will be benefited. Finally, it may be said that while the medical profession does not hold out hopes of speedy or large money returns or of great power, it does give to those who love it always a good livelihood and sometimes enduring fame.

SMALLPOX IN THE UNITED STATES.

During the past ten years smallpox has been unusually prevalent in the United States. The number of cases of smallpox reported to the Surgeon-General of the Public Health and Marine-Hospital Service during the calendar year 1908, by the local and State health officers of the various States, was 35,174. In Minnesota, 7,031 cases occured, giving a case rate per 1,000,000 of population of 3,397. In Kansas there were 3,458 cases, with a case rate per 1,000,000 population of 2,096, and Montana had 732 cases and a case rate per 1,000,000 population of 2,339. However, these records are by no means accurate, owing to the difficulty of obtaining precise information. Further and more satisfactory co-operation is required between State health authorities and the Public Health and Marine-Hospital Service. In a paper on this subject read by John W. Trask of the U. S. Public Health and Marine-Hospital Service, at the meeting of the American Public Health Association in October, 1909 (*American Journal of Public Hygiene,* February, 1910), the author expressed his belief that in 1908 there were probably more than 70,000 cases of smallpox. Now, in a highly civilized and enlightened country it is something of a public scandal that there should have been in the neighborhood of 70,000 cases of smallpox in one year. The situation, too, is aggravated when it is known that the disease can be virtually eradicated if proper measures are practised. Of course, vaccination will, in time, and in not a long period either, stamp out smallpox if the method is thoroughly enforced. This has been proved. Smallpox was eradicated from the German Army by systematic vaccination. It may be said, and with a considerable degree of truth, that means possible in an army are not available in an ordinary community. But as Trask points out, smallpox has been eradicated to all intents and purpose, from some of our States.

Perhaps the most convincing argument in recent times in favor of vaccination has been supplied in the Philippines. The Director of Health of the Philippines, in his annual report for the fiscal year 1907, says: "During the year there has been unquestionably less smallpox in the Philippines than has been the case for a great many years previous. In the provinces of Cavité, Balangas, Cebu, Bataan, La Union, Rizal, and La Laguna, where heretofore there have been more than 6,000 deaths annually from this one cause alone, it is most satisfactory to report that since the completion of the vaccination in the aforesaid provinces, more than a year ago, not a single death from smallpox has been reported." En passant, reference may be made to the prevalence of smallpox in certain parts of the province of Quebec. Dr. E. Pelletier, Secretary of the Quebec Provincial Board of Health, in the annual report of the board just issued draws attention to this prevalence and also to the fact that owing to the control of vaccination being in the hands of the municipalities, vaccination in Quebec is really optional and enforcement is practically a dead letter. There is no need to multiply proofs as to the efficacy of vaccination, the question is how to render it general throughout the country and thus to stay the spread of smallpox. Trask rightly shows that in order to eradicate a disease the first essential is an accurate knowlege of its distribution and prevalence; in other words, it is necessary to be supplied with accurate morbidity statistics. Without such statistics the Public Health and Marine-Hospital Service is fatally hampered in its endeavor to stamp out a disease or to use effectual preventive measures. Therefore, the statement can be made that in order to inaugurate and wage a successful campaign against smallpox, State and local health officers must cooperate loyally and earnestly with the service by providing it with reliable morbidity statistics.

Meningitis and Meningism.

With the introduction of lumbar puncture into the medical armamentarium the diagnosis of meningitis has become a much more definite procedure than it was a few years ago, the generally accepted opinion to-day being that an absolute diagnosis of any of the various forms of this disease without the identification of the causative microorganism in the intraspinal fluid is about as justifiable as calling a case measles without seeing either rash or Koplik's spots. The necessity of the bacteriological diagnosis is especially important in the light of the studies of Dupré and others of the French school who have shown that not at all infrequently the symptoms of acute meningitis including opisthotonus, Kernig's sign, and coma may appear when no actual involvement of the meninges has occurred. This class of cases which Dupré grouped as pseudomeningitis or meningism is familiar to all who come much in contact with sick children. It is especially common in association with otitis media, where it is supposed that the toxins diffuse through a developmental fissure in the temporal bone and cause meningeal irritation by direct contact. It is, however, also a frequent accompaniment of enteritis, pneumonia, and diphtheria, and as was pointed out by Porter in the *Archives of Pediatrics* for January, 1910, in an excellent résumé of the subject, in typhoid fever, rheumatism, and the exanthemata as well. In fact, in any febrile condition in a child, and more rarely in an adult also, either the fever itself or the action of

the toxins upon the meninges or spinal nerve roots may produce all the classical symptoms of meningitis, these disappearing immediately upon the subsidence of the fever, the crisis of the pneumonia, or the rupture of the ear drum. The first duty of the physician upon seeing a patient with symptoms of meningeal irritation is by a thorough and careful physical examination, including inspection of the ear drums, to exclude every possible cause of meningism, and the second is to do a lumbar puncture, and examine the fluid so obtained for pyogenic bacteria and the tubercle bacillus. Only in the case of a positive bacteriological finding is he justified in making a diagnosis of meningitis.

The Stools of the Newborn.

In the majority of the text-books on obstetrics and pediatrics, the statement is made that for three days the stools of the healthy newborn infant are dark brown in color, consisting of meconium, and that after the fourth day they are light yellow and of a homogeneous consistency. Such statements are usually taken as invariable rules by the physician, and more frequently by the nurse and the mother, and any variations therefrom are apt to produce consternation in the newly enlarged family and may even lead to the belief that the mother's milk is not all that it should be, and be used as an argument in favor of immediate weaning. The fallacy of such a deduction is emphasized in an article by Southworth in the March number of the *Archives of Pediatrics*. The author shows that the transition from meconium to a smooth yellow stool on the fourth day is the exception rather than the rule, and that in perfectly healthy and properly nourished infants the classical text-book stool may not make its appearance until the tenth day or even later. During this period the change is gradual, the first signs thereof often being the appearance of masses of yellow stools, so well covered with intestinal mucus and bile that they appear green or even brown. In such cases smoothing out the fecal masses will usually reveal the fact that the stool itself is normal and that digestion is progressing properly. The lesson to be drawn from this paper is that during the first two weeks of an infant's life one must be especially conservative in condemning a woman's milk on the evidence of the stool alone. If the child is gaining in weight, and in other ways appears to be healthy, the color of the stool, though possibly of value as indicating some minor changes in the hygiene of the mother and the child, should not be taken too seriously, and certainly should not lead the attending physician to advocate the weaning of the baby.

Muscular Spasms in Men Exposed to High Temperatures.

Asst.-Surgeon M. E. Higgins, U. S. Navy, writes in the United States Naval Bulletin, April, 1910, on a disorder due to exposure to intense heat. The cases reported have occurred usually among men exposed to high temperatures in foundries and rolling mills and the affections, while a type of heat exhaustion, differ d materially from the condition generally understood by the term.

Higgins states that the condition is very frequently observed among men working in the firerooms of naval and merchant vessels, and records a more or less typical case. The symptoms are, as a rule, tonic muscular spasms, particularly of the flexors associated with fibrillary twitching of the affected muscles, very profuse perspiration was a concomitant feature in the case recorded, and when urine was passed, which was not until the morning following the attack, albumin and casts were voided. This is, however, not a usual occurrence, nor is profuse perspiration at the time of the seizure. The author, while admitting that high temperature is a predisposing factor, is of the opinion that the determining cause is individual susceptibility. Workers in firerooms perspire profusely, and to make up for the loss of fluids consume large quantities of water. Little or no urine is excreted and nearly all the work of elimination is thrown upon the skin. If the function of the skin is impaired or the gastrointestinal canal fails to absorb sufficient fluid to maintain a proper balance, there will probably supervene a condition not essentially different from the uremic state. Clinically, the disorder is one of motor irritation. The cramps of cholera and the convulsions of nephritis are, in a measure, analagous conditions. As to treatment, the indications are to supply fluid, secure elimination, and relieve the pain. Saline solution, either by rectum or under the skin, meets the first two, and a full dose of morphine lessens the pain. If the patient is not perspiring a hot pack or a hot bath is indicated.

News of the Week.

Measles on Shipboard.—The steamship *Carpathia* arrived at Quarantine in New York recently with 40 of the 325 children in the steerage suffering from measles.

To Purify Lake Michigan.—On May 12 the U. S. Senate passed a bill to prohibit the dumping of refuse in Lake Michigan in the vicinity of Chicago.

Smallpox in Philadelphia.—A number of cases of smallpox have been discovered in Philadelphia and in other parts of the State of Pennsylvania and several deaths have resulted. Vaccination has been undertaken on an extensive scale. One of the victims was a policeman, who contracted the disease while guarding a quarantined house.

A "Medical Mill" in Chicago.—Three physicians of Chicago were arrested by federal officers on May 13 charged with selling medical diplomas from the "Crescent Medical University" at the price of $40 each. The technical charge was using the mails for defraud.

Optician Fined.—A clerk in an optical company in New York was fined $500 recently for practising medicine without a license. The defendant had prescribed some eye drops to a man who had gotten dust in his eyes, and it was claimed that as a result the sight of the eyes was destroyed.

Arms Valued at $41,000.—In the Supreme Court at Syracuse recently a man of 22 was awarded $41,000 damages for an accident which resulted in the loss of both arms.

Jefferson Medical College of Philadelphia.—Mrs. Marie Gross Horwitz has made a gift of $60,000 for the foundation of the Samuel D. Gross Professorship of Surgery in honor of her father, who was professor of surgery in Jefferson Medical College from 1856 to 1884.

Contagious Hospital for New Haven.—According to an agreement recently reached between the New Haven Hospital and the city authorities, it is

probable that the latter will aid the former in the erection of a much needed contagious disease pavilion.

Psychiatric Institute on Ward's Island.—Governor Hughes on May 12 signed Assemblyman Ward's bill creating the Psychiatric Institute on Ward's Island to be maintained as a part of the Manhattan State Hospital.

New Hospital for Stafford Springs, Conn.—Plans are being prepared for the erection by Mr. Cyril Johnson of a hospital for Stafford Springs.

Fire in Hospital.—A fire in the chemical laboratories of the Medico-Chirurgical College at Philadelphia on May 6 did damage to the amount of $25,000 to the building and of $50,000 to equipment, apparatus, etc.

Charitable Bequests.—By the will of the late John H. Converse of Philadelphia the sum of $25,000 is bequeathed to the Presbyterian Hospital and a like sum to the Eliza Cathcart Home for Incurables at Devon.

District Nurses' Home in Brooklyn.—Mrs. Alfred T. White, a director of the Brooklyn Bureau of Charities, has presented the three-story house at 78 Schermerhorn street to the bureau on condition that it be used only for the district nursing work.

Miss Florence Nightingale, the nurse who first won fame in the Crimean War and has since been prominent as an author on army nursing, celebrated her ninetieth birthday on May 12.

The Arkansas Medical Society met at Little Rock, May 6, 1910. The election of officers was as follows: *President,* Dr. R. C. Dorr of Batesville; *Secretary,* Dr. Morgan Smith of Little Rock. The meeting in 1911 will be held at Fort Smith.

The Oklahoma Homeopathic Medical Society met in Oklahoma City, May 4, 1910. Officers were elected as follows: *Honorary President,* Dr. J. Sensley of Oklahoma City; *President,* Dr. S. C. Whitcomb of Hastings; *Vice-President,* Dr. L. S. Cunningham of Tulsa; *Secretary-Treasurer,* Dr. W. L. Bonnell.

The Connecticut River Valley Medical Association held its annual meeting at Bellows Falls, Vt., May 3 and elected the following officers: *President,* Dr. F. L. Osgood of Townshend; *Vice-President,* Dr. J. J. Osterhaut of Keene; *Secretary and Treasurer,* Dr. J. Sutcliffe Hill of Bellows Falls.

The Franklin (Mass.) District Medical Society held its annual meeting at Greenfield, May 10, and elected officers as follows: *President,* Dr. C. L. Upton of Shelburne Falls; *Vice-President,* Dr. L. A. Newton; *Secretary and Treasurer,* Dr. H. N. Howe of Greenfield.

The Claiborne Parish (La.) Medical Society held a meeting in Athens April 19, 1910. The following officers were reelected: *President,* Dr. J. W. Day of Homer; *Vice-Presidents,* Dr. P. Gibson of Homer, Dr. Lee Waller of Haynesville, and Dr. Simpson of Athens; *Secretary-Treasurer,* Dr. W. L. Stone of Homer.

The Pike County (Ill.) Medical Society has elected the following officers: *President,* Dr. G. U. McComas of New Canton; *Vice-President,* Dr. C. E. Beavers of Barry; *Secretary,* Dr. H. T. Duffield of Pittsfield.

The late Dr. Augustin H. Goelet.—At a regular meeting of the Clinical Society of the New York School of Clinical Medicine, held on May 3, 1910, the following resolutions were adopted: *Whereas:* We have learned with deep sorrow of the sudden and untimely death of our esteemed associate and colleague, Dr. Augustin H. Goelet, who for more than twenty years had given his best efforts to this institution, and *Whereas,* Professor Goelet was a man of high honors and integrity, beloved and respected by all who knew him for his geniality, his sincerity, and his many scholarly attainments, therefore be it *Resolved,* That we now record this our last sad tribute to his memory, and join in expressing to his bereaved family our sincerest sympathies, and be it further *Resolved,* That these resolutions be spread on the minutes of this society, and that a copy thereof be transmitted to his family and to the medical press as a token of our respect and as reverence to his memory. Abr. L. Wolbarst, M.D., Edward L. Kellogg, M.D., Theodorus Bailey, M.D., Committee.

Obituary Notes.—Dr. George H. Kenyon of Providence, R. I., died at his home May 7, 1910, aged 65 years. He was a graduate of Brown University in 1864 and the medical department of the University of Vermont in 1866. Dr. Kenyon was a veteran of the Civil War and for 32 years was connected with the Rhode Island militia, of which he finally became Surgeon-General with the rank of Brigadier-General. He was at one time president of the Providence Medical Society, and treasurer of the Rhode Island Medical Society, and was a member of the American Medical Association.

Dr. Robert Martin of Milwaukee, Wis., died at his home May 2, 1910, aged 69 years. He was a graduate of the Starling Medical College in 1875. He was at one time Health Commissioner of Milwaukee.

Dr. Joseph Brackbill died at Reading, Pa., on May 6 at the age of 64 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1839.

Dr. Louis G. Bauer died at Philadelphia on May 6 at the age of 64 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1872. He was a member of the Philadelphia County Medical Society, the Medical Society of the State of Pennsylvania, and the American Medical Association.

Dr. George Arnold Bellows of Waterloo, N. Y., died at his home May 10, 1910, aged 54 years. He was a graduate of the Detroit Medical College in 1881. He was a member of the Seneca County Medical Society, the Medical Society of the State of New York, and the American Medical Association. Dr. Bellows has held the position of Health Officer, Coroner, County Physician, and U. S. Pension Examiner.

Dr. Tomlinson Fort Brewster of Atlanta, Ga., died in the Grady Hospital May 1, 1910. He was a graduate of the Jefferson Medical College and for fourteen years was superintendent of the Grady Hospital.

Dr. Robert T. Gwin of McKenzie, Tenn., died at his home April 29, 1910, aged 80 years. He was a graduate of the Jefferson Medical College in 1856.

Dr. Samuel T. Haffner of Frederick, Md., died at his home May 6, 1910, aged 61 years. He was a graduate of the College of Physicians and Surgeons of Baltimore in 1874. He was physician to the Montevue Hospital, at one time County Health Officer, and was a member of the Frederick County Medical Society, the Medical and Chirurgical Faculty of Maryland, and the American Medical Association.

Dr. Cynthia Maria Nordstrom of Malden, Mass., died at her home May 6, 1910, aged 77 years. She was a graduate of the Boston University School of Medicine in 1883, and was secretary of the medical board of the Malden Hospital.

Dr. Alonzo E. Robertson of Mason City, Neb., died May 3, aged 38 years. He was a graduate of the University of Michigan and of the Rush Medical College in 1893.

Dr. Marshall P. Robinson of Lexington, Ky., died May 6, 1910, aged 63 years. He was a graduate of the Eclectic Medical Institute of Cincinnati in 1876.

Dr. Charles Ward Thorpe, U. S. Army, died at his family home in Nicholasville, Mich., April 16, 1910. He was a graduate of the Gross Medical College in 1896. He entered the army in 1903.

Dr. Samuel Charles Weeks of New Orleans died April 28, aged 43 years. He was a graduate of the medical department of Tulane University in 1893.

Dr. Barton H. Potts of Philadelphia died on May 8 at the age of 41 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1890, and he was Chief of the Nose and Throat Division of the German Hospital, as well as Laryngologist to the Children's Hospital.

Dr. R. B. Wilson, formerly of Tower City, died at Ardmore, Pa., at the age of 80 years. He had been engaged in the practice of medicine for almost 50 years.

Dr. S. Beach Jones of New York died at his home May 13, 1910. He was a graduate of the College of Physicians and Surgeons of New York in 1872, and was a member of the New York Academy of Medicine, the Medical Society of the County of New York, and the Medical Society of the State of New York.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

TUBERCULOSIS WITH RESEARCH—WOMEN DOCTORS AT MANCHESTER INFIRMARY—ORTHOPEDIC HOSPITAL—DENTAL DISPENSARIES—MORTUARY FOR CITY CORONER—NURSES AND MIDWIVES: PROPOSED DIPLOMA, CONFERENCE, AND EXHIBITION—BAZAARS—WOMEN L.R.C.P.—OBITUARY.

London, April 29, 1910.

In this year's report of the Medical Officer of the Local Government Board there is an account by Professor Delépine of the important researches which he has made as to tuberculous milk. His experiments convince him that by means of subcutaneous inoculation of guinea pigs the degree of infectiveness (for those animals) can be estimated of the products of inoculation. He uses the sediment of milk as a test for tubercle bacilli. Of samples of milk from farms supplying Manchester nearly 9 per cent. contained bacilli to an extent likely to produce infection. On 75 per cent. of these farms tuberculous lesions of the udder were found on one or more of the cows, and Professor Delépine regards the diseased udder as the principal source of the bacilli. Many cows with early tuberculosis of the udder yield large quantities of milk, and if that should be mixed with the milk of the whole herd, as it usually is, the danger of infection must be enormously widespread. One part of tuberculous milk was found capable of infecting 100,000 parts of pure milk. The danger of a single diseased animal in a herd is therefore extreme, and as it is not easy to detect the disease in the early stage bacteriological examination of the milk from the suspected udder is of the greatest importance. When this discovers bacilli in a mixed milk, or when inoculation of a guinea pig indicates infectiveness, a skilled veterinary surgeon will generally be able to discover the diseased cow of the herd.

In view of these facts it is satisfactory that a milk and dairies bill has been read a first time in the House of Commons amid the cheers of all parties, being considered noncontroversial, so that there is some hope of effectual regulation being some day brought into operation.

The Manchester Royal Infirmary has refused to admit women doctors to its resident appointments. The decision led to a discussion in "another place," to wit, the local Medicoethical Society, when Sir William Sinclair presided. The case for women was stated by Dr. Margaret M. Smith, inspector of midwives in Manchester, who argued that women's college records were as good as men's—often better; that as to junior posts neither sex had any experience, but women were unfairly handicapped for senior posts; that for character and physical capacity there was no difference; as to the attendance of women on men being shocking to their modesty, the reverse argument was just as good. As women doctors had come to stay, it was only right they should have every opportunity for perfecting their education.

Dr. Margaret Smith's plea, to the surprise of many of her supporters, seemed to be generally accepted by the meeting. At any rate, no one rose to reply, and after one or two had spoken in support the president called on some members by name to state the case on the other side. They all, however, excused themselves and he himself confessed that he agreed with Dr. M. Smith. Among those who supported her one speaker had hinted that women were perhaps more neurotic than men, but another declared he had found this element just as prominent and quite as common in men. Another admitted that in slight emergencies women did not show up well, but when the greatest courage was needed they were equal to men. In the end it was agreed *nem. con.* that the claim for admittance to resident offices was not to be rejected.

The Lord Mayor, Lady Mayoress, and the Sheriffs last Friday paid a visit in state to the Royal National Orthopedic Hospital, which is now the only one of its kind in London, the three which existed having amalgamated. The new building, you may remember, was opened by the King and Queen last year and represents the latest advances in the specialty. Unfortunately, there is still a debt of about £17,000, to aid which this visit was made, and many eminent supporters were present. The Earl of Denbigh, who is the chairman of the institution, made a practical appeal to those present. Taking a little deformed boy from a nurse, he showed that he could not stand, but, thanks to surgery, he expected he would soon be able to run about like other children, as many they had cured could do. They could take in 200 at a time if the money were forthcoming, and 400 cripples were waiting for admission, but they had only enough money to fill 130 beds.

The Lord Mayor said English people gave freely to help in all foreign disasters and should not forget such institutions as this at home.

There is some stir among dentists, and even doctors, too, by an alleged promise of £200,000 offered on loan at 5 per cent. to establish a number of dental surgeries where treatment could be obtained at minimum prices by those who could only contribute small sums. Of course, only qualified dental surgeons are to be eligible for the staffs, but it seems doubtful whether many will be ready to accept the appointments at first. At present the scheme is only being talked about and definite information is not forthcoming.

The Coroner for the city reports to the Common Council that the apparatus for the preservation of bodies by formalin has proved of great service. One man was found drowned and the body was stored for four months awaiting identification and remained free from decomposition. This is the first installation set up and it is to be hoped other health authorities will follow the example. Coroners and their juries will be sure to approve and may well demand that the act authorizing such plans be put in force.

There is a bill in the House of Lords for further amendment of the Midwives Act. One clause will be satisfactory to medical men, as it provides for payment to be made in cases in which the midwives have summoned assistance, as they are required to do by the act. Hitherto no provision has been made and the doctor called in has usually found that there was no prospect of remuneration. If he had refused to go, of course he would have had abundant abuse from his neighbors.

At a meeting of graduates of the University of Wales it was proposed to form a faculty to confer a degree or a diploma for nursing. There were medical graduates present who not only professed sympathy with the proposal, but were prepared to support it, though others said the matter concerned clinical practice rather than university. We have already a multiplicity of diplomas, which is generally thought to be disadvantageous.

Another move of the nurses is an annual conference and exhibition, the third of which is being held in London. It was opened by H. R. H. Princess Christian of Schleswig-Holstein on Wednesday and closes to-morrow. The object is to make nurses and midwives acquainted with all inventions and improvements produced and further to give them the opportunity of hearing lectures and taking part in discussions of subjects affecting their work. There is a large show of surgical, chemical, and pharmaceutical preparations, patent foods, sanitary appliances, etc. In another apartment the conferences are held under the presidency of Dr. F. W. Champneys. Not a few doctors look upon these doings with disapproval, but they have allowed so many encroachments on their domain without protest that it is idle to regret the results.

Another bazaar is also being held. This is on behalf of Fairlight Sanatorium, Hastings, and was opened yesterday by Lady Troubridge, who gave a short address, declaring that since science pronounced that consumption was curable the element of hope was not excluded. The bazaar was organized by one of the small hospitals for this disease (the Margaret street one). A number of ladies are holding the stalls and musical selections are being given afternoon and evening.

Yesterday at the Royal College of Physicians 90 new licentiates were admitted, among them the first woman. The ladies' room is Dossibai Rustomje Cowasji Patell.

Dr. Charles Plowright died on Tuesday in his sixty-second year. He was Hunterian professor of comparative anatomy and physiology, 1890-1894, and was made honorary Fellow of the Royal College of Surgeons during his professorship. He was president of the British and the French Mycological Societies and correspondent of other foreign societies. He had practised at King's Lynn and was for thirty-two years Medical Officer of Health for the District Council. He was also Justice of the Peace for the county (Norfolk) and a member of the Lunacy Commission. His work on the fungi is a standard in most countries. He was also deeply interested in folk-lore and his opinions upon the subject greatly valued.

Dr. Stewart Lockie, consulting physician to the Cumberland Infirmary, has died at the age of seventy-four. While physician to the infirmary it was mainly to his influence and energy that it was greatly enlarged and its management improved. The committee on the 20th inst. passed a resolution expressing their appreciation of his eminent services extending over thirty years. He was elected vice-president in 1901, in which year he retired from practice and was presented by his friends and professional brethren with his portrait, accompanied by a cheque and piece of plate.

Lieutenant-Colonel Sparkes, late of the R. A. M. C., who has died at Aldershot, was born in 1859, became surgeon in 1885, surgeon-major 1897, lieutenant-colonel 1905. He served with the Sikkim expedition and received a medal with clasp. In the South African war he took part in the operations in the Transvaal, in the Orange River Colony, and Cape Colony, and was awarded the Queen's medal with four clasps.

Dr. Herbert Nelson Cappe, senior medical officer of the Surrey County Asylum, has died at the age of forty-four. He qualified at the two colleges in 1888.

Dr. Alfred L. Griffith has died at the age of seventy-three. He qualified in 1859-1860 and proceeded to M.D. St. Andrews in 1862. He described a successful case of intussusception treated by the inflation of air in the *Lancet*, 1885.

Care of Tuberculosis in Denmark.—Under legislation enacted in 1905 the Danish Government pays three-fourths of the expenses of all poor persons who desire to be treated in tuberculosis sanatoria. When the hospitals under construction are completed, Denmark will have one bed in tuberculosis hospitals or sanatoria for every 1,200 inhabitants, a fact which will mean that the length of treatment can be considerably extended. In the United States there is one bed for every 4,500 inhabitants.

HEART SUTURE—ANESTHESIA OF THE LUNG—FERMENTS IN TUBERCULOUS ABSCESSES—URIC ACID METABOLISM—COXA VERA—URINARY FINDINGS IN CARCINOMA—THE INHERITANCE OF ACQUIRED CHARACTERISTICS.

VIENNA, March 15, 1910.

OSKAR FÖDERL has performed an operation for suture of the heart in a case of a bullet wound. The wound of entrance was found in the left ventricle; no wound of exit could be discovered; the pleura in the neighborhood was injured. Blood coagulum was removed from the pericardium and a liter of blood taken from the pleural cavity. All of the wounds were stitched up. The pneumothorax caused by opening the pleura was overcome by pressing the anesthetic cone tightly upon the face, so that it was air tight; the air pressure in it and also in the lungs was raised, and the air driven out of the pleural cavity. The patient is quite well, though the projectile is still in the heart in the neighborhood of the apex.

N. Chilaidit has had under observation a ten-year-old boy with the following findings: The left half of the thorax is collapsed, remains quiet during breathing, and shows a well developed venous plexus. There is dullness over the entire left lung; the normal right lung extends two fingers' breadths to the left of the midline. Auscultation of the left side shows distant, here and there high pitched, breath sounds. The apex beat is to be felt two fingers' breadths outside of the left mammary line, and besides this there is a second pulsating center in the second left intercostal space in the mammary line, where a blowing systolic murmur and a diastolic shock can be heard. Otherwise the sounds are clear. In the *x*-ray picture the whole left side of the thorax is dark, this increasing laterally. The retraction and dullness of the left side of the thorax were noted immediately following birth. The child also had the following malformations: Hypospadia, hypoplasia of the genitals, shortening and thinning of the left arm, atrophy of the left thumb, and a suggestion of scaphocephalia. The child was born with atresia ani, which was corrected by operation. The condition is apparently a fetal anesthesia of the left lung.

Dr. Schüller has addressed the Society of Physicians upon his researches in the treatment of tuberculous processes with ferments. Tuberculous pus is very poor in ferments, as it contains but few polymorphonuclear leucocytes, which are the ferment carriers. The method of treatment consists, after puncture of the abscess and withdrawal of the pus, in injecting a 1 per cent. sterile trypsin solution into the cavity. The trypsin dissolves the proteins of the pus and stimulates an invasion of leucocytes. Schüller has punctured tuberculous abscesses of the soft parts daily and injected trypsin every second day. Usually three to four injections sufficed for a cure; in a few cases only one was needed. Under the influence of the injections the pus changed its consistence, the secretion decreased, and granulations developed. In tuberculous abscesses of the soft parts the results were very good, as they were in serous inflammations, as bursitis, hydrops genu, and hydrocele. Tuberculous arthritis cannot be cured by this method.

Professor Biernacki has carried on an investigation into the relation between general and urinary metabolism—excretion of uric acid. He studied the influence of feeding of large amounts of fat and carbohydrates upon the uric acid secretion in dogs, and showed that the quantity of uric acid at times remained unchanged, at times was increased, and at times decreased. The latter occurred when the fat acted in saving the protein. The variations in the nitrogen metabolism produced by feeding fat and sugar caused a diminution in the uric acid coefficient and a relative and absolute increase in the purin bodies. Biernacki considers that a decrease in the amount of uric acid in the urine does not signify a retention of uric acid in the body, but a weakened purin metabolism. Such a theory would explain the clinical decrease of uric acid in the urine associated with a full purin diet, as meat diet. The general picture of the metabolic changes found in the uric acid diathesis resembles closely the conditions observed in his researches. Professor Biernacki believes that therapeutically an overfeeding of the patient is to be avoided; that the uric acid content of the blood cannot be studied, for a large amount of

blood (circa. 200 c.c.) is needed, and the withdrawal of even 50 c.c. of blood would greatly change the significance of the experiment, and that finally he had seen clinically not a single patient suffering from renal calculi who was not the subject of uric acid diathesis.

Professor Lorenz presented at the Society of Physicians a patient who one and a half years before had received the bloodless treatment for coxa vera. As the onset of the disease antedated the treatment by more than a year, radical treatment could not come into consideration. The reposition of the dislocated head was also ruled out. Lorenz, in this as in all similar cases, had used the procedure, the so-called inversion, for which, in the interest of all sufferers from coxa vera, he asked a greater recognition and appreciation. By inversion he understood the changing of a given habitual position of the joint into a position of the opposite kind, an overcorrection of an existing contracture by intraarticular reduction. The inversion method differed from the usual reduction, in that the hypercorrection was of a much higher grade, so that the joint was forced into a new permanent position and secured there by careful measures. The eighteen-year-old patient showed a mobility of the operated hip joint far beyond the normal physiological limits, in the case of abduction and hyperextension, while the rotation was normal. Functionally one could call the case a perfect recovery, for the patient not only walked without a limp, but had normal endurance. She could hop without effort on the affected leg and could elevate the well half of the pelvis high up. In the light of these results, Lorenz considered that treatment by resection was unjustified. The *x*-ray picture showed the head of the bone to be quite markedly dislocated. It was evident that such a dislocation, provided it was not of such an exceptionally high grade, might occur with normal function if the joint had complete mobility in respect to abduction and extension. This and earlier observations had induced him to treat systematically, that is by inversion, coxa vera from congenital ricketts and from arthritis deformans juvenilis also. The existing contracture caused a much greater interference with the functional activity of the extremity than the often insignificant deforming of the head of the femur.

Docent Hans Saloman and Paul Sax have reported a new urinary finding in carcinoma. Of 103 noncancerous patients examined, 100 cases showed an oxyproteinic acid value at the highest not over 2 per cent. of the total nitrogen. On the other hand, of 40 cases of cancer examined, 31 showed an oxyproteinic acid content of 2.5 to 3.5 per cent., 5 cases from 2.2 to 2.5 per cent. and only 4 cases with a content less than 2 per cent. of the total nitrogen. The accuracy of the diagnosis of the cancer cases was usually determined by operation or autopsy. Of the 4 cases with a low oxyproteinic acid content 2 were clinically doubtful cases of cancer. After it was demonstrated that an increase of oxyproteinic acid excretion occurred in cancer, the urine of a series of pregnant women were examined, on account of the often observed parallelism between cancer and embryonic tissue. In 15 women in late pregnancy 14 had an oxyproteinic acid excretion in the neighborhood of 3 per cent. and one of 2.3 per cent.; one woman in the second month of pregnancy excreted 2.4 per cent. of her total nitrogen in the form of oxyproteinic acid. The theoretic value of these researches was that for the first time a suggestively specific metabolic change was found in cancer. This occurred, with the exception of one case of liver disease, equally strongly in pregnancy. Practically the increase in oxyproteinic acid excretion might be considered as a symptom of cancer. If this symptom was found, a diagnosis of cancer received a powerful confirmation. Further testing of the specificity of the symptom, its value for the early diagnosis of cancer, and perhaps for pregnancy also, needed further investigation in order to establish it.

The inheritance of acquired characteristics was the subject of an address in the Royal and Imperial Society for Physicians by Dr. Paul Kammerer of the Biological Institute. It is no longer open to doubt that characteristics may be changed by associations and that the changes may be transmitted to the offspring. There is, therefore, an inheritance of acquired characteristics, and the one point upon which opinions still differ is in comparison to this great truth, almost unworthy of mention, namely: whether the influence of the outer world when it produces inherited characteristics takes the direct physical road to the germ center, or the indirect physiological way via various bodily changes to the germ. Are the organs of generation influenced immediately by the external factors, or are they changed through the mediation of stimuli transmitted from the surface of the body? This is the question to which he hopes to offer an answer. From exact observations of careful breeding various things point towards the first method of acquired characteristics acting upon the germ, and at least no sufficient reason has been produced to deny that this is the sole method. The lecturer summarized the present knowledge of the subject as follows: In one or more generations B a change is brought about which did not exist in the previous generation A or in the generation B at the beginning of the experiment. From the changed generation B the next generation C is then produced, but this is brought about without any further action of the artificially produced factors, under a reversion to the normal life of the earlier generation. If in spite of this there appears in C the acquired characteristic changes seen in B, the breeding experiments have demonstrated the congenital transmission. Proof of the inheritance of acquired characteristics which fulfill such requirements are present in the sphere of zoology, a great many of which have been established by the experiments of the speaker.

SANITARY REFORMS IN MONTREAL—HIGH DEATH RATE FROM INFANT MORTALITY AND TUBERCULOSIS IN THE PROVINCE OF QUEBEC—ALEXANDRA HOSPITAL FOR INFECTIVE DISEASES, MONTREAL—THE COLD STORAGE OF FOOD AND PUBLIC HEALTH IN CANADA—EMPLOYMENT OF WOMEN AND CHILDREN IN FACTORIES IN THE PROVINCE OF QUEBEC—RESIGNATION OF DR. SHEARD FROM THE POSITION OF MEDICAL OFFICER OF HEALTH FOR TORONTO—BILL INTRODUCED INTO ONTARIO LEGISLATURE TO ALLOW THE STERILIZATION OF CRIMINALS, IDIOTS, AND IMBECILES—AMENDMENTS INTRODUCED INTO THE ONTARIO MEDICAL COUNCIL—OSTEOPATH BILL FOR ONTARIO—DOMINION LEGISLATION—COST TO THE STATE OF PUBLIC INSTITUTIONS IN ONTARIO—NEW BUILDING FOR TORONTO ACADEMY OF MEDICINE—NEW BUILDINGS IN CONNECTION WITH TORONTO UNIVERSITY.

MONTREAL, April 20, 1910.

A REFORM government is in power in Montreal, and the old adage that new brooms sweep clean appears as if it were about to be realized in this city. It must be said that there is room for great improvement, for in most respects Montreal is backward from a public health point of view. In the first instance, the sewage system is antiquated and insufficient for the needs of the inhabitants. There are districts in which a sewage system is nonexistent. Many of the city sewers date from 1844, and the city has spread so rapidly that many of the trunk sewers are inadequate. Further, half of the area within the city limits is over the dividing line between the rivers St. Lawrence and the river known as the Back River, so that all the drainage of this area must be carried to the Back River. The territory includes five large city wards and two-thirds of another, all of which have to be provided with drainage and sewage facilities. One large sewer has been constructed in these districts and a sewage farm of twenty acres on the filtration system has been laid out, but, of course, only a beginning has as yet been made. While the sewerage system is out of date, the water supply is open to grave suspicion. As mentioned in a former letter, the frequent outbreaks of typhoid fever which occur in Montreal are attributed by the best authorities mainly to a polluted water supply. A commission appointed by the two universities of Montreal have come recently to a similar conclusion, and have stated in emphatic terms that until measures have been taken to thoroughly safeguard the water supply, typhoid fever will be more or less prevalent. The new city government and the more intelligent of the citizens recognize the force of these statements, and steps are being taken to introduce the necessary innovations. The city has practically resolved to install a filtration plant, and the Montreal Water and Power Company, which supplies about 170,000 of the inhabitants, have drawn up plans for the installation of a mechanical filtration plant. In the meantime both the city and the private company are purifying their water supplies by the agency of common bleaching powder, with, it is said, great success. According to existing views, Montreal is to undergo a sanitary transformation, her streets are to be solidly and evenly paved, drainage and sewerage is to be rendered adequate and effective, and last, but not least, her water supply is to be freed from contamination.

These reforms when carried out should result in a very considerable decrease of sickness and death. In a previous letter comment was made on the high rate of infant mortality which prevailed in Ontario, and especially in Toronto. Recently the annual report of the Board of Health of the Province of Quebec has been published, and reveals a similar condition of affairs in this province. During the year covered by the report, from June 31, 1908, to June 31, 1909, 34,247 deaths occurred in the province. Of the number 12,842 were infants under the age of one year and 3,522 were infants from one to five years of age. Thus 16,364 deaths out of a total of 34,247 occurred in children under five years of age, that is to say, the appalling proposition of 477 deaths under five years of age in 1,000, or nearly half. Tuberculosis is a very fatal disease in Quebec. During eleven years, from 1896 to 1906, the death rate for 100,000 inhabitants of the province was as follows: For urban districts, 289.85; for rural districts, 163.07; for urban and rural districts combined, 192.0. Tuberculosis, indeed, has caused more deaths in the period mentioned than all the other contagious diseases together. The reason for this predisposition to consumption among the French-Canadians is ascribed by some as due to their habit of shutting out the air from their homes. The French-Canadian in town and country appears to have a perfect horror of fresh air in the house.

The annual meeting of the governors of the Alexandra Hospital for Infectious Diseases, Montreal, was held under the presidency of Dr. Roddick on April 14. The year's work of the hospital has been highly successful, but Dr. Roddick in his report emphasized the lack of accommodation for mixed infectious cases. The same difficulties prevail in regard to provision for patients suffering from erysipelas. Moreover, the accommodation for nurses is insufficient, and it would seem that the erection of a nurses' home is imperative.

An important decision relating to public health has just been delivered in Montreal. The cold storage question is in Canada almost as acute as in the United States. It is alleged that the large meat packers, in order to keep up the prices of foodstuffs, retain these in cold storage frequently for such a length of time that they become to a certain extent a menace to health. The Civic Law Department has handed in an opinion to the Board of Control of Montreal that the Provincial Board of Health has powers to interfere with cold storage warehouses if it is thought that these establishments are storing meat so long that it becomes unfit for human consumption. It is expected that the City of Montreal will request the Provincial Board of Health to take measures rendering it illegal to keep foodstuffs in cold storage beyond a given period.

Up to the present time the laws of the Province of Quebec relating to the employment of women and children in factories have been very lax. Last week, however, the Federal Government enacted that women and children should not be permitted to work in factories for longer than fifty-eight hours in the week.

Dr. Chas. Sheard, who has been for eighteen years medical officer of health for Toronto, has resigned. Dr. Sheard was a man of much energy, of independent character, and of original views. He was a capable medical officer of health, who held to what he thought was right with great tenacity.

During the present session of the Ontario Legislature several bills of interest to medical men have been introduced. Among these was a bill introduced by Dr. Forbes Godfrey. This bill was somewhat similar to that of Indiana for the sterilization of criminals, idiots, and imbeciles. The premier Sir James Whitney spoke very strongly against the bill, chiefly basing his arguments on the fact that it would place too great powers in the hands of medical men.

Amendments were proposed to be introduced into the Ontario Medical Council. The amendment of greatest importance proposed was that as soon as any registered practitioner is convicted in any court of Ontario of a criminal offence his name shall be automatically removed from the register. Another amendment was to the effect that the executive committee may now institute inquiry in alleged cases of infamous conduct. Formerly Council ordered investigation and nothing could be done for a year.

An osteopath bill was introduced into the Ontario Legislature with the hope of establishing a legal and professional status for this class in the province. The bill asked for power to establish a college and to provide a curriculum of studies, to set examinations, and to grant diplomas to practise osteopathy. To show the cunning methods of the framers of the bill, at the end of one section it was stated that osteopaths should not be allowed to prescribe medicine to be used externally or internally, except anesthetics, antiseptics, and antidotes. These cover a fairly large field, and exhibit plainly that the object is to get in the small end of the wedge. If the osteopaths are given a legal status they will be able to practise medicine and surgery to the fullest extent on equal terms with the regular medical profession. The matter, so far as the Province of Ontario is concerned, is laid over, to come up next session.

Dominion legislation has been shelved again. Quebec stands in the way. She wishes to raise a very high fence against outside competition, or rather against competition from any part of the Dominion. There are at the present time signs of partial reciprocity. Two or more of the provinces have agreed upon a common standard—Manitoba, Saskatchewan, Alberta, and British Columbia have settled upon a base of interprovincial reciprocity.

Public institutions for the care and treatment of the sick and injured in Ontario have received during the past year from the State $1,219,000.

The Academy of Medicine of Toronto is to have a fine new home. From $25,000 to $30,000 is to be expended on a new building on a new site in Queen's Park.

The managers of the Massey estate intend to build as a memorial to the late Hart A. Massey a magnificent series of buildings for the use and amusement of the Toronto University students.

Progress of Medical Science.

Boston Medical and Surgical Journal, May 5, 1910.

Intestinal Perforation of Unusual Etiology.—H. G. Giddings gives the history of a farmer's boy who fell on the point of a pitchfork which entered the rectum for about three inches. There was considerable pain, slight bleeding, and a moderate tenesmus when the bowels moved, but no evidences of serious injury. The accident happened in the forenoon and the boy worked through the rest of the day. Next day the symptoms grew more pronounced and by night a diagnosis of ruptured appendix was made. Operation was determined to be the only rational procedure. On opening the abdomen the operator found a quantity of turbid fecal stained matter but no perforation in the appendix, but in the posterior wall of the cecum rather toward the outer side at a point about three-quarters of an inch proximal to the attachment of the appendix, was a perforation a little larger than a slate pencil. The author's theory as to the cause of the perforation is that when the pitchfork entered the rectum it brought about, probably through a quick dilatation of the colon by the contained gases a partial rent in the gut which subsequently being so near the appendix simulated appendicitis and later, undoubtedly on the day following the injury this partial rent became complete. It was closed with a purse-string and two Lembert sutures and the belly was washed out with a saline solution, about a quart being left inside. The wound was closed after the insertion of one gauze drain down to the pelvis. The patient's condition was very unpromising but recovery was complete.

Imperforate Hymen.—F. W. Johnson says that this condition is a rare one and before the days of asepsis almost all cases operated on died. Infection undoubtedly took place through the walls deprived of their epithelial covering by long maceration in the retained fluid, of the vaginal, uterine, and tubal cavities. He then reports the case of a girl of 18 years, of a phthisical family history, who entered the hospital February, 1910. She had not only never been unwell as far as the appearance of blood externally, but she had never had any symptoms which would indicate that menstruation had been established. Her general health was excellent. On examination by the rectum, assisted by pressure on the abdomen, a soft, semi-fluctuating mass was felt occupying the position of the vagina. The uterus was pushed up into the abdominal cavity and was on top, so to speak, of this mass. With the actual cautery an opening was burned through the septum where the hymen should have been and 12 ounces of thick tarry material were excavated. The vagina was then thoroughly washed out with sterile water and a sterile T bandage was applied. Sterile douches were given twice a day as long as there was any colored discharge. The septum was one-half inch in thickness and two and a half days after the operation menstruation occurred. The flow lasted four days and was normal in every respect. On leaving the hospital the vagina easily admitted the index finger.

Exophthalmic Goiter.—W. H. Robey, Jr., has had a personal experience of sixteen cases during the last year and gives detailed histories of seven interesting ones. He says that any case which has tachycardia and extreme nervousness should arouse a suspicion of this malady. The size of the gland, however, is no guide to the course of the disease nor to the degree of toxemia. Medical treatment should precede surgery, although in Germany operation is a first resort. The physician should not allow his patient to grow worse nor stand still in a condition of invalidism without the advice of an experienced surgeon and operator. It is unsafe to allow an exophthalmic goiter with distressing symptoms to continue without improvement because the toxemia sometimes exerts a sudden and alarming influence on the heart. Patients with a well-developed case of this disease do not stand ordinary intercurrent infections which would hardly trouble a normal individual. Surgery is not all that can be desired in this affection, for besides reducing the gland we must know how to limit its secretion. It does, however, give both patient and physician a decided advantage in pursuing medical treatment by reducing the amount of thyroid secretion.

New York Medical Journal, May 7, 1910.

Significance of the Various Enlargements of the Thyroid Gland, with Special Reference to Basedow's Disease.—Carl Beck presents an elaborate paper with many photographs illustrating the various forms of goiter, describing in the text histological features of each and the varying forms of therapy. He says that experiments in regions in which goiter is endemic point to the drinking water as the carrier of thyrogenous element. Simple goiter is a prevalent attribute of the poor, while the Basedow type is found among all classes. The question of the favorable soil for development seems to be the most important therefore in practice. As to the etiology of Basedow's disease our ignorance is still greater. There are, however, many points of resemblance to simple goiter, and that predisposing moments serve as exciting moments cannot be doubted. Especially neuropathic disposition, continuous mental insults, and similar irritations of the nervous system may give the first impulse. It is significant that nearly all the author's patients afflicted with Basedow's disease were women and that all his cases of simple goitre were foreigners, most of them coming from Russia and Galicia with a few from Germany and Switzerland, while most of the Basedow cases came from the United States. The author's methods of treatment naturally vary according to the variety of the lesion, and while he offers nothing essentially new, his careful separation of his patients, according to lesions presented, is accountable for his excellent results.

Norway for Neurasthenia.—C. E. Nammack described the country from a climatological point of view and the various restful journeys which may be taken within its confines. The democratic spirit of the people and the absence of the servility so noticeable in other parts of Europe render the country particularly agreeable to the American tourists. He says they are industrious, sober, phlegmatic, religious, and contented, and a few weeks spent among them in sight of their everlasting hills would be the best tonic for a restless, sceptical, neurotic invalid. Their absolute belief in the mercies of an all-wise Creator, their absolute confidence in one another, their respect for law and order form a refreshing picture in these days of religious unbelief, social unrest, business dishonesty, and official corruption. Norway has an excellent system of district physicians and midwives for attendance upon the sick poor. Vaccination is compulsory and no child can be confirmed without producing a certificate of successful vaccination. The death rate would be very low if the drowning incident to the shipping, lumber industries, and fisheries were excluded. Acute bronchial catarrhs are among the most frequent epidemic diseases, and tuberculosis occupies the prominent place among the chronic infections. Leprosy, under the policy of segregation, is markedly decreasing, but is still so commonly seen as to excite no hysterical leprophobia.

Heredity as a Factor in the Etiology of Tuberculosis.—E. L. Shurly says that it would seem irrational to ignore the condition of hereditary tendency as playing a great part in the susceptibility or resistance of disease whether infectious or not. For it seems highly probable that certain tissues or groups of tissues, certain conditions of the internal secretions, or certain organs are stamped with either a high, a low, or a peculiar degree of activity—independently of those peculiarities termed idiosyncrasies. If this is so and if heredity is really an important factor in the production of tuberculosis and other diseases, then is it not obvious that more attention should be paid to the breeding of civilized man? Everybody should keep in mind some such homily as—that a bull pup (although a canine) cannot be produced by two setter dog parents; and hence if two individuals with tuberculous or cancerous or insane tendency, marry—it may be expected that the progeny of such union will in all probability be physically defective in some particular at least, and will have a low resisting power toward the acquirement of tuberculous, cancerous, or perhaps other diseases. The progeny of inebriates both in "high life" and "low life" are often good illustrations of altered vitality. Among the poor they die off in infancy, though partly from want of care and nutrition; while among the rich, they may sometimes be reared, at the cost of extra care and attention, to live for some years their sickly lives. Equipped with the common knowledge regarding heredity or hereditary tendencies in man and the lower animals as the medical profession is, it is surprising that so many scientific writers treat the subject so lightly. The majority of the lay and medical tuberculosis preachers deride heredity as a casual factor at all. The author has heard a lay tuberculosis preacher say to his audience: "Tuberculosis (consumption) is not hereditary in any way. Dismiss that from your mind; It is the most curable of diseases, and depends entirely upon your getting the bacillus, the germ! Kill the germ and you stamp the disease out," etc. Now, who knows how many hearers belonging to a tuberculous family, would, after this harangue, straightaway take a spouse from another tuberculous family—and breed tuberculous children?

Fibroid Tumors Complicating Pregnancy.—G. Torrance refers to the statistics of this condition and then reports the case of a primiparous colored woman of 32 years of age who had been in labor for twenty-four hours under the care of an intelligent midwife who called a physician. He found one hand presenting but could not feel the os which was high up behind the pubes. The pelvis was filled with a large, hard tumor mass and a number of nodules could be palpated in the right side of the abdomen just below the liver and were apparently attached to the uterus. Chloroform was given and an attempt was made to relieve the obstruction, failing in this the author was called in with the view of operating. The woman was sent to the hospital and under ether the child was delivered by cesarean section; the placenta was detached and there was considerable maceration of the placenta and child, and the contents of the uterus had a very foul odor. A large tumor about the size of a child's head which filled the pelvis, was shelled out without necessitating the use of a single ligature. The uterus was then removed with the attached masses above. Drains were passed out through the vagina and one in the cul-de-sac passing out through the abdominal wound. There was considerable oozing, and the patient showed that she suffered greatly from shock. The operation lasted about forty-five minutes. There had evidently been a good deal of absorption of toxic material from the macerated and septic materials found in the uterus. The patient was put in a bed with the foot elevated and was given stimulants and salines but to no avail. The tumors, including the body of the uterus, weighed five and a half pounds.

Journal of the American Medical Association, May 7, 1910.

Abuse of Hypodermic Medication During Operation.—H. G. Wetherill condemns the practice of hypodermic stimulation during and after operations, and states that anesthetists and surgeons who have had the largest experience seldom use it. The best results and the lowest mortality of the busiest surgeons of to-day are attained by the simplest methods. Careful diagnosis and accurate estimates of the ability of the patient to undergo the operation are made. He is prepared with care, the anesthetic is wisely chosen and skillfully given; he is operated on without avoidable exposure, delays, or hemorrhage, he is returned to a warm bed, placed in a favorable position, watched by a competent nurse, and let alone. If he is very restless and really suffering from shock or severe pain as he emerges from the anesthetic he may be given a moderate dose of morphine and atropin but, notwithstanding its stimulating and soothing effect, he is ordinarily better off it it can be omitted. No strychnine, no spartein, no digitalin, no nitroglycerine—no whip and spur for a tired and jaded and played out or overworked heart, if such he has—no piling up of new poisons to impose additional burdens on the organs of elimination. Let him alone. Keep him warm and very quiet. Give him all the water he can absorb by the avenue of choice; mouth, rectum, under the skin, or within the peritoneal cavity, and as few drugs as possible.

Cancer.—J. W. Vaughan critically reviews the theories of cancer, the mechanical irritation theory of Virchow, the lack of tissue tension theory of Ribbert, the trophic nerve theory, the parasitic theories, and the infection theories generally, and suggests a theory of his own. This appears to be that there is stored in each cell a reproductive zymogen which is called into action when more cells are required to be made; and that this call might depend on chemical or mechanical irritation from outside. In the case of cancer, clinical observation has shown the probability of mechanical irritation being the *a priori* factor in stimulating this activity—especially a low grade of irritation; insufficient to cause cellular death, but enough to keep the specific reproductive ferment in an abnormal activity. It has been demonstrated by modern research that chemical ratios are different in cancer individuals. Crile and others have shown that the blood of cancer patients is capable of causing hemolysis of normal blood corpuscles. The recent works of V. C. Vaughan concerning the chemistry of the bacterial cells tend to prove that in bacterial infections, especially of the lytic type, a ferment is formed which is capable of destroying the bacterial cell through the injection of a specific residue of that bacterial cell within the human body. With this in mind, the author has attempted to induce the formation of a ferment in the human body capable of destroying the cancer cell through injections of its nontoxic residue into the body from which the cancer was obtained. The formation of such a substance in the host might serve to explain the few cases of apparent self cure of cancer which have been observed. Belief in this theory and in the efficacy of the method based on it does not do away with the need of a radical operation. His attempts have been to establish the ferment which destroys the cancer cell in cases already beyond surgical relief. In such it can do no harm and no other method is available. The preparation of the residue, as described by V. C. Vaughan, is given essentially as follows: "The cancer material is dissected as freely as possible from all surrounding tissues, after which it is ground in a meat grinder. The material is next washed with water, dilute salt solution, alcohol, and lastly ether. This process removes salts, fats, wax, several protein bodies, and traces of carbohydrates. The remaining substance is then heated in a flask with a reflux condenser with from 15 to 20 times its weight of a 2 per cent. solution of sodium hydroxide in absolute alcohol, and by this means it is split into a toxic and a nontoxic group. The toxic portion is soluble in the alcohol, the non-toxic is insoluble, and it is with this portion we have to deal."

His practical work in this line has all been done since September, 1907, and the time is too short to report results, therefore only a few cases of recurrent cancer treated on this principle are reported. The results so far have been encouraging. Immediately after the first injection of cancer residue the pain ceases and, while the growth of new tissue in all cases treated has not been entirely stopped, Vaughan thinks it safe to say its rapidity has been lessened. The cases were all of superficial forms of cancer in which recurrence occurred, and were chosen so that results could be quickly and accurately estimated. Every tumor should be examined microscopically and the patient treated preferably with a residue from his own tumor cells. The treatment by this method should follow radical surgical removal as soon as possible. If the majority of surgeons who have a large amount of material of this kind would utilize this method Vaughan says some definite conclusions as to its value could soon be obtained.

Gastric Analysis in Infants.—The results of gastric analysis in 62 infants are summed up by D. H. Sherman. The technique used was to examine the gastric contents one-half hour after a meal of plain barley water, and also one-half hour after a proprietary food containing starch made up without milk. The Topfer method was used which is sufficiently accurate for clinical purposes. Free hydrochloric acid was estimated by using phloroglucin vanillin, and quantitatively by titration with decinormal sodium hydrate solution, using dimethylamido-azobenzol as an indicator. Total acidity was estimated by using phenolphthalein as an indicator and combined acidity by alizarin. The conclusions are as follows: "1. The normal infant gastric analysis, shown in degrees, after barley water, is, free hydrochloric acid. 2.1; total hydrochloric acid, 5.6; total acidity, 9. 2. It is the hyperacidity which is one of the common causal factors of the vomiting of infants. 3. Clinical experience corroborates our tests, that longer intervals of milk-feeding are less apt to be followed by sour vomiting. 4. Milk going into a hyperacid stomach forms curds more quickly, they are larger and harder, and hence may produce vomiting. 5. The analyses explain the good results following the exclusion from the dietary for a time of cow's milk, the reason for gastric rest, with or without lavage, and also the chemical antidotal effect of alkalines."

Cerebral Syphilis.—E. L. Hunt calls attention to the course and prognosis of syphilis in certain patients who may present many of the physical and mental characteristics of general paresis, and yet unlike sufferers from paresis are to a certain extent amenable to treatment. The group of symptoms which these cases present is twofold in character, physical and mental. These occur in men about 35 years of age, who have contracted the disease probably fifteen years before. The physical signs consist of changes in the reflexes, both of eyes and knees, the Romberg symptom, and the tremor of the facial muscles. The mental symptoms consist of a lack of confidence, a loss of judgment, a sense of depression, and inability to perform regular work; a certain amount of mental deterioration, degradation, and confusion. These patients do not care for their personal appearance; their clothes are not neat; their shoes are never cleaned; they do nothing, they are hypochondriacal. In treatment, Hunt says that the best results have come from large and systematic dosage of the iodide and mercury. The mercury can be given either by inunction or by hypodermic injection. The latter is the preferable plan from the point of view of both of the patient and of the physician. The dosage can be made more exact, and it enables the physician to keep a constant supervision over the patient. The iodide should be begun in doses of from 25 to 35 drops a day and steadily and rapidly increased to 300 or even 400 drops. Another important factor in the improvement of these patients is the environment. They ought to be surrounded in every way with what is agreeable and congenial. Exercise and diet should be carefully regulated. Such patients also require a great deal of rest and do better with long hours in bed.

The Lancet, April 30, 1910.

Fatal Hemoptysis in Childhood.—R. Brown's patient was a girl of three years, admitted to hospital with the signs of tuberculosis of the lungs. Percussion resonance was poor over the entire left side, the breath sounds were harsh and over the left lung almost of a tubular character. Medium râles were audible all over the chest. The apex beat was felt in the sixth space one inch outside the nipple line. There was an irregular and feeble heart action, and irregular fever. The child died on the fourth day after admission with a profuse hemoptysis. The autopsy findings are given. There was a cavity in the lower lobe of the left lung and the hemorrhage had extended to the stomach, which was occupied by clot. The most striking features of the case are undoubtedly that the immediate cause of death was a sudden profuse hemoptysis, and that this was the first and only attack thereof. This is uncommon in children of such tender age and is rarely fatal. Cavitation appears not to be unusual in children, but difficult to recognize clinically. On this account it was formerly thought to be of less frequent occurrence than is actually the case. The presence of a cavity was not diagnosed in this case. Cavities are usually small and of recent origin, while this one was, comparatively speaking, of large size.

The Pressor Bases of the Urine.—W. Bain offers the following conclusions: (1) The pressor bases which are present in the urine of normal adults can be most readily obtained by slaking the urine with Fleming's blood charcoal and subsequently extracting the charcoal with suitable reagents. (2) The urine of growing children contains these bases in minimal amount. (3) So far as the influence of diet is concerned very little can at present be stated. In the two cases investigated the substitution of a milk and biscuit diet for one rich in meat makes but little difference. Medicinal doses of antiseptics administered by the mouth do not make any appreciable difference in the amount of these products of protein putrefaction which is excreted in the urine. (4) In all cases of high blood-pressure hitherto examined the urine contains very little of the bases in question and in some cases they are altogether absent. The non-elimination of the bases probably indicates that they are retained within the body and play an important part in the production of high pressure. (5) So far as the cases of gout are concerned, the author's material has been rather scanty and conclusions must be taken with reserve. He scarcely thinks there is any relationship between gout *per se* and the retention of the pressor bases, and yet in most cases which he has examined the diminution in the excretion of the bases is not proportional to the increase of arterial pressure observed. (6) In cases in which the urine contains a deposit of uric acid there is a marked diminution of the colloid matter of that fluid. This colloid consists of or contains a sulphur com-

pound—Chondroitin sulphuric acid—which is a constituent of cartilage. The association of this condition with the frequency of urate deposit in cartilage is suggested and deserves fuller investigation.

Vicious Circles Associated with Disorders of the Nervous System.—J. B. Hurry enumerates some of the most common of these associations. Under functional disorders he mentions first, neurasthenia caused by insomnia, with mental depression and malnutrition and a mental condition set up in neurotic persons when attacked or threatened by illness. Vicious circles may also be set up by the use of alcohol and various drugs, especially morphine. There are forms of neurasthenia in which some peripheral organs are reciprocally involved with the central nervous system. The sufferer, by fixing his consciousness with morbid intentness on his organs, creates not merely unhealthy sensations, but also functional disorders as nausea, palpitation, flatulence, and polyuria. A vicious circle is frequently associated with sexual malpractices and spermatorrhea, while anemia in its secondary effects on nutrition may form a grave complication of neurasthenia. Considering other functional disorders, there are various conditions in which cause and effect bear reciprocal relations to each other. Overwork supplies a common example. Between the nervous system and the gastroenteric tract many illustrations of disordered correlations may be observed. Under the heading of organic diseases of the nervous system Hill draws attention to a vicious circle which is established when intracranial hemorrhage causes increased cerebral compression, and thus leads to a secondary increase of compression by obliteration of veins and capillaries in the affected area and a consequent congestive edema. Another form of circle may be established in cases of hydrocephalus in which the ventricles are dilated with fluid. The dilated ventricles may so displace the adjacent parts as to press on and increase the obstruction to which the accumulation of fluid was originally due. So also inflammatory conditions in which toxins dilate the blood vessels after the metabolism of the tissues and raise the osmotic pressure (by increasing the crystalloidal cell-products) are often complicated by a vicious circle. Finally vicious circles may be established by erroneous treatment in various disorders of the nervous system though such errors are less common than formerly. The abuse of potassium bromide in traumatic neurasthenia is a case in point. Another artificial circle may be established when minor uterine or ovarian disorders receive undue attention and thus provoke in the patient an unhealthy condition which exaggerates and perpetuates the trivial local disorder. Strychnine is often abused in its use for severe shock accompanying major operations. Under such circumstances there is a fall of blood pressure following dilatation of the splanchnic area and exhaustion of the nerve centers. Stimulants are useless in stemming this fall of pressure. Many fatal cases might have recovered but for the strychnine. The use of this drug still further exhausts the nerve centers. In other words, the symptoms of shock led to the administration of the drug which administration in turn increased the shock.

British Medical Journal, April 23 and 30, 1910.

A Note on Defective Nipples.—H. B. Billups comments on the varying aspects of the nipples commonly met with in obstetric practice. He finds that much damage may be done to the nipples during the age of childhood by improper manipulation, owing to various old-woman theories as to the proper preparation of the breasts for the secretion of milk in the later marriageable period. He does not believe that the old theory of defects from pressure by the corsets holds true, nor that the condition in question is a congenital one but that it is due to improper manipulation by ignorant midwives soon after birth. It is the duty of physicians and nurses to prevent the pinching of the breasts by the patient or family friends.

The Surgical Treatment of Certain Cases of Glycosuria.—A. W. Mayo Robson says that the practical outcome of his experience may be thus stated: (1) The early recognition and treatment of interstitial pancreatitis or of pancreatic catarrh by drainage of the bile ducts and thus indirectly of the pancreatic ducts and the removal of the cause whether that be gallstones, duodenal ulcer, or other conditions, may be the means of averting diabetes. (2) In certain diseases of the pancreas even after the appearance of glycosuria surgical treatment is well worth considering as in a number of cases it has led to a complete disappearance of sugar from the urine, and in others to an arrest of the disease causing glycosuria. (3) Every case of diabetes should be considered from its etiological point of view, seeing that certain cases of glycosuria of pancreatic origin are curable, and in others the progress of the disease may be arrested by suitable surgical methods that can be carried out with very small risk.

Malarial Fevers and Quinine.—J. H. Whelan speaks of the varieties of the malarial organisms and the blood state in fevers. We know that the blood cells are greatly diminished in numbers, much more so than can be accounted for by the ratio of cells infected. The hemoglobin content is much reduced, the resistance is lowered, and there is a leucopenia, but both a relative and actual increase of the large mononuclear cells. I think we may take, says the author, the lowering of the resistance of the blood disks to be Nature's method of cure. If the infected disks break down before the asexual parasites can sporulate, a permanent cure ensues unless the gametes may revert under favorable conditions to the asexual type. Quinine lowers the resistance of the blood disks and in malignant malaria we have in the tropics, blackwater fever, acute hemoglobinuria. It nearly always occurs in patients taking quinine. If quinine is cautiously given in this class of fevers it causes the gradual premature breakdown of infected cells before their guests can sporulate; in other words, quinine cures malarial fevers by destroying the homes and food of the plasmodia before they can sporulate, yet the cured patient may remain a source of infection to his neighbors because, while the patient himself may be cured, he is able to infect mosquitoes which may carry the poison to others.

The Results of Thyroid Treatment in Infantile Wasting.—J. W. Simpson has given thyroid in a diluted milk and cream mixture with sodium citrate, one or two grains to the ounce of milk. In a day or two cream was gradually added, half a teaspoonful to the feeding bottle. Out of 80 cases thus treated 72 were infants under nine months and their history was simply one of wasting. The other 8 had a wasting supervening on some acute diseases; sixty-three cases did well; five cases presented syphilitic histories in which wasting was a marked symptom. Mercury was first given and later thyroid. Three immediately gained and eventually recovered. In older children the results have also been favorable, except when tuberculosis was present. In children under nine months' the author began with one-third grain of dried thyroid once daily. Larger doses often seemed to induce a diarrhea. In the giving of thyroid it is advisable to test the stools frequently to see whether they are acid or alkaline. In case acidity is found the bicarbonate of soda may be given three times daily, and when the natural alkalinity of the stools is restored the thyroid will begin to exert its beneficial results. No grave symptoms followed the thyroid therapy. In six cases a punctiform rash appeared, confined in two cases to the front of the chest. It was evanescent and disappeared without treatment in the course of 12 to 24 hours. In only one case was it necessary to stop the thyroid (3 days) in order to cause the rash to disappear. Cases treated at home did better than those treated in hospital. It seems probable, says the author, that the amount of nursing and general "mothering" that is possible at home but not in hospital, is very beneficial in such cases and conduces to a more rapid recovery.

Treatment of Depression of the Skull in a Newborn Infant.—The child under the care of W. R. Cossham was, when born, found to have a depression in the left frontoparietal region about one and one-half or two inches in diameter. It was born after a tedious first labor. As it was hoped that recovery might occur spontaneously, and the child seemed in no way affected by the condition, nothing beyond a fruitless manipulation was done till the tenth day. The child was then taken into our cottage hospital where, with all needed help, operation was done under an anesthetic as follows: The surgeon provided himself with an awl made from a large-sized knitting needle and an elevator made of stout wire with bowed handle and a point, somewhat flattened, bent to a right angle, so as to be about one-eighth inch in length. "I dissected back a small tongue of scalp, including the pericranium, over the center of the depression, and cautiously bored through the skull. Inserting his elevator he then easily drew the part into position. A suture and dressing were applied, and the child was sent home in a few hours. Healing took place in the course of a week without the smallest complication.

Hospital Infection of Tuberculosis.—J. E. Squire presents in a statistical form the report of one of the English hospitals for a period of fifteen years, and also comparisons with other institutions. From Table I it appears that out of 1,730 medical resident officers, dispensers,

nurses, female servants and porters, 38 became affected with the disease. Table II gives the statistics of 26 cases which contracted the disease in the special hospital referred to in the 15 years. Of 33 past resident medical officers to whom he has written and of whom he has positive knowledge, one was dead, 27 replied, and of the 27 all but four were able to state that they had never suffered from tubercle, either before, during, or since their stay in hospital. Of the four exceptions two had suffered before entering the hospital, the disease having been arrested. Both are well and continuing at work. The other two had some local manifestations on the skin, but both recovered. Regarding hospital positions in general the author says that the risk of infection is no greater to the workers in any well-ordered hospital than among the general mass of town dwellers of similar social position. Infection does occasionally result in nurses, but probably not oftener in a hospital for consumptives than among the general body of nurses. The risk of tuberculous infection even in a hospital for consumptives appears to constitute a very small danger. The author publishes a list of cases, one of which illustrates unsuspected tuberculosis detected by examination on entry, occurring in a ward maid, and several cases of apparent infection during residence. He calls attention to the difficulties in securing absolute accuracy in the preparation of an article of this kind, stating, however, that it is undesirable that those who have tuberculous family histories should take work as nurses or maids in a special hospital for consumptives.

An Immunizing Subinfection in Scarlatina.—A. E. Edwards says that our continued experience with scarlatina convinces us that the predominant factor in spreading the disease is personal contact. He refers to the lower grade of infection in the disease, saying that, because it varies so greatly in its characteristics so as to produce all grades of rash from the brilliant and vivid eruptions, hemorrhagic and accompanied by miliary vesicles to a slight erythema of low punctiform character which is hardly visible, it is not illogical to expect that the rash-producing properties of the infection may be traced to the vanishing point. Some patients present the strawberry tongue, but no other sign. It is not irrational to suppose that these children may have had so low a degree of infection that, while it was too feeble to produce the typical lesions, it could produce an effect on the delicate tissues of the tongue, and, further, that the attenuated infection by which they had been attacked had immunized them against the more marked disease. The infection of persons therefore during the prevalence of scarlet fever may be classed as follows: (1) The well-developed cases, (2) the mild ones, in which the infection has caused sore throat and a slight evanescent rash, with subsequent peeling, and (3) the cases where there is still milder infection, not sufficiently concentrated to cause a rash, but which produces a sore throat and possibly exfoliation of the tongue. From the standpoint of public health these cases may be disadvantageous to the community, for the infection which will have produced only a protective and immunizing effect on one person may, when transferred to other persons of low resistance, result in graver pathological conditions. If these subcases of the disease are infectious, it would appear that usually their infectivity is of low degree. The infection is not likely to produce otorrhea or rhinorrhea, but if these discharges are coincident, then the infection is likely to be spread. This leads to the conclusion that every effort should be made to cure such discharges, especially in school children who come into close contact with others, and herein, as in so many other directions, there is hope of much benefit from the institution of routine school medical inspection.

Berliner klinische Wochenschrift, April 11, 1910.

Chlamydozoa in Trachoma and Blennorrhea.—Halberstaedter and Prowazek refer to their previous paper in which they reported the finding of the so-called trachoma bodies in cases of nongonorrheal blennorrhea neonatorum and in the vaginal secretion from the mothers of some of these cases. They state that to prove that these organisms found were trachoma bodies, it was necessary to produce a conjunctivitis by injecting into the eye of a monkey, and then to find the same cell inclusions in the secretion from the infected animal. This is an especially valuable proof as the monkey's conjunctiva is immune to gonococcus infection. The chlamydozoa have also been found by Lindner in the male urethra in cases of nongonorrheal urethritis. The authors have confirmed this finding. While it is shown that the chlamydozoa blennorrhea is due to infection from the genital tract of the mother, there is no reason why infection with other organisms, especially the gonococcus, may not take place at the same time producing a mixed infection. The present status of the question is as follows: In fresh trachoma one finds the characteristic bodies which the authors have called chlamydozoa. These are also found in a definite form of ophthalmia neonatorum, in the genitals of the mothers of the diseased children, and in the urethra in nongonorrheal urethritis in males. It is possible to infect the conjunctivæ of monkeys with the secretion of trachoma, with the pus from chlamydozoa blennorrhea, with material from the genitals of the mothers of such children, and with the urethral secretion in men, in a similar manner, and then to find typical chlamydozoa in the epithelium of the monkeys' conjunctivæ. These infected conjunctivæ in the monkeys later show the typical clinical picture of human trachoma.

Münchener medizinische Wochenschrift, April 5, 1910.

The Production of Atypical Epithelial Growth by Injection of Scarlet Red and Amidoazotoluol Oil.—H. Stoeber refers to the action of scarlet red in stimulating epithelial growth, both on the surface in man, as in case of ulcers, and in the subcutaneous tissues of the ear of the rabbit. He says that he has been anxious to try deep injections in the normal skin of a man, and recently has had the opportunity in the case of a man eighty years of age, who was to have an amputation of the leg for an ununited fracture. The operation was postponed for two weeks, and with the patient's consent subcutaneous injections of scarlet red, amidoazotoluol, and *a*-naphthylamin were made. After amputation, two weeks later, distinct epithelial proliferation was found at the site of injection of the scarlet red and the amidoazotoluol.

Dosage of Bier's Hyperemia.—M. zur Verth discusses the production of hyperemia by means of the elastic bandage, and says that the maximum hyperemia occurs in association with the minimal arterial pressure, and may be obtained by producing a pressure somewhat below the minimal arterial pressure obtained by the auscultatory method. Researches have shown the highest blood pressure in the hyperemic area is obtained by producing a pressure just equal to the diastolic blood pressure. The acoustic phenomenon heard between maximal and minimal arterial pressure is the indicator which prevents too vigorous an application of the bandage.

A Method of Differentiating Serologically Between the Blood of Different Men.—v. Dungern and Hirschfeld have investigated the serological reactions between the sera of monkeys and the blood corpuscles of men, and find that there are very marked individual differences, some men giving marked hemolysis and others none. They have carried the work further by using the sera of chimpanzees, oxen, goats, horses, pigs, rabbits, cats, dogs, and chickens. With all of these they find similar individual variations with different men. The authors offer this multiple test, that is, trying the hemolytic reactions of the various sera with any given blood as a proof of the identity of any blood specimen. They are now studying the question of the heredity of the individual hemolytic characteristics according to Mendel's laws. If the characteristics are uniformally inherited the test may be of value as a proof of legitimacy.

Relation Between Tone, Acid Production, and Position of the Stomach.—H. Bräuning has studied a series of patients in regard to the chemical analysis of the gastric contents, the tone, and the position of the lower border of the stomach as shown by the *x*-rays. From a study of twenty-two cases, he finds that where a hyperchlorhydria exists, there is a diminished tonicity of the fundus, and that in cases where there is a diminished tonicity, the lower border of the stomach lies lower down than in cases with a normal tonicity. He does not say that the hypotonicity is the cause of the hyperchlorhydria, or *vice versa*, but that probably both are the result as an asthenic constitution.

The Newfoundland Society for the Prevention of Tuberculosis is carrying on a vigorous and necessary campaign this year in the island. The death rate from the disease in Newfoundland is very large. About one in every five of the total population dies of it, and, what is worse, in the last six years the death rate, which is stationary or decreasing elsewhere, has increased about 50 per cent. This is due largely to the native horror of fresh air in the house.

Book Reviews.

Vital Economy, or How to Conserve Your Strength. By John H. Clarke, M.D. New York: A. Wessels, 1910.

Dr. Clarke has written an interesting little monograph, which tells rather how to conserve one's strength than how to get strong. The stream of popular health books seems to be increasing in volume, and there is really little need for another book on this hackneyed subject. For an Englishman, Dr. Clarke holds peculiar views on baths and bathing. Bathing, he says, is not essential to cleanliness, and cold baths do not always protect the person using them from colds. He says that it is perfectly possible to wash away so much of the epidermis as to leave the skin quite sensitive and subject to even slight changes of temperature. Coffee he considers more of a food than tea, and not nearly so trying to the digestion, even helping this function in some cases, rather than hindering it. There are chapters on exercise, stimulants, fresh air, the extravagance of worry, and an appendix in which are published abstracts from various reviews and personal letters concerning the English edition.

Health in the Home. A Practical Work on the Promotion and Preservation of Health. With illustrations and descriptions of Swedish gymnastic exercises for home and club practice. By E. Marguerite Lindley, Lecturer on Health Culture. New and Revised Edition. Passaic: The Health Culture Company, 1910.

The writer says that this book was written at the request of many patrons of her lecture courses on home gymnastics, and that a flattering list of subscribers awaits the issue of this second edition, thus proving the growing interest in the work as well as the reliability of the book. Doubtless this little confidential statement will help in the sale of this as well as other editions. Certainly one cannot wish Miss Lindley any other fortune. Twelve chapters are devoted to prescriptions for the use of Swedish exercises in home practice, with especial reference to those exercises best suited to children. The chapters on fatigue and rest, emergency work and first aid to the injured, and home nursing are not devoid of interest to the medical man, and will doubtless be of service to the lay reader, for whom they were written.

Anleitung zur Diagnostik der Abdominaltumoren, unter Zugrundelegung der Palpation. Eine klinische Erläuterung zur Palpation des Abdomens. Von Prof. Dr. G. L. Sacconaghi, Dozent für innere Medizin an der kgl. Universität zu Pavia. Nach der italienischen, vom Autor verbesserten Ausgabe. Uebersetzt von Dr. V. Plitek in Triest, mit einem Vorwort von Prof. Dr. C. von Noorden in Wein. Berlin: Verlag von S. Karger, 1910.

This interesting work presents in a concise but carefully elaborated manner a most important chapter in diagnostic methods. Although fully recognizing and noting the value of other procedures, Prof. Sacconaghi places the main reliance on palpation in making the diagnoses of abdominal lesions. The author claims that only in a limited number of conditions involving the abdominal organs will the trained hand be unable to detect the sources of the trouble, and as the result of a long continued period of study and observation he has worked out a suitable schematic method for the desired purpose. His conception of the word "abdominal tumor" is not synonomous with "neoplasm," and is made to include every abnormal circumscribed projection as well as every complete or partially enlarged, distended, indurated, or displaced organ, which affords a sense of resistance during the act of palpating the abdomen. On this basis the author takes up in great detail the diagnosis by palpation of all the abdominal contents, which results in the production of the most complete work on the subject which has come to our notice. The book is encyclopedic in character, and as worthy of translation into English as it was into German.

Travaux d'Obstetrique. Par le Docteur Samuel Gache. Professeur Argégé à la Faculté de Médecine de Buenos-Aires; Directeur de la Maternité de l'Hôpital Rawson; Lauréat de l'Institut de France et de la Faculté de Médecine de Paris; President de la Ligue Argentine Contre la Tuberculose, etc. Paris: G. Steinheil, 1910.

The introduction to this volume is written by Dr. Sobre-Casas, of Brazil, whose excellent monograph on cancer was noticed in these columns some months since. Modern ideas on the subject of obstetrics are expressed in this book with much clearness, and if there is not as much system in the statement of facts as might be desired, such facts as are stated are of clinical value. The author is evidently a man of experience, who knows how to state his ideas in a clear and concise fashion. Among the therapeutic remedies employed to increase uterine contractions, he considers sulphate of quinine and ammonium succinate as possessing much merit. Ergot he thinks should not be used, and objects to lactose because it provokes vomiting. Manual dilatation of the uterus is his method of choice, but in case it is not readily accomplished, instrumental dilatation of the neck may be begun with the Tarnier balloon, followed by the Champetier de Ribes bag. The Bossi dilator, he says, is easy to use and gives certain results. In urgent cases it is superior to all other procedures, for one can secure complete dilatation with it in fifteen minutes. This work has some value as a book of reference, but its value would have been greatly increased by the use of illustrations—so essential in these days in the teaching of practical obstetrics.

Pulmonary Tuberculosis and Sanatorium Treatment. A record of ten years' observation and work in Open-Air Sanatoria. By C. Muthu, M.D., M.R.C.S., L.R.C.P; Associate of King's College, London; Physician, Mendip Hills Sanatorium, Wells, Somerset; Late Physician Inglewood Sanatorium, Isle of Wight: author of "Some Results of Sanatorium Treatment of Phthisis," "The Inhalation of Formic Aldehyde in the Treatment of Pulmonary Tuberculosis," "The Diagnostic Value of Tubercle Bacilli in the Treatment of Phthisis," "A Short Account of the Aryan System of Medicine," etc. London: Baillière, Tindall & Cox, 1910.

Although not so stated in the preface, the author doubtless intended this little volume more as a handbook for the lay patient than as a treatise on the subject for the professional man, and as such, while there are numerous shortcomings, and while it must be acknowledged that the work contains many statements which, when the lay reader is considered, are of doubtful expediency, nevertheless, it possesses many points of unique and practical value. The author considers his subject under three principal headings: Part 1 consists of a brief general discussion of the etiology, communicability, symptomatology, and prognosis of pulmonary tuberculosis. It is in this part particularly that the author's views are at greatest variance with those generally accepted to-day. For instance, it is rather shocking to be told that the tubercle bacillus is merely a predisposing factor in the causation of tuberculosis and is no more to be considered the determining factor than is poverty, etc. (page 33). One familiar with the modern views as to the etiology and communicability of tuberculosis can follow the author's argument and soon discover that his views are not so radical as at first appears, but the expediency of entering such a discussion in a handbook evidently intended for the laity is, to say the least, questionable. This first part of the work abounds in metaphor and a rather vague nomenclature in which "vital energy," "resistance," "personality," etc., appear in somewhat confusing figures of speech. Part 2, devoted to the subject of sanatorium treatment, is much better. The author has done well to limit his discussion of this subject to his personal experience in his own sanatorium, and in this section he has brought home some very important truths regarding sanatorium treatment—truths too often lost sight of in the popular discussions of the subject. Part 3 is devoted to the social and economic factors of tuberculosis, and presents the author's views as to the ideal method of solving some of the great social problems, of which he considers tuberculosis a phase. On the whole, the book is interesting, of convenient size, well illustrated, and perhaps safer for popular distribution than many another written for the purpose.

Transactions of the 31st Annual Meeting of the American Laryngological Association, held at Boston, Mass., May 31, June 1 and 2, 1909. New York. Published by the Association, 1909.

This volume is a fitting successor to those which have been published in previous years, and shows well how rapidly the kindred sciences dealing with the nose, throat, and ear are advancing. There are several papers upon the influence of disease of the nasopharynx upon diseases of the ear. There is a symposium also upon the surgery of the esophagus. Two helpful papers are those on the use of calcium lactate in hemorrhage and the report of a fatal case from injection of cocaine-adrenalin solution in tonsillectomy.

Society Reports.

AMERICAN SURGICAL ASSOCIATION.

Annual Meeting Held in Washington, May 3, 4 and 5, 1910.

RUDOLPH MATAS, M.D., OF NEW ORLEANS, PRESIDENT.

Tuesday, May 3—First Day.

(Special Report for the MEDICAL RECORD.)

Concerning Operation on the Hypophysis.—Prof. A. VON EISELSBERG of Vienna, Austria, read this paper, reporting six cases in which he had operated. The operation had been done in each instance by a low frontal incision making an incision through both eyebrows and down the side of the nose, turning the nose soft parts to one side, and opening frontal sinuses and nasal fossæ, removing superior turbinate bones, nasal septum, vomer, scooping out the sphenoidal cells and opening the posterior lamella of the body of the sphenoid exactly in the median line. All unnecessary bone destruction was avoided. This frontal approach was easier than the temporal, but gave greater chance of infection. It should be done after a preliminary tracheotomy with packing off of the nasal cavities to avoid pulmonary complications. A chronic nasal catarrh was a common accompaniment of acromegaly. Of the six cases operated on by him two were carcinoma, two sarcoma, one a mixed tumor and one a simple cyst. Two of the patients had acromegaly and both had died; a third had had no acromegaly but after the operation the size of the bony framework of the body had markedly decreased in size. A hat that was formerly worn now dropped down over the ears and the trousers were too large round the waist and too long. Two of the cases had been of the juvenile type and two of degeneration of the hypophysis with the Froelich syndrome. In most of the cases there had been an improvement in the headache and the vision. The first case had an uneventful recovery and after two years was at work again as a clerk. The second case was improving in vision though the field of vision was still very limited. The third case, a cyst with removal of two ounces of chocolate-colored fluid, did well for several weeks, then developed meningitis and a lumbar puncture showed pure pus. This cleared up on antistreptococcus antitoxin and two years later the patient's general condition was good, though the vision was limited. The fourth and fifth cases were of acromegaly, the fourth a sarcoma and he died within forty-eight hours of the operation. He was hopeless before operation. The sixth case was the most difficult of all with an abscess in the hypophysis. Since the operation he had shown a decrease in his bony framework in spite of the fact that there had been no acromegaly before the operation. During his visit to America Prof. von Eiselsberg had seen the remarkable surgery of the Americans and felt that it was now time for the European surgeon to visit America as well as for the American to visit Europe and that the mutual interchange of ideas would be of benefit to both.

Operation for Removal of Tumor of the Hypophysis.—Dr. ALBERT E. HALSTEAD of Chicago sent this paper and reported two cases. After discussing the advantages and disadvantages of the several routes of approach to the hypophysis he described a case in a man 37 years of age whose eyesight had gradually failed and bitemporal hemianopsia had developed; he was married, but had no children and had diminished sexual tendencies. His field of vision was diminished in every radius and not over ten degrees on the temporal sides. The operation was done through a low nasal exposure. The incision was through the mucous membrane between the gum and lip, the nose being retracted upward after a preliminary tracheotomy. The turbinates were removed with the nasal septum, and the sphenoidal cells curretted out and then the sella turcica opened and the cystic tumor curetted away. For the first forty-eight hours the temperature was 100 to 102 and the pulse not above 120. The cavity was repacked and promptly the temperature rose to 105° and the patient became somnolent. The packing was taken out and the wound redressed. The pulse fell to normal and the temperature also; and there continued steady improvement in all ways until he resumed work as driver of a wagon. This patient was presented to the Association for examination. The second case was a woman of 22 years with eye symptoms. Under operation she did well except for one time when she stopped breathing from obstruction of the tracheotomy canula. After the operation her temperature remained near 102° for two days, then rose antemortem to 107°, and the patient died with the symptoms of toxemia, tremor, and stupor.

Dr. MIXTER of Boston reported a case that he had operated on in December. A boy of 17 years with symptoms of the juvenile type and hemianopsia. At the operation two or three ounces of cholesterin containing fluid were removed. The boy had made steady improvement.

Dr. CUSHING of Baltimore thought the nasal route the more useful, but that radical removal of the tumor was rarely possible. These tumors, like many of the long-standing tumors, as in the thyroid gland, frequently were malignant, and rarely a pure cyst. The neighborhood symptoms of the optic nerve might be relieved by simple splitting of the capsule which also relieved the headaches. In the cases of hyposecretion partial removal was followed by improvement after relief of the pressure. In one of his cases the menses had returned after several years of amenorrhea simply from relief of the pressure on the anterior lobe of the pituitary body.

Dr. KANAVEL of Chicago had been responsible for the technique in the case presented by Dr. Halstead, and had assisted at that operation. The operation had been quickly done and had given a good exposure of the bulging of the sella. In the second case of Dr. Halstead's the tumor and sella could not be seen so well, and the same trouble had occurred in Dr. Kanavel's own case. Hence he had made a series of measurements on fifty normal skulls and had found a number of important facts. In two of the fifty there had been no sphenoidal cells. In twenty-one there had been no bulging of the sella into the sinus. In ten the distance from the sella to the medulla oblongata had been but three millimeters or less, so that puncture of the medulla would be very easy. In seven the cribriform plate was so low that an extradural superior frontal operation would have been very difficult.

Dr. E. L. LEWIS of Chicago considered that the cases giving the Froelich syndrome were usually cystic tumors of the infundibulum. The tumors of the anterior lobe were of a type simulating carcinoma. Three cases had been reported of cysts of the pars intermedia.

Giant Cell Sarcoma of Bone; A Clinical and Pathological Study in the Conservative Treatment of Bone Tumors.—Dr. J. C. BLOODGOOD of Baltimore spoke of bone cysts, giant cell sarcoma, and bone aneurysm as three types of bone tumor often mistaken for each other and for malignant growths, but none of them were malignant. In the bone cysts there was a medulary lesion in which simple incision with evacuation of the cyst contents cured. In the giant cell sarcoma cure followed local removal. The bone aneurysm did form metastases, but as a rule its local removal cured. The bone cysts were subdivided into three classes, first, the medullary type with no lining membrane; the contents were not hemorrhagic and did not include any large blood clots. The second type was lined by a connective tissue membrane; the cyst cavity was of small size and the medullary cavity of the bone filled with fibrous tissue giving the name ostitis fibrosa. The third type was one of multiple cysts. He had seen eighty-nine cases operated on conservatively, and only one of them was dead

and that death was from tuberculosis. An *x*-ray picture taken six years after the operation of the first case showed a restoration of normal bone. The differential diagnosis between these types of bone cyst was of course made by incision determining whether the contents of the cyst were fluid, or fibrous. The giant cell sarcoma was cured by curetting, repeated if necessary. The bone aneurysms had cavities filled with large blood clots. Before operation it was always wise to examine the blood for the Bence-Jones bodies of multiple myeloma. The bone cysts occasionally underwent spontaneous cure.

Dr. Brewer of New York asked if the presence of blood in the bone cysts was to be taken as an indication of malignancy.

Dr. Carstens of Detroit emphasized the change in ideas that formerly any bone tumor meant a high amputation, but such was not now the idea. One case of a boy of eighteen he had operated on removing a giant cell sarcoma. The boy was well. Two years later a swelling of the humerus appeared, and again a partial resection of the humerus was done leaving only a shell of bone. The cavity was filled with an emulsion containing over two ounces of iodoform and the boy developed an iodoform poisoning. He now preferred to fill the bone cavity with a bismuth paste.

Dr. Ferguson of Chicago called attention to the fact that sixteen years ago Halstead had said that in one bone in the body, the jaw bone, sarcomata were benign.

Dr. Halstead of Chicago noted the implantation of the bone tumors at times into the soft tissues and suggested the application of strong disinfectants to the bone cavity after curretting out the tumor mass.

Dr. von Eiselsberg of Vienna said that he poured boiling water into the bone cavity, after the curettage. He found that filling the cavity with water was just as efficacious as filling it with emulsions or pastes.

Dr. Bloodgood in closing said that he too believed in disinfecting the wound after curettage with either phenol or heat. He had not found blood in any large quantities in any of the bone cysts upon which he had operated. In sarcoma of the jaw cauterization of the bone and tissues with phenol saved the teeth and destroyed the growth.

Removal of a Tack from the Left Bronchus.—Dr. Carson of St. Louis reported this case. The tack had been shown head down in the trachea in an *x*-ray photograph. Attempt at removal with the esophagoscope had pushed the tack further down into the left bronchus. On the next day edema of the mucous membrane shut off the left bronchus, and a later *x*-ray picture showed the tack at the base of the lung. Operation at that time was refused, but several weeks later consented to, when an abscess of the back had formed and discharged an ounce or more of pus. A rib was resected and the tack found behind the artery and the bronchus in a cavity containing a dram or more of pus. The operation was followed by favorable progress except for a cerebral embolus with partial paralysis. Then on the eighth day the boy suddenly started to bleed from the nose and mouth and died in a few hours. The tack had ulcerated into the artery.

The Surgical Treatment of Esophageal Diverticula.—Dr. Charles H. Mayo of Rochester, Minnesota, said that while these diverticula were rare, they were very serious. The two types of diverticula were pressure sacs from lodgment of food above a stricture, and traction sacs from adhesions due to inflammation around the esophagus usually in the neighborhood of the left bronchus. The traction sacs did not so often give symptoms. The pressure sacs occurred most frequently at the site of the laryngoesophageal juncture, and were found almost always in adults. Cardiospasm gave the same symptoms, but a tube would pass the cardiospasm into the stomach. Stricture gave the same symptoms, but the diagnosis could be made with sounds. Large diverticula appeared as tumors in the neck when dilated. Sounds passed entered either the stomach or the sac. Esophagoscopy was helpful in making the diagnosis. One sure method of diagnosis was to fill the sac with a bismuth paste and then take an *x*-ray picture. The chain and shot-filled-tube pictures were not as satisfactory. Frequently the diagnosis of cancer of the esophagus was made and gastrostomy done for its relief and then when the patient failed to die in due time from the expected cancer a new diagnosis was sought. Plummer's test was a very valuable one. The patient was given three yards of thread to swallow and the upper end of the thread fastened in the mouth. Later another three yards of thread were swallowed and then a probe was passed on the thread. The probe went into the diverticulum and then on tightening the thread, the probe was lifted out of the sac and passed on down into the stomach. The condition was to be relieved only by operation. The incision was made along the anterior border of the sternomastoid and that muscle pulled away from the median line while the other neck muscles were pulled toward the median line, exposing the esophagus. The sac was opened, amputated, closed by a mattress suture, and the wound closed. Primary union was essential. At times it was desirable to empty the sac before operation to avoid infection of the wound. In cases of fistula following the operation a thread was passed through the mouth and out of the fistula and then the fistula closed at its outer end and tied to that thread. The tract was then dissected free and the fistulous tract inverted by the thread in the mouth, and the wound closed, leaving the fistulous tract hanging in the esophagus to atrophy. He had had eight cases operated on without mortality and two not operated on, but the diagnosis confirmed by *x*-ray pictures.

Some Observations Regarding Thoracic Surgery on Human Beings.—Dr. Willy Meyer of New York said the keynote to this intrathoracic surgery lay in the differential pressure apparatus for continuing respiration after the pleural cavity had been opened. In the ordinary empyema operations immediately after emptying the pleura of the pus it was always a great help to fill the lung with air by this apparatus, then closing the opening by a rubber band for several days, although it might have to be opened again for drainage, yet the convalescence from the empyema was markedly shortened. He had had two cases of bronchiectatic abscess with foul pus expectoration for years. After a careful examination both cases had been operated on and the cavity extirpated. Both cases were lost soon after the operations. In the future he would do less extensive operations and repeat if necessary to cure. In his second case with resection of the lower lobe of the lung all went well until the last ligature was to be applied on the bronchus. Artery and vein had been tied off without trouble. Then in tying off the bronchus the patient suddenly collapsed. Apparently the pneumogastric nerve had been caught. In a case of carcinoma of the esophagus he had operated following the technique used in dogs in which he had pulled both ends of the esophagus out of the wound, resected, and done a gastrostomy with good result. In men the scapula was in the way so that an incision similar to that used in the Schedé thoracoplasty was made following the spinal border of the scapula down to the tenth rib and then forward along the rib and up in the mammary line to the second rib. The scapula, latissimus dorsi, and pectoralis major were pulled upwards with the arm. He had incised first in the sixth interspace for about ten inches, pushed the lung back, and held the ribs apart with a special rib separator. This however gave insufficient exposure at the upper end of the growth and so after partly freeing the growth in its lower portion through this incision, a second intercostal incision of similar length was made in the third interspace. This gave a beautiful exposure of the apex of

the lung, arch of the aorta, and all the growth. To enucleate the growth an incision then had to be made an inch and a half long behind the carotid artery and this portion of the esophagus was enucleated and pulled down into the thorax. It was found then that the pneumogastric nerve was involved in the growth and it had to be cut following which the patient suddenly collapsed and died. For anesthesia, nitrous oxide and oxygen were given, there was no hemorrhage and so the only cause of death was shock. He would, however, propose to operate in every case of carcinoma of the esophagus, and if the vagus nerves were involved would cut one and see whether the second could not be cut later without fatal effect. Cocaine injected into the nerves might reduce the shock. Stimulation of no kind helped in vagus injury, but respiration by the differential pressure apparatus might help.

Dr. Halstead of Chicago said that he had operated on three cases of diverticuli of the esophagus, but that he did not consider operation essential in all cases. Passing a bougie at times allowed dilatation of the stricture and displacement of the spur between the diverticulum and the esophageal channel so as to allow passage of food. Some patients were able to pass their own bougies and probangs. Operation on the spur itself through an esophagoscope might some time supplant external operation as cutting of the spur was all that was necessary to the cure of the condition. He had found that the spur in many of the cases consisted simply of a fold of mucosa with no essential structures in it, and in such cases a simple cutting of the spur would be safe. But he had not yet found the case in which he was prepared to do this operation.

Dr. Crile of Cleveland said that he had seen the Plummer test for diverticula work perfectly satisfactory. He had operated on two cases of diverticulum with recovery.

Dr. Murphy of Chicago said that as primary union of the skin wound was essential in the cure of diverticula he had not opened the sac but folded it up and sewed it to the esophagus, thus avoiding the risk of infection from the alimentary canal. The result had been perfectly satisfactory. He reported a case of supposed foreign body in the bronchus of some twenty months' duration in which he had been unable to make a corroborative diagnosis and had refused to operate. Then a throat specialist had had the case operated on and the child had died under operation. No foreign body was found, but the thymus was found very much enlarged and compressing the softened trachea.

Dr. Brewer of New York noted the great distress caused by diverticula and the special characteristic symptom rarely mentioned of the collection of thick mucus in the sac and the persistent vomiting of this mucus. He had seen three cases and operated on one of them. The sudden onset of dyspnea in the cases of large thymus not infrequently led to the supposition of a foreign body in the bronchus.

Dr. Jacobson of Syracuse reported a case of the lodgment of a bean in a bronchus, the bean swelling up from absorption of mucus. The diagnosis was made and the bean removed by bronchoscopic examination. He had seen one case with the sudden onset of dyspnea that gave rise to the suspicion of a foreign body in the air passages and tracheotomy had shown a marked thickening of the trachea obstructing its lumen due in this case to syphilis.

Dr. Vanderveer of Albany thought that the bronchoscope should be used only after tracheotomy and the attempted removal of the body with alligator forceps.

Dr. Ransohoff of Cincinnati approved of the inversion of the esophageal end of the fistula in the cases of esophageal diverticula. He had seen cerebral embolism in one case of foreign body in the air passages after coughing up of the foreign body from its abscess cavity. In one case of his own there had been dyspnea from some unknown cause sufficient to indicate a tracheotomy which he had done and a few days later the tube was removed. Not long after the child coughed up a foreign body which had not been even suspected.

Wednesday, May 4—Second Day.

Postoperative Intestinal Obstruction was considered by Dr. Woolsey of New York City. He said that the most common cause of obstruction following peritonitis was an angulation and valvular closure of the intestine, there being an adhesion of the intestine to the parietes of the abdomen or less often to other loops of intestine with a subsequent kinking of the gut, most often the small intestine. Only the firm adhesions remained holding the intestines in some abnormal positions usually above the pelvis. Pressure of the contents of the loop increased the kinking and the obstruction. At times there were adhesions to the abscess wall and then evacuation of the abscess might cure the obstruction. In three cases he had considered the Trendelenburg position a contributory cause to the obstruction. In the cases of septic peritonitis there was paralysis of the gut from reflex inhibition, or possibly from overdistention. In two cases he had seen overdistention of the intestine with obstruction following an extraperitoneal kidney operation. Obstruction was most common in the cases of acute appendicitis. The cause of death in these cases was usually autointoxication from absorption of the decomposed intestinal products. In some cases there was a distention of the splanchnic area with blood causing a subsequent lowering of blood pressure sufficient to produce symptoms. In those cases enterostomy relieved the blood pressure and might reestablish the balance of circulation. In the cases of strangulation there was intense abdominal pain. In obturation there was less pain. The location of the obstruction could be determined roughly by the time of onset of vomiting and the degree of obstruction at onset. When peritonitis was present and spreading, after the patient became toxic, rigidity of the abdominal wall might be wanting. Then absolute constipation was expected. Acute dilatation of the stomach was associated with the same factors. The condition could be prevented by avoiding sepsis, and operating in all cases as early as possible. Physostigmin was helpful in the treatment of postoperative atony with early distention, associated with the use of stupes and the lavage of stomach and colon. Adhesions could be prevented by early, careful operation, avoiding denuding of the intestines.

Experimental Surgery of the Heart and of the Thoracic Aorta.—Dr. Carrel of New York read this paper. During all of his work on dogs at the Rockefeller Institute artificial respiration was carried on through a laryngeal tube. He found that in doing blood vessel surgery it was perfectly feasible to substitute for one portion of the functioning vessel a section of another artery or vein or a tube of peritoneum, and that in 80 per cent. of the cases blood vessels that had been preserved in cold storage were perfectly satisfactory. The main difficulty in operation upon the aorta lay in the impossibility of stopping the circulation through that vessel long enough to do the operation. In fourteen or fifteen minutes paralysis of the hind legs occurred. And if the circulation were cut off in the ascending aorta, then paralysis of the brain followed. So that in those cases he had introduced a short cut for the blood, leading it from the apex of the ventricle to the descending aorta. In operating on the descending aorta he did a temporary intubation of the aorta, a glass tube being inserted and held in place by rubber bands until the operation of resection was done and then the normal circulation restored and the glass tube removed after the main operation was finished. In the ascending aorta more difficulty was found and a lateral diversion of blood current was found less efficacious than the formation of a

new channel for the blood. He had inserted a bit of vein in the apex of the heart anastomosing the other end into the side of the descending aorta, and then clamped the ascending aorta just above the heart valves. This made the blood supply the main portion of the body after going in the usual direction, but the blood to the brachiocephalic arteries went through the aorta in the reverse direction. These operations were intended as the pathfinders for the treatment of aneurysm of the thoracic aorta in its various locations, but also opened the possibility of curetting off vegetations of the heart valves and dilating aortic or auriculoventricular stenosis, and possibly of anastomosis of the coronary arteries. It was feasible to stop the heart action completely for one minute. That stopped respiration also and produced a temporary death, but so long as no cellular death followed it was perfectly feasible to start up the functions of the heart and lungs again. There was no true death without elemental death, and organic death could continue for five minutes without any psychological trouble due to brain destruction. He showed pictures of dogs living five months and more after resection of the aorta. Dr. Carrel said that his work had not been done on human beings and that he was merely looking for operative principles which would lead to later treatment of disease.

Dr. Keen of Philadelphia had seen the marvelous work of Dr. Carrel in an operation on the aorta with both pleuræ open, the lungs and the heart exposed, the aorta clamped, cut, and reunited. Anesthesia was carried on by the Meltzer method which was very safe. There had been no respiratory movements of the chest walls during the hour and a half of this operation. In this case there had been a subsequent paralysis of the back legs of the dog from clamping of the aorta, but these paralyses do at times recover. He would have the members of this association go abroad as missionaries for the Rockefeller Institute against the antivivisectionists, who threatened to do such harm in blocking the path of this wonderful surgery as well as medicine.

The Surgery of the Vascular System.—Dr. Rudolph Matas of New Orleans then delivered the presidential address on this subject. He showed the need of testing the efficiency of collateral circulation before tying off any of the large vessels called terminal vessels of the leg and neck. The tying of a large vessel was safe only in the cases where the anastomotic circulation was assured. And if that was not sure then the only safe operation was one which would not deprive the existing vessel of its vascular function. The child with the elastic arteries was much safer to operate on and in whom to produce sudden changes in blood pressure, than the older persons with sclerotic arteries, and diseased heart. And yet it was these latter that were the usual patients with aneurysm. In every peripheral aneurysm attempt should be made to retain the parent trunk of the artery, but that was not always feasible, and then heroic or even adventurous surgery might be resorted to. Aneurorrhaphy was safer than occlusion of the artery. In 145 cases he had had necrosis or gangrene in only five, and in one of the last sixty. In the early cases there was in each case an injury to the vein. All five of these cases had had an obliterative operation. The function of the collateral circulation should be known in every case before an obliterative operation was done. This was essential in the extremities and in the neck. The fitness of the collateral circulation was to be tested by applying compression to the artery proximal to the aneurysm. Then to put on an elastic bandage from the tip of the extremity up to the compression point and squeeze all of the blood out of the part up to the top of the aneurysm. After five or ten minutes the elastic bandage should be taken off leaving the compression on, and the flush of the return circulation noted. The hyperemic blush should continue to the tip of the extremity. This was Moschcowitz's test for the line of demarcation and amputation in gangrene, but the physiology of Moschowitz seemed wrong as the blush went on to the tip of the extremity. In the test of the collateral circulation if the blush did not go to the tip of the extremity in five or six minutes, hot water was to be applied to the toes to encourage the wave and if the hyperemia could not be gotten in the toes, then the collateral circulation was not efficient and an obliterative operation was contraindicated. The popliteal, aneuroraphy was followed by good function of the knee and increasing flexion. In the carotid aneurysms a temporary clamp was applied to the cervical vessels, and such was of advantage in operations on brain tumors instead of ligation of the artery. Dr. Matas applied a metal band of aluminum the width of the artery that could be compressed easily between the fingers. This was compressed until the distal pulse ceased. These aluminum band clips did no injury to the endothelium if left on for a period up to seventy-two hours. Ninety-six hours was not safe as in some instances there was an injury to the endothelium.

Dr. Halsted of Baltimore said that in one case of popliteal aneurysm he had done a vein transplantation, but that the vein had later thrombosed. No symptoms were developed, however, as evidently the collateral circulation was adequate. If he had tried the Moschowitz-Matas test he would have saved the venous transplantation. He considered the rolled band preferable to the flat band in the temporary compression of the artery and did not find it more difficult, if the appropriate instruments were at hand. He had seen no trouble after six months of closure by the rolled band.

Dr. Charles Mayo of Rochester, Minn., reported one case in which he had operated on a patient who had previously had one common carotid tied. He had applied a compression band of block tin to the remaining common carotid and at first the patient had complained of blindness as the compression was being applied. The operation was done under cocaine. He loosened the compression and the eyesight returned promptly. Six months later the patient was still well and the eyesight satisfactory.

Dr. Ransohoff said that in tumors of the jaw it was often desirable to tie the common carotid and that if the circulation was normal above the point of ligature the common carotid could be tied with impunity.

Dr. Oliver of Cincinnati said that in one case he had tied first one common carotid and after an interval of eight months the other common carotid without ill effect on the circulation.

Dr. Matas in closing said that while Dr. Halsted's rolled bands for temporary compression of an artery might be better, the flat clip applied with the finger was much easier of manipulation.

A Device for Performing Aseptically End-to-End and Lateral Anastomosis of the Intestine.—Dr. Halsted of Baltimore read this paper. He suggested the clamp and cautery division of the intestine in two places. Then the coats of the intestine were cut through down to the mucosa and the intact wall beyond the line of incision gathered down on a grooved stick of licorice. Over that stick of licorice then, in place of over a hammer head, the ends of the intestine were united. The stick of licorice dissolved in a few moments and left the lumen of the intestine clear except for the two layers of mucous membrane which perforated later, as the mucous membrane was held together only by the juxtaposition following the cauterization.

Dr. MacDonald of Albany said that keratin would probably be a better substance to use than licorice.

Dr. Ochsner of Chicago said that intestinal obstruction had practically disappeared in his clinic since the introduction of the standing order that gastric lavage should always be used in cases of nausea or distention. To this he had added the proctoclysis of Murphy which supplied the

patient with fluid, and helped remove the secretion, which, according to Maury, was the cause of the postoperative toxemia. In the cases of obstruction occurring months and years after operation a second operation might be needed. In the cases where there has been no catharsis before operation he had no mortality from postoperative obstruction. In the cases of obstruction where catharsis was useful, it was not needed; and in the cases where it was useless, it could only do harm, so that he would say that in no case where obstruction was expected should cathartics be given. During operation for obstruction, after doing an enterotomy, the gut was threaded on a large glass tube, thus evacuating the intestine. Then the intestine was irrigated through the tube and the clammy toxic condition was followed by a marked reaction.

Dr. Andrews of Chicago spoke of the several types of aseptic anastomosis of the type of the McGraw ligature. He did not, however, consider aseptic anastomosis as essential as the free lumen in the intestine.

Dr. Ferguson of Chicago to prevent adhesions powdered the raw surfaces with subgallate of bismuth on all stumps and raw surfaces and stitch holes. He had applied it over several feet of bowel and mopped of the excess with salt solution, and found it harmless.

Dr. Gerster of New York City called attention to the number of cases of intestinal adhesions after operation in which no symptoms were found, and the other cases where only a few adhesions caused grave symptoms. Even after operations done under ideal conditions adhesion formed. No cause had yet been given to account for this difference and he laid it to a difference in blood condition and in assimilative processes.

Dr. Woolsey in closing also objected to catharsis as a delay to operation.

(To be continued.)

Philadelphia Neurological Society.

At a stated meeting held April 22 Dr. Edward Mercur Williams reported "A Case of Family Spastic Paraplegia," and he demonstrated the patient. The latter was a colored boy, 17 years old, who began to walk at the age of four, and presented wasting, weakness and spasticity in the lower extremities, with exaggerated reflexes, and preserved mental powers and motor power in the upper extremities. A maternal uncle was said to suffer from a similar disorder. Dr. Andrew H. Woods reported "A Case of True Muscular Hypertrophy, with Diminished Power," and he demonstrated the patient, a colored man, about thirty-five years old, who had for many years been engaged in fairly arduous laboring work. He presented apparently excellent general muscular development, although there was wasting of a portion of one trapezius. Nevertheless there was marked weakness and want of endurance in muscular effort. For a time there had been some drooping forward of the head upon the neck, but this had disappeared under treatment. Reflexes were increased and sensibility was preserved, while the sphincter of the bladder was enfeebled. Electric reactions were essentially unchanged. Microscopic examination of an excised bit of muscle disclosed a condition of true hypertrophy of the fibers. The affection was considered an independent malady. Dr. William G. Spiller presented a communication entitled "Gradually Developing Hemiplegia as Indicative of Brain-Tumor," and he exhibited a specimen of subcortical tumor in which the symptom mentioned led to a correct diagnosis and operative intervention. In addition there was sensory aphasia and paraphasia. The tumor, however, was not discovered, and, moreover, it was infiltrating and, accordingly, not operable. Dr. Spiller dwelt upon the diagnostic significance of gradually developing hemiplegia in the recognition of tumor of the brain, and pointed out that cerebral thrombosis may give rise to a similar train of symptoms, with the difference, however, that the symptoms are likely to present some suddenness in evolution at one stage of another. Dr. George E. Price presented a communication entitled "Myxosarcoma of the Right Frontal Lobe; Extensive Degeneration in the Cord." The patient was a man who presented symptoms of focal epilepsy, for the relief of which operation was undertaken. A disc of bone was removed from the right parietal region, but the cause of the disturbance was not discovered, and death followed in three days. Autopsy, however, disclosed the presence of a new growth in the motor region on the right side, that could have been removed, and this on histologic study proved to be a myxosarcoma. In addition a rather diffuse degeneration was found in the spinal cord resembling that observed in connection with pernicious anemia. Dr. William B. Cadwalader read a communication entitled "Apoplectiform Onset of Paralysis in Pott's Disease and Its Pathology." The condition arises from sudden giving way of the softened vertebræ, with resulting destructive inflammation of the cord. Drs. George P. Muller and T. H. Weisenburg read a paper entitled "Circumscribed Spinal Serous Meningitis; Operation; Recovery," and he demonstrated the patient, a girl, 17 years old, who had complained of weakness with sensory disturbances in one lower extremity following a fall and in quick succession similar phenomena on the opposite side of the body. In the belief that the underlying condition was a tumor of the spinal cord laminectomy was performed, but an accumulation of serous fluid was found and evacuated and the patient made a complete and permanent recovery. Dr. John N. W. Rhein presented a communication entitled "Paralysis in Wild Animals," detailing the results of histologic study of the nervous system of a number of animals that had died in the Zoological Gardens. The lesions found consisted in degenerative changes in the ganglion cells of the anterior horns of the cord and of the cerebral cortex with cellular multiplication and vascular hyperemia. Dr. Alfred Gordon reported "A Case with Symptoms of Polyneuritis; Death in Ten Days; Exhibition of the Brain." The patient was a man of 20 who developed pain and weakness in the lower extremities of indeterminate origin. After death softening was found in the internal capsule on each side, without noteworthy vascular changes.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Connecticut State Medical Examining Board.

March 8 and 9, 1910.

ANATOMY.

1. Give (*a*) the number of bones in the human body; (*b*) classify them by regions of body; (*c*) classify by variety and give examples of each. Give briefly the macroscopical and the microscopical structure of bone.

2. Describe the bony relationship and landmarks of the elbow joint.

3. Describe (*a*) the anatomical relations and the structure of the mammary gland; (*b*) its nerve supply, and (*c*) its lymphatic drainage.

4. Of what does the sympathetic nervous system consist? What does the cerebrospinal system comprise?

5. State the origin and mention three branches of the ophthalmic nerve. To which system does this nerve belong, and what is its function?

6. Give the surface topography of (*a*) the appendix vermiformis; (*b*) the apex of the heart; (*c*) the apices of the lungs; (*d*) the two kidneys posteriorly.

7. What vessels unite to form (*a*) the basilar artery? (*b*) What its course.

8. Define epigastric region and tell what organs or parts of organs are found in the same. Diagram.

9. What is (*a*) the stomach? (*b*) Give its gross anatomy. (*c*) Give the minute anatomy of its mucosa.

10. Write briefly on (*a*) the decidual teeth; (*b*) the permanent teeth.

PHYSIOLOGY.

1. What is the relation of the red and white corpuscles as to (*a*) size, (*b*) numbers, (*c*) function? What causes the variation in the color of the blood?

2. State the source and describe the function of the saliva. Explain the importance of thorough mastication as related to digestion.

3. Describe the muscular movements of the large intestine and explain their function.

4. Give a physiological explanation of the rapid respiration of pneumonitis.

5. Give the localization in the cerebral cortex of the motor function of (*a*) the left side of the face; (*b*) the right arm; (*c*) the left leg. Also illustrate the external cranial topography of the same.

6. Describe the physical and nervous mechanism in normal urine evacuation.

7. How is the cornea nourished?

8. Define secretion and excretion. What organs of the body are purely excretory?

9. What part of the retina is most sensitive to visual impressions? Explain this.

10. Explain the condition causing muscle fatigue.

CHEMISTRY AND HYGIENE.

1. (*a*) How dangerous is impure air? (*b*) How tested? And what would be index of impurity? (*c*) What hygienic measures should be observed in our public schools?

2. Give chemical name and formula for the following: (*a*) blue vitriol; (*b*) common salt; (*c*) plaster of paris; (*d*) paris green; (*e*) sugar of lead; (*f*) corrosive sublimate.

3. (*a*) What are peptones? (*b*) How evolved? (*c*) What are proteoses? (*d*) What are ptomaines?

4. (*a*) What is urea? (*b*) What is the pathological significance of urea in the urine? (*c*) How estimated?

5. (*a*) Given a neutral or faintly acid urine, and on heating it a precipitate forms. What is this precipitate, and how do you determine it? (*b*) Given an alkaline urine, and on heating no precipitate is seen; is albumen present?

6. (*a*) What are ferments? (*b*) Classify them. (*c*) Name three.

7. Name the chief constituents of the bile.

8. (*a*) Discuss the influence of alcohol on the race. Is it food or poison?

9. Is sanatorium treatment of tuberculosis worth while?

10. What are the symptoms of (*a*) acute poisoning of phosphorus? (*b*) Treatment and antidote. (*c*) Test.

MATERIA MEDICA AND THERAPEUTICS.

1. What is the physiological action and therapeutics of phenacetin?

2. What are the secondary effects of alcohol upon (*a*) stomach; (*b*) liver; (*c*) vasomotor system; (*d*) nervous system?

3. What are emetics? In what way do they act? When indicated? When contraindicated?

4. What changes take place in the blood when illuminating gas is inhaled? Give treatment.

5. What is the action and dose of pilocarpine? Of apomorphine?

6. What is the physiological action and what are the uses of potassium acetate?

7. Name three heart depressants and tell how they act.

8. How and upon what portion of the alimentary tract do the following drugs act: cascara, phosphate of soda, aloes, jalap and calomel?

9. Write a prescription in Latin, unabbreviated, for acute bronchitis, containing four ingredients, and give the action of each.

10. Treat a case of infantile convulsions.

PRACTICE, PATHOLOGY AND DIAGNOSIS.

1. Describe the varieties of stomatitis: (*a*) simple, (*b*) aphthous, (*c*) mycotic, (*d*) ulcerative. Give the causes and treatment.

2. Give the etiology of congestion of the liver, active and passive.

3. Differentiate cardiac asthma from bronchial or spasmodic asthma—symptomatically and pathologically.

4. What are the causes of albuminuria, renal and extrarenal?

5. Describe a case of acute inflammatory rheumatism: state its complications and sequels.

6. What are the varieties of influenza? Give the prominent symptoms of each variety.

7. Diagnosis of scarlet fever, smallpox, measles, and chickenpox; (*a*) period of incubation; (*b*) eruption; (*c*) course of each disease.

8. Differentiate between cerebrospinal fever and tubercular meningitis, pathologically.

9. Give the symptoms and treatment of chorea.

10. When is the eye ametropic, and what are the forms of ametropia?

OBSTETRICS AND GYNECOLOGY.

1. (*a*) Describe the relation between ovulation and menstruation; (*b*) what is the present belief as regards migration of the ovum?

2. (*a*) State the cause of the premature detachment of the placenta; (*b*) what are the dangers? (*c*) Treatment.

3. (*a*) Give all the causes of prolonged first stage labor; (*b*) the dangers; (*c*) management.

4. (*a*) What are the indications for the use of forceps? (*b*) What condition necessitates version rather than forceps? (*c*) What cesarean section rather than version?

5. (*a*) What are the changes that occur in the uterus during pregnancy? (*b*) After delivery?

6. Differentiate an ovarian cyst from (*a*) ascites; (*b*) hydramnios; (*c*) fibroid tumor; (*d*) distended bladder; (*e*) hematometra.

7. (*a*) What is sapremia? (*b*) How does it differ from septicemia? (*c*) Should treatment differ?

8. (*a*) What pathological conditions require curettage? (*b*) Give the operative technique.

9. (*a*) Give three causes for post-partum hemorrhage. (*b*) Your treatment for each.

10. What are the operative procedures in the treatment of prolapsus uteri? Give indications for each.

SURGERY.

1. Aneurysm: (*a*) causation; (*b*) varieties; (*c*) diagnosis.

2. Carbuncle: (*a*) defined; (*b*) predisposing causes; (*c*) diagnosis; (*d*) treatment.

3. Local anesthesia. Technique of its application in hernia, removal of appendix, or thyroidectomy?

4. Practical demonstration of the use of Janeway's manometer.

5. State your views as to the scope and value of blood pressure determinations in operative surgery under general anesthesia.

6. Describe or depict the arrangement of the synovial sheaths of the palm and fingers.

7. Give the differential diagnosis between a fracture and dislocation at the hip.

8. Diagnosis and treatment of fractured clavicle.

9. What do you consider the best operation for internal hemorrhoids? Describe your technique.

10. Carcinoma: (*a*) varieties; (*b*) location in order of frequency; (*c*) metastasis; (*d*) differentiation?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

CONNECTICUT STATE MEDICAL EXAMINING BOARD.

March 8 and 9, 1910.

ANATOMY.

1. (*a*) There are 206 named bones in the human body. (*b*) *By regions:* The spine, with sacrum and coccyx; cranium, and face, with ossicles of the ear; hyoid, sternum, and ribs; upper extremities; and lower extremities. (*c*) *By variety:* Long bones, as femur and humerus; short bones, as carpal and tarsal; flat bones, as parietal and scapula; irregular bones, as vertebræ and sphenoid.

For *structure*, see Cunningham's "Anatomy" (1909), pages 71 and 72; or, Gray's "Anatomy" (1908), pages 34 to 40.

2. There are three bony points: The external condyle of the humerus, the internal condyle of the humerus, and the olecranon process of the ulna. When the forearm is extended these three points are in a straight line; when the forearm is flexed, the olecranon is a little below the line joining the two condyles. The head of the radius can be felt from behind, nearly one inch below the external condyle. The internal condyle is more prominent than the external condyle; the olecranon is nearer to the inner than to the outer condyle.

3. See Cunningham's "Anatomy" (1909), pages 1207 and 923; or, Gray's "Anatomy" (1908), pages 1516 and 810.

4. "*The sympathetic nervous system consists of* (1) a series of ganglia connected together by a great ganglionic cord, the gangliated cord, extending from the base of the skull to the coccyx, one gangliated cord on each side of

the middle line of the body, partly in front and partly on each side of the vertebral column; (2) of three great gangliated plexuses or aggregations of nerves and ganglia, situated in front of the spine in the thoracic, abdominal, and pelvic cavities respectively; (3) of smaller or terminal ganglia, situated in relation with the abdominal viscera; and (4) of numerous fibers."

The cerebrospinal system comprises the central nervous axis (brain and spinal cord) and the peripheral nerves (cranial and spinal).

5. The ophthalmic nerve is a branch of the trigeminal (fifth cranial) nerve. Its three branches are the Lacrymal, Frontal, and Nasal. It is a sensory nerve belonging to the cerebrospinal system. Its function is to supply sensation to the anterior half of the scalp, conjunctiva and skin of upper eyelid, cornea, skin of nose, mucous membrane of nose, and lacrymal gland.

6. See Gray's "Anatomy" (1908), (*a*) page 1331; (*b*) page 580; (*c*) page 1405; (*d*) page 1434.

7. (*a*) The two vertebral arteries. (*b*) It is situated in the center of a groove on the under surface or front of the pons, extending from the posterior to the anterior border. It lies between the sixth pair of cranial nerves.

8. See Cunningham's "Anatomy" (1909), pages 1046 and 1047; or, Gray's "Anatomy" (1908), pages 1243, 1244, and 1246.

9. See Cunningham's "Anatomy" (1909), pages 1050 to 1060; or, Gray's "Anatomy" (1908), pages 1277 to 1285.

10. See Cunningham's "Anatomy" (1909), pages 1016 and 1022; or, Gray's "Anatomy" (1908), page 1206.

PHYSIOLOGY.

1. (*a*) Red corpuscles are about 1/3200 of an inch in diameter; white corpuscles are about 1/2500 of an inch in diameter.

(*b*) There are about 4,500,000 to 5,000,000 red corpuscles in each cubic millimeter of blood, and about 7,000 to 10,000 or 12,000 white corpuscles in each cubic millimeter of blood.

(*c*) The function of the red corpuscles is to carry oxygen from the lungs to the tissues. Function of the white corpuscles: (1) To serve as a protection to the body from the incursions of pathogenic microorganisms; (2) they take some part in the process of the coagulation of the blood; (3) they aid in the absorption of fats and peptones from the intestine, and (4) they help to maintain the proper proteid content of the blood plasma. The variation in the color of the blood is due to the presence of oxygen in combination with hemoglobin, giving to arterial blood its red color, and the presence of carbon dioxide (with lessened oxygen), giving to venous blood its bluish color.

2. *Source of saliva:* The parotid, submaxillary, and sublingual glands (and the small mucous and serous glands of the mouth).

The functions of the saliva are: (1) To moisten the mouth, (2) to assist in the solution of the soluble portions of the food, and thus (3) to administer to the sense of taste; (4) to lubricate the bolus of food, and thus (5) to facilitate the acts of mastication and deglutition, and (6) to change starches into dextrin and sugar. Thorough mastication prepares the solid and fibrous foods for the more ready and speedy action of the various digestive juices; it enables these foods to present also a larger surface to the action of these juices. Food that is imperfectly masticated may cause suffocation; it is also a well-known cause of indigestion.

3. The muscular movements of the large intestine are chiefly of the peristaltic or vermicular kind. This is a wave-like motion, characterized by a contraction of the circular fibers behind a bolus and a relaxation of the fibers in advance of it. The result is a movement forward of the bolus, and as it moves it is followed by a ring of constriction and preceded by a ring of relaxation or inhibition. Under the influence of this peristaltic movement the contents of the large intestine (food residues and excrementitious matter) are gradually carried downward toward the sigmoid flexure, where they accumulate prior to their extrusion from the body. The effects of the peristaltic waves are to some extent interfered with by antiperistaltic waves, which, beginning in the transverse colon, run toward and to the cecum. The intestinal contents are thereby driven back toward the cecum. The effect is a still further admixture with the secretions and exposure to the absorbing mucosa. There is some evidence also that the antiperistaltic wave may force some of the liquefied contents through the ileocolic opening into the small intestine because of the relaxation of the sphincter muscle. (From Brubaker's *Physiology.*)

4. The rapid respiration in pneumonia is due to: (1) Toxemia, which affects the respiratory center; (2) the amount of lung involved; (3) the limited air space left for use; (4) pain.

5. See Cunningham's "Anatomy" (1909), pages 1224 and 1227; or, Gray's "Anatomy" (1908), pages 966 and 970.

6. "The urine trickles drop by drop down the ureters, into the bladder, where it collects and gradually distends it. The exit from the bladder is opposed by the sphincter vesicæ, or, as some believe, by the elastic and muscular fibers of the urethra. The urine is expelled by the contraction of the walls of the bladder, more especially by the detrusor vesicæ, and is assisted when much distended by the contraction of the abdominal walls. Micturition is a reflex act, but one which (with the exception of infants) is under the influence, if not under the control of the will. The mechanism appears to consist of an automatic center in the lumbar part of the cord, maintaining the constant contraction of the sphincter, a second center, which, when stimulated, excites contraction in the detrusor. These centers are antagonistic, so that an afferent impulse from the bladder excites the detrusor center, at the same time inhibiting the sphincter center. These centers are normally under the control of the will, so that, although an afferent impulse may ascend from the bladder to the centers of the cord and up to the sensorium, yet by an effort of will the sphincter center may be assisted and the detrusor inhibited, or *vice versa.* Thus when the bladder becomes distended an afferent impulse from the bladder reaches both lumbar center and the brain; if the opportunity is favorable for micturition the controlling influence of the will is removed, the reflex contraction of the detrusor taking place, assisted perhaps by the voluntary abdominal muscles." (Ashby's *Physiology.*)

7. The cornea is nourished chiefly by the lymph in the corneal spaces or lacunæ and canaliculi. At its border, for a very short distance, there are also capillary loops from the sclera and conjunctiva.

8. *Secretion* is the process by which certain organs (glands and membranes) separate from the blood certain constituents which are further elaborated and serve some further office in the economy.

Excretion is a similar process by which there are removed from the blood waste materials, and products of no further use to the body, and which, if retained, would be injurious.

The purely excretory organs are: Kidneys and skin.

9. The fovea centralis in the macula lutea is the part of the retina most sensitive to visual impressions. Here the end organs of the optic nerve are most highly developed; the cones are here increased both in number and in size.

10. *Causes of fatigue in muscle:* Presence of sarcolactic acid and acid potassium phosphate in the muscle; using up of the material from which the energy is obtained; and accumulation of carbon dioxide and other waste products.

CHEMISTRY AND HYGIENE.

1. (*a*) The danger of impure air depends upon: (1) The amount of oxygen present; (2) the amount and nature of impurities present (the chief being carbon dioxide, organic matters, crowd poison, disease germs, combustion products, emanations from sewers or marshes, contaminations from trade and manufacturing processes, and decomposition products).

(*b*) *Pettenkofer's method of determining the percentage of carbon dioxide in the air:* A large cylindrical container of known capacity, say, 15 liters, is filled with the air to be examined; a known volume of barium hydroxide is then added and shaken up with the air. The carbon dioxide combines with the barium hydroxide to form a barium carbonate, which is insoluble, and also incapable of acting upon an indicator. The barium hydroxide employed is of known strength, *e.g.* it may be of such strength that 1 c.c. of the solution neutralizes 1 c.c. of carbon dioxide at normal temperature and pressure. If then we find that 10 c.c. of the barium hydroxide has been neutralized by the carbon dioxide present in the air, we know that 10 c.c. of carbon dioxide is present in 15 liters or 15,000 c.c. of the air examined.

2.

	CHEMICAL NAME.	FORMULA
(a) Blue vitriol.	Cupric sulphate.	$CuSO_4$.
(b) Common salt.	Sodium chloride.	NaCl.
(c) Plaster of Paris.	Calcium sulphate.	$CaSO_4$.
(d) Paris green.	Cupric aceto-metarsenite.	$Cu(C_2H_3O_2)_2 + 3CuAs_2O_4$.
(e) Sugar of lead.	Lead acetate.	$Pb(C_2H_3O_2)_2$.
(f) Corrosive sublimate.	Mercuric chloride.	$HgCl_2$.

3. (*a*) *Peptones* are the final products of the action of proteolytic ferments on proteids.

(*b*) By the action of proteolytic ferment (pepsin and trypsin) on proteids.

(*c*) *Proteoses* are the intermediate products in the conversion of proteids into peptones.

(*d*) *Ptomaines* are basic, nitrogenous compounds, produced from protein material by the bacteria which cause putrefaction.

4. (*a*) *Urea* is the end product of the proteid metabolism of the body. It is a crystalline solid, soluble in water, colorless, odorless, with a slightly bitter taste; it is neutral in reaction, but basic in character; dilute aqueous solutions are not decomposed by boiling, but by prolonged boiling urea is hydrolized to ammonia and carbon dioxide; urea forms compounds with acids and also with certain salts and oxides. Formula is CON_2H_4.

(*b*) Urea is always present in the urine, a healthy man excreting about 500 grains of urea daily. Pathologically, the amount of urea excreted may be diminished or increased, as follows:

A *diminution* may be due to some condition interfering with the normal transformation of proteins in the body, as in certain chronic diseases. More frequently, however, a diminished proportion of urea in the urine is not due to a diminution in the production, but to the fact that the urea formed has not been separated by the kidneys as in uremia, and in diseases attended with dropsical effusions. Pathologically it is *increased* in the early stages of all acute febrile diseases, except when these are attended by the formation of dropsical deposits or by diarrhea; during reabsorption of dropsical fluids; in both forms of diabetes, and in chronic interstitial nephritis.

(*c*) "The specific gravity of the urine is carefully determined, as well as that of the liquor sodæ chlorinatæ. One volume of the urine is then mixed with exactly seven volumes of the liquor sodæ chlorinatæ, and, after the first violence of the reaction has subsided, the mixture is shaken from time to time during an hour, when the decomposition is complete; the specific gravity of the mixture is then determined. As the reaction begins instantaneously when the urine and reagent are mixed, the specific gravity of the mixture must be calculated by adding together once the specific gravity of the urine and seven times the specific gravity of the liquor sodæ chlorinatæ, and dividing the sum by eight. From the quotient so obtained the specific gravity of the mixture after decomposition is subtracted; every degree of loss in specific gravity indicates 0.7791 gram of urea in 100 c.c. of urine. The specific gravity determinations must all be made at the same temperature, and that of the mixture only when the evolution of gas has ceased entirely." (Witthaus' *Manual of Chemistry.*)

5. (*a*) Albumin or phosphates. Add HNO_3; this will dissolve the phosphates, but not the albumin.

(*b*) Albumin may or may not be present.

6. *Ferments* are certain microorganisms (bacteria, mould and yeast fungi) which, by their growth, cause definite chemical changes in certain substances contained in the media in which they develop. They are *classified* as: (1) Proteolytic, *e.g.* trypsin; (2) amylolytic, *e.g.* ptyalin; (3) steatolytic, *e.g.* steapsin; (4) inverting, *e.g.* invertin; (5) coagulating, *e.g.* milk curdling ferment.

7. Water, sodium glycocholate, sodium taurocholate, bilirubin, biliverdin, fats, soaps, cholesterin, lecithin, urea, sodium chloride.

8. The influence of alcohol on the race cannot be discussed in the space at our disposal. Most of what is written on the subject has absolutely no scientific value, being characterized by prejudices and diatribes rather than by logic and science. Probably most races would benefit if some of the individuals of these races consumed less alcohol. That alcohol is abused or misused is true; so are money and many other things, and the abuse of a thing is no argument against its legitimate use. As to whether alcohol is a food or a poison, there is also much difference of opinion. Taken in excess, it may be a poison; but many scientists believe that it has also a food value. Much depends on the conditions under which it is used and the quantity in which it is taken. The student (and examiner) will easily find any quantity of "literature" which will favor his own particular views or prejudices in the matter, but very little of it is of scientific value.

9. See French's "Practice of Medicine" (1907), page 394; or, Osler's "Practice of Medicine" (1909), page 354.

10. (*a*) Eructation of gas having the odor of garlic. The mouth, when observed in the dark, is frequently faintly luminous (phosphorescent). After several hours, pain in the throat, a sense of heat in the epigastrium, nausea, and vomiting. The vomited matters are sometimes bloody, and frequently luminous when agitated in the dark. The abdomen is tender, and there are diarrhea and colicky pains. After one or two days these symptoms cease, there remaining only pain in the back and limbs and a feeble pulse. Death sometimes occurs suddenly in from two to four days. Usually about the fourth day the patient becomes jaundiced, suffers from headache, insomnia, and retention of urine, rapidly becomes delirious and comatose, and dies.

(*b*) The unabsorbed portion is to be removed as speedily as possible by an emetic of copper sulphate or apomorphin. No chemical antidote is known. French oil of turpentine (the older the better) should be given as a physiological antidote. The food should be free from oils and fats.

(*c*) The matters supposed to contain phosphorus are rendered fluid by dilution with water and acidulated with sulphuric acid. They are placed in a flask upon a sand bath and the flask connected with a Liebig's condenser, which is placed in absolute darkness. Upon heating the flask any phosphorus present is volatilized, and, condensing in the tube, forms a luminous ring. This reaction is very delicate, and the appearance of the ring is proof positive of the presence of unoxidized phosphorus. (From Witthaus' *Essentials of Chemistry and Toxicology.*)

MATERIA MEDICA AND THERAPEUTICS.

1. PHENACETIN. *Physiological Action:* Lowers body temperature, and is an analgesic; it is also a cardiac depressant. *Therapeutics:* In fevers, as an antipyretic, and to relieve pain; also used in epilepsy.

2. The stomach is overstimulated and congested, the gastric glands are similarly affected, gastric catarrh ensues, digestion is impaired, and morning vomiting may occur. The liver and hepatic cells suffer in a similar way. Degenerative changes may follow. It is a vasodilator, and lowers arterial tension. The nervous system is specially affected, and eventually paralysis or epilepsy may result from the long continued use of alcohol.

3. *Emetics* are agents which produce vomiting. They *act:* (1) By irritating the nerves of the stomach, esophagus, or pharynx; (2) through the circulation; (3) by irritation of the vomiting center in the medulla. *Indications:* To produce vomiting or nausea; in catarrhal conditions of the respiratory tract; to remove poisons or foreign bodies from stomach, esophagus, etc.; to empty the stomach. *Contraindications:* Severe cardiac lesions and aortic aneurysm; atheroma; when the patient is so weak that there is danger of collapse; in poisoning by caustics; in hernia or peritonitis, or in cases of high arterial tension.

4. When illuminating gas is inhaled, the color of the blood is a very bright red, much brighter than normal; the cells are not altered in *appearance,* but the red corpuscles are incapable of carrying oxygen to the tissues, as the carbon monoxide forms with the hemoglobin a compound which is very much more stable than oxyhemoglobin. The spectroscope shows, also, a characteristic absorption spectrum. *Treatment:* Stimulants, fresh air, bleeding, and hypodermocleisis, or infusion of normal salt solution.

5. PILOCARPINE: *Dose,* gr. 1/5. *Action:* Stimulant of secretory nerves and of involuntary muscles, myotic, nervous depressant, sudorific.

APOMORPHINE HYDROCHLORIDE. *Dose:* As an emetic, gr. 1/10 subcutaneously; as an expectorant, gr. 1/30. *Physiological action:* It acts on the vomiting center in the medulla, hence is emetic; it increases pulse, blood pressure, and rate of respiration; it is also an expectorant.

6. POTASSIUM ACETATE. *Physiological action:* Antacid, increases alkalinity of the blood and of the urine, is a diuretic, and a diaphonetic. *Uses:* In rheumatism, gout, fevers, dropsy, nephritis, cystitis, and irritation of the urinary tract.

7. *Three cardiac depressants:* (1) Antimony, which depresses the motor ganglia; (2) pilocarpine, which stimulates the inhibitory ganglia and depresses the heart muscle and also the motor ganglia; (3) hydrocyanic acid, which is a direct cardiac poison, depressing the heart muscle and the motor ganglia.

8. *Cascara* is a stomachic and laxative, and acts on the stomach and small intestine. *Phosphate of sodium* is a saline, hepatic stimulant, and cholagogue; it acts on liver and colon. *Aloes* is a purgative, hepatic stimulant, and cholagogue, and acts on the large intestine (chiefly descending colon and rectum) and liver. *Jalap* is a drastic purgative, and acts on the small intestine. *Calomel* is a simple purgative, and acts on the small intestine.

9. ℞. Ammonii carbonatis, ʒj.
Spiritus chloroformi, ʒj.
Syrupi pruni virginianæ, ʒj.
Misturæ glycyrrhizæ compositæ, q.s. ad. ʒviij.
Misce.
Signa: One tablespoonful every three hours.

The ammonium carbonate is a respiratory stimulant and a stimulating expectorant. The chloroform disguises the taste of the ammonium. The prunus virginiana is a sedative and expectorant. The glycyrrhiza is an expectorant.

10. See French's "Practice of Medicine" (1907), page 1124; or Osler's "Practice of Medicine" (1909), page 1058.

PRACTICE, PATHOLOGY, AND DIAGNOSIS.

1. See French's "Practice of Medicine" (1907), pages 707 to 710; or Osler's "Practice" (1909), pages 434 to 437.

2. See French's "Practice of Medicine" (1907), page 817; or Osler's "Practice of Medicine" (1909), page 541.

3. See French's "Practice of Medicine" (1907), page 659; and Osler's "Practice of Medicine" (1909), page 610.

4. *Albuminuria* is found: "(1) In fevers, as typhoid and pneumonia. (2) In valvular heart lesions, degeneration of the heart muscles, diseases of the coronary arteries, impeded pulmonary circulation, in pregnancy by pressure upon the renal veins, in intestinal catarrh, and in Asiatic cholera. (3) In purpura, scurvy, leukemia, pernicious anemia, jaundice, diabetes, and syphilis. (4) After taking lead, mercury, iodine, phosphorus, arsenic, antimony, chloroform, cantharides, oxalic, carbolic, salicylic, or the mineral acids, turpentine and nitrates. (5) In large amounts in acute nephritis and chronic parenchymatous nephritis; in small amounts in chronic interstitial nephritis, and amyloid kidney."—(Witthaus' *Essentials of Chemistry.*)

5. See French's "Practice of Medicine" (1907), pages 222 to 230; or Osler's "Practice of Medicine" (1909), pages 219 to 226.

6. See French's "Practice of Medicine" (1907), pages 132 to 136; or Osler's "Practice of Medicine" (1909), pages 153 and 154.

7. *Scarlet fever:* Period of incubation, from a few hours to seven days. Stage of invasion, twenty-four hours. Character of eruption, a scarlet punctate rash, beginning on neck and chest, then covering face and body; desquamation is scaly or in flakes. The eruption is brighter, is on a red background, punctiform, and is more uniform; the temperature is higher, the pulse quicker; the tongue is of the "strawberry" type, the lymphatics in the neck may be swollen, and there is sore throat; Koplik's spots are absent. *Smallpox:* The eruption usually appears first on the forehead and wrists, and on the third or fourth day; it is first mascular, then papular, then vesicular, and finally pustular; it does not appear in successive crops; the spots are multilocular, and do not collapse on being punctured; the papule is hard and shotty, and does not disappear on stretching the skin. Period of incubation is from eight to fourteen days. *Measles:* Period of incubation, ten to twelve days. Stage of invasion, four days. Character of eruption, small, dark red papules with crescentic borders, beginning on face and rapidly spreading over the entire body; desquamation is brauny. The eruption is darker, less uniform, more shotty; the temperature is lower, pulse slower, the tongue is not of the "strawberry" type; coryza, coughing, and sneezing may be present; Koplik's spots are present. *Chickenpox:* The eruption usually appears first on the trunk, is evident on the first day, comes in successive crops, is not shotty, and disappears on stretching the skin; the spots are unilocular, and collapse on being punctured. The period of incubation is from four to fourteen days.

8. See Osler's "Practice of Medicine" (1909), pages 159 and 301.

9. See French's "Practice of Medicine" (1907), pages 1118 and 1120; or Osler's "Practice of Medicine" (1909), pages 1048 and 1052.

10. The eye is *amctropic* when, in a condition of rest, parallel rays of light are focussed either behind or in front of the retina, and not on it. The forms of ametropia are: Hyperopia, myopia, and astigmatism.

OBSTETRICS AND GYNECOLOGY.

1. See Williams' "Obstetrics" (1909), pages 83 and 85; or Hirst's "Obstetrics" (1909), pages 65 and 62.

2. See Williams' "Obstetrics" (1909), pages 805, 808, and 810; or Hirst's "Obstetrics" (1909), pages 583 and 585.

3. See Williams' "Obstetrics" (1909), pages 658 to 663; or Hirst's "Obstetrics" (1909), pages 439 to 444.

4. (*a*) *Indications for the use of forceps* are: "1. *Forces at fault:* Inertia uteri in the presence of conditions likely to jeopardize the interests of mother or child. (*a*) Impending exhaustion; (*b*) arrest of head, from feeble pains. 2. *Passages at fault:* Moderate narrowing, 3¼ to 3¾ inches, true conjugate; moderate obstruction in the soft parts. 3. *Passenger at fault:* A.—Dystocia due to (*a*) occipitoposterior, (*b*) mentoanterior face, (*c*) breech arrested in cavity. B.—Evidence of fetal exhaustion (pulse above 160 or below 100 per minute). 4. *Accidental complications:* Hemorrhage; prolapsus funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother or child, or both." (*b*) *Indications for version* are: (1) In transverse presentations: (2) in placenta prævia; (3) in malpresentations of the head; (4) in simple flattened pelvis, and in minor degrees of pelvic contraction; (5) in prolapsed funis; (6) in sudden death of the mother, and (7) in any case where speedy delivery is imperative. (*c*) *Indications for cesarean section* are: Extreme pelvic contraction or deformity in which delivery by forceps or version or symphyseotomy is impossible, and in which craniotomy is either impossible or would be more dangerous to the mother; the presence of extreme atresia of the vagina; rupture of the uterus; sudden maternal death.

5. See Williams' "Obstetrics" (1909), pages 165 to 169, 185, and 332 to 334; or Hirst's "Obstetrics" (1909), pages 182 and 348 to 353.

6.

ASCITES.	OVARIAN CYST.
1. Previous history of visceral disease.	1. No such history.
2. Enlargement comparatively sudden.	2. Gradual.
3. Face puffy; color waxy; early anemia.	3. Facies ovariana. Anemia absent, or later.
4. Patient on back, enlargement symmetrical; flat in front.	4. Asymmetrical until tumor is quite large; prominent in front.
5. Sitting up, abdomen bulges below.	5. No appreciable change.
6. Navel prominent and thinned.	6. Navel usually unchanged.
7. Fluctuation decidedly clear, diffuse throughout abdomen, but avoids highest parts in all positions, and always has a hydrostatic level.	7. Less clear; limited to cyst; not modified by change of position. No hydrostatic level.
8. Intestines float on top of fluid; hence percussion gives clear tympanitic note over the highest parts of abdominal cavity, and dullness in lowest parts for all positions, *i.e.* areas of resonance and dullness change with position.	8. No change in areas of dullness and resonance with change of position. Dullness over cyst. Clear resonant note in all parts beyond cyst limits, *i.e.* in flanks and toward the diaphragm.
9. Vaginal touch detects fluctuation, bulging into vagina.	9. Vaginal fluctuation less clear or absent.
10. Uterus in prolapsed location, but position unchanged. Size and mobility unchanged.	10. Uterus displaced forward or backward, or laterally by pressure of cyst.
11. Hydragogues and diuretics temporarily remove the fluid.	11. Medicines have no effect.
12. Fluid light straw color and thin. Coagulates spontaneously.	12. Fluid light or dark and of varying consistency; albuminous, but does not coagulate spontaneously; may contain colloid matter.

HYDRAMNIOS.	OVARIAN CYST.
1. Evidence of pregnancy.	1. Not usual.
2. Rapid development.	2. Less rapid.
3. Ballottement.	3. Absent.
4. Distention symmetrical.	4. Distention more on one side.

FIBROID TUMOR.	OVARIAN CYST.
1. Slow growth.	1. Usually more rapid growth.
2. Facial expression unchanged. Face may be full and flushed; later pale from hemorrhage.	2. Facies ovariana.
3. General health usually unimpaired except from loss of blood, if submucous or mural; may be painful.	3. General health early impaired from emaciation. Not painful.
4. Abdomen usually very asymmetrical from irregular shape of tumor.	4. Abdomen more symmetrical, especially when tumor is large.
5. Abdominal veins not usually enlarged.	5. Usually enlarged, especially in large polycysts.

FIBROID TUMOR.	OVARIAN CYST.
6. Action of kidneys normal.	6. Kidneys less active.
7. Usual menorrhagia.	7. Menstruation unchanged or diminished.
8. Elasticity, not fluctuation. No percussion wave.	8. Fluctuation marked. Percussion wave marked.
9. Surface firm and usually lobulated.	9. Surface yielding; in monocysts, regular; in polycysts, irregular.
10. Vaginal touch and conjoined examination show tumor dense and firm, and, unless pedunculated, continuous with uterus. Uterus large and heavy.	10. Uterus normal, except displacement from pressure. Tumor compressible, fluctuating, detached from uterus.
11. Uterine cavity much elongated.	11. Not materially elongated. (This is a most important diagnostic point.)
12. Uterus moves with tumor.	12. Does not move with tumor.

Distended bladder: The use of a catheter will absolutely settle the diagnosis.

Hematometra: The enlargement is perfectly symmetrical, and external os or cervix will be found completely closed.—(Tables from Dudley's *Gynecology.*)

7. See Williams' "Obstetrics" (1909), pages 852 and 856; or Hirst's "Obstetrics" (1909), page 764.

8. CURETTAGE. *Pathological Indications:* To remove pieces of retained placenta or decidua, endometritis, mucous polypi, hemorrhage, dysmenorrhea, endocervicitis. *Dangers:* Sepsis, perforation of uterus, hemorrhage, abortion, inflammation of uterus, or adnexa. *Procedure:* All antiseptic and aseptic precautions are necessary, the patient should be in the dorsal position, the vagina is to be disinfected, and the cervical canal dilated; a speculum is introduced into the vagina and the cervix is drawn down with volsella; the uterine cavity is irrigated with creolin or lysol; a curette is inserted to the fundus and moved down to the internal os; the operator should begin at one cornu and go in the same direction all around till he reaches the starting point, and if necessary repeat till no more spongy or hyperplastic tissue appears; the fundus should be scraped separately by moving the curette along it from side to side; in going towards the fundus no scraping should be done, and care must be taken not to perforate the uterus; should this happen no fluid must be injected; otherwise the uterus and vagina are again irrigated, and one or more strips of iodoform gauze are inserted into the cavity to act either as a hemostatic plug or as a drain, which is diminished with two days' interval and withdrawn on the sixth day. A hemostatic tampon should be placed in the vagina and withdrawn the following day. If any fever arises, the tampon is at once removed and the vagina douched with antiseptic fluid every three hours. If not, the vagina is only swabbed with the same every day, and packed loosely with iodoform gauze. After the final removal of the gauze the antiseptic douche is given twice a day until there is no more discharge. The patient should remain in bed for a week.

9. See Williams' "Obstetrics" (1909), pages 818 and 821; or Hirst's "Obstetrics" (1909), pages 585 and 587.

10. "A prolapsed uterus must first be placed in proper position, or a procidentia reduced. In many cases the introduction of a rubber ring pessary will then suffice to prevent recurrence. But it will often be found necessary to repair a torn perineum, removing at the same time redundant portions of the vaginal walls, before the ring will remain in the vagina. When such an operation is contraindicated, and the vaginal orifice is so wide that a ring cannot be kept in, some form of pessary with a vaginal stem and perineal bands will be required. In cases of procidentia, where the exposed surface is much ulcerated, the patient should be kept in bed, emollient applications made to the ulcers, and vaginal douches given. When the ulcers have healed, a pessary may be introduced. Procidentia due to supravaginal elongation of the cervix must be differently dealt with. Amputation of a portion of the cervix must therefore form the first step in the treatment, and it may be required also when the hyperplasia is secondary to descent. Cases of prolapse and procidentia which resist milder measures require further operative procedures, such as ventrofixation of the uterus or the shortening of the round ligaments. It is in cases of this kind that hysteropexy has often given satisfactory results. Total extirpation of the uterus has been advised and practised for the treatment of procidentia."—(Sutton and Giles' *Diseases of Women.*)

SURGERY.

1. See Rose and Carless' "Surgery" (1908), pages 307, 308, 310, and 311; or Da Costa's "Surgery" (1908), pages 359, 356, and 361.

2. See Rose and Carless' "Surgery" (1908), pages 399 and 400; or Da Costa's "Surgery" (1908), page 1057.

3. See Rose and Carless' "Surgery" (1908), page 1318; or Da Costa's "Surgery" (1908), page 1047.

4. "The portable instrument of Janeway is accurate and practical because of its broad arm piece, which excludes the errors (high readings) inherent in the narrow compression bands when applied to unusually fat or muscular arms, and because of its accurate regulation of pressure by a stopcock. *Technique:* The hollow armlet applied midway between shoulder and elbow is inflated by the hand bulb until the radial pulse is lost, then by the outlet thumbscrew the pressure is lowered until the pulse return is just perceptible. As the pressure is equal in all parts of the closed system, the height of the mercury column in the manometer tube is an exact index, and the reading represents the 'maximum' or 'systolic' pressure. 'Diastolic' or 'minimum' pressure is determined by noting for ten or twelve pulsations the increasing amplitude of the pulse wave registered by the mercury column as the pressure is reduced in 5-mm. series. The point causing maximum excursion is the index of diastolic pressure. Below that is a limited pressure area of equal amplitudes. The 'mean' pressure represents the average of systolic and diastolic readings. Diastolic readings run about 25 to 40 below systolic, and in low tension vary 50 to 80, and in regurgitation up to 100 mm. A loose band or a rapid or excessively small pulse makes diastolic pressure determination impossible, and in every case the arm band should be closely adjusted, the arm supported at the heart level and the same position taken for a series of tests. The limit of error in calcareous arteries is but 5 to 10 mm., and is negligible or easily estimated. The same figures represent the difference between females and <males and the standing> and sitting posture. In normal pressure four factors are concerned, viz., the initial heart energy, peripheral resistance, blood volume, and the elasticity of the vessels. The normal readings, according to Janeway, are: For young adults, 100 to 130; older adults, 100 to 145; children, 90 to 110; infants under two years, 75 to 90. Excitement may cause a rise of 40 mm., and concentrated physical effort a slight increase."—(Greene's *Diagnosis.*)

5. The blood pressure is an indication of the degree of shock; in severe operations it is generally lowered below 100 mm.; and below 80 mm. is supposed to be indicative of danger. It is not in general use but is (theoretically) of value.

6. See Gray's "Anatomy" (1908), page 494; or Rose and Carless' "Surgery" (1908), page 247.

7. In fracture of the neck of the femur, the head of the femur will be found in the acetabulum; in dislocation, the acetabulum will be empty, and the head of the femur will be found elsewhere, *e.g.* on the dorsum of the ilium. In the fracture, crepitus may be elicited; in the dislocation, never. In the dislocation there is inversion and a fixed position of the limb, both of which are absent in fracture.

8. See Rose and Carless' "Surgery" (1908), pages 494 and 495; or Da Costa's "Surgery" (1908), page 482.

9. See Rose and Carless' "Surgery" (1908), pages 1152 and 1153; or Da Costa's "Surgery" (1908), page 1015.

10. (*a*) *Varieties of carcinoma:* (1) Glandular or spheroid carcinoma. (2) Squamous carcinoma. Synonyms, epithelioma; squamous epithelioma. (3) Rodent cancer or rodent ulcer. (4) Columnar carcinoma. Synonyms, columnar epithelioma; adenoid cancer. (5) Thyroid carcinoma (resembling in structure the thyroid gland).—(From Gould and Pyle's *Cyclopedia.*) (*c*) By the lymphatics. For (*b*) and (*d*), see Rose and Carless' "Surgery" (1908), pages 209 to 217; or Da Costa's "Surgery" (1908), pages 333 to 336.

BULLETIN OF APPROACHING EXAMINATIONS.†

*No reciprocity recognized by these States.
†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Connecticut.—From and after January 12, 1914, no person will be permitted to take the examinations, unless his preliminary education included satisfactory courses in chemistry, physics, and general biology.

Indiana.—At a recent meeting of the State Board of Medical Registration and Examination, the board increased the medical college entrance requirements to one year of collegiate work, beginning January 1, 1910, and two years of collegiate work, beginning January 1, 1911.

Virginia.—This State now reciprocates with Vermont.

California.—At the December meeting of the board a resolution was passed, requiring those who failed in an examination, but who received 80 per cent. in one or more branches, to be reexamined only in those branches in which they had received under 80 per cent., if they came up for reexamination within one year. An opinion has been rendered by the attorney of the board that that resolution was contrary to law and therefore void.

State Board Statistics for 1908.—Statistics based on the examinations by State licensing boards show that 7,770 candidates, representing 137 medical colleges, were examined during 1908, with 21.7 per cent. of failures. There were 6,477 candidates who graduated during the last five years, of which number 17.3 per cent. failed. Of the 796 who graduated previous to 1903 31.5 per cent. failed. Non-graduates were examined in seven States, the total being 494, with 56.8 per cent. of failures. Of the 4,741 candidates who graduated in 1908 about 65 per cent. took examinations in the States in which their colleges were located, showing that any State allowing low-grade colleges to exist is itself the chief recipient of the poorly trained output. The colleges of Illinois furnished 843 candidates, with 12.9 per cent. of failures. Pennsylvania furnished 700 candidates, with 6.9 per cent. of failures. The failure percentage for New York colleges was 3.2; for Maryland colleges, 24.2; for Tennessee colleges, 35.7, while for the Mississippi colleges it was 77.8 per cent. All States, except New Mexico, require an examination of every applicant unless the candidate already holds a license from some other State. In the classification of colleges only 48 have failure percentages of less than 10 per cent., 29 have between 10 and 20 per cent., 46 colleges have over 20 per cent. of failures, and 15 are unclassified. During 1908 altogether 7,360 physicians received licenses; 6,084 by examination, 184 under exemption clauses, and 1,092 through reciprocity. Of those licensed under the reciprocity provision 225, or over 20 per cent., received their original licenses in Illinois, the two next highest figures being 100 in New York and 94 in Iowa.—*Journal of the American Medical Association.*

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of May 14, 1910:

	Cases	Deaths
Tuberculosis Pulmonalis	620	168
Diptheria	467	45
Measles	1,306	29
Scarlet Fever	608	26
Smallpox	—	—
Varicella	131	—
Typhoid Fever	38	3
Whooping Cough	33	6
Cerebrospinal Meningitis	10	14
Malarial Fever	—	—
Totals	3,213	291

Strangulated Ovarian Tumor in a Child.—Swainson reports the case of a child of two years of age, admitted to the hospital for acute abdominal symptoms, of four days' duration. A tumor was felt in the right iliac fossa. On laparotomy a strangulated ovarian tumor the size of a tangerine orange was removed.—*Proceedings of the Royal Society of Medicine.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended May 13, 1910.

ACUTE, SUBACUTE, AND CHRONIC INFECTION OF THE KIDNEYS AND OF OTHER ORGANS BY THE BACILLUS COLI.*

BY W. HANNA THOMSON, M.D.,

NEW YORK.

IN a paper published in the MEDICAL RECORD, March 21, 1908, entitled "Acute Invasion of the Kidneys by the Bacillus Coli," I related a number of instances of this serious, but usually manageable disorder, which I had met in my consultation practice. My subsequent experience confirms me in the opinion that such occurrences are by no means uncommon, and that it is important that their nature should be at once recognized, as the following case illustrates.

On the 6th of October last Dr. Robt. Abbe operated at St. Luke's Hospital on a lady who was a patient of Dr. J. L. Barton of this city, for the removal of a pelvic tumor, which proved to be an extrauterine pregnancy. After the operation the patient seemed to be doing very well, when suddenly on the 5th day she began to complain of cramps and pain in the abdomen, extending to the rectum, accompanied by nausea and frequent vomiting, followed by a rapid rise of temperature to 104.3°. She then grew drowsy and apathetic, with some muscular twitchings in the face and upper extremities. This was her first attack of the kind, and naturally suggested some general infective process from the wound of the operation. Nothing of the kind, however, could be discovered, the wound proceeding to heal as if by first intention. After this she gradually improved, and on the 21st day after the operation she spent two and one-half hours going about in a wheel chair. The next afternoon, however, she had slight chills, lasting twenty minutes, accompanied by rise of temperature to 103.5°, and the same constitutional symptoms developed as on the previous occasion, with the pulse rapid, small, and irregular, while the vomiting became much more frequent.

As she seemed to be very ill, I was then called in consultation, and I had no hesitation in pronouncing it a case of acute invasion of the kidneys by the *Bacillus coli*, on account of the symptoms appearing to me to be well nigh pathognomic, namely, sudden onset in a adult, with early cerebral symptoms, these soon passing with some into coma, but not convulsions, along with rapid rise of temperature and uncontrollable vomiting, a group of symptoms occurring in such sequence in no other renal derangement except those caused by invasion of the kidneys by some septic organism of which the colon bacillus is the most common. Along with these symptoms the next day, the urine which had been clear, became loaded with pus, blood, and numerous casts. I requested, therefore, that the urine be examined for *Bacillus coli*, but meanwhile to lose no time to administer 10 grains of sodium benzoate with 10 of urotropin every three hours, per rectum, as she could retain nothing on her stomach. I may say that these two drugs should always be combined in equal proportions in such cases, as the results are so promptly favorable compared with the administration of either of them singly. Thus urotropin sometimes causes irritation of the urinary passages like strangury, but never in my experience if conjoined with the benzoate. Some writers mention giving urotropin without producing any effect on this bacilluria, but it is quite otherwise in my experience if given with the benzoate. As often before in my experience, the relief of the serious constitutional conditions in this patient was rapid, the temperature the next day dropped to 99°, the vomiting ceased, and the cerebral symptoms disappeared.

The marked pyuria in this patient was undoubtedly due to the rupture of numerous small abscesses in the kidneys. The subsequent history of this patient was interesting. From the time of the operation, October 6, to my first visit on the 21st, the daily measure of urine was from sixteen to twenty-six ounces, and her physician, Dr. Barton, thought that she had oligouria for some time before. I, therefore, ordered enteroclysis with two gallons of normal saline at 120° F., night and morning, administered through Kemp's rectal irrigator. The effect was immediate, the kidneys then seeming to make up for lost time with 60, 80, 100, and finally 112 ounces in 24 hours. Meantime the urine became colorless, but continued acid and the specific gravity averaged 1008. But the chief feature was that though there were neither pus, blood, nor mucus and no ammoniacal odor, yet the urine showed a diffused white cloud which is very characteristic, and is mentioned by several writers. It was caused, as the daily examination in the laboratory showed, by immense numbers of colon bacilli in suspension. I was then puzzled to know where they came from so persistently, until on the 28th day she developed plain symptoms of subacute appendicitis. Dr. Abbe then operated with local anesthesia and removed an extensively diseased appendix with several hemorrhagic points in its lumen and a large ulcer at its base in the cecum. She recovered rapidly from this second operation and left the hospital on December 5 in better condition than she had been for months and with entire disappearance of the bacilli from the urine.

It is possible that the marked diuresis above mentioned may not have been wholly due to the

*Paper read at the New York Academy of Medicine, March 31, 1910.

rectal irrigation, because two weeks before she left the hospital it was deemed advisable to lessen the quantity of the urotropin and benzoate by administration once in six hours instead of once in three, the irrigations being continued the same. The very next day, however, the urine fell off one-half, from eighty ounces to forty, and she had headache. On renewing the former time doses the amount passed rose again to former figures.

As might be expected, invasion of the kidneys by the *Bacillus coli* is not an uncommon and sometimes a fatal complication of typhoid fever in its later stages when the intestine is extensively ulcerated. Its supervention should be suspected when markedly increased albuminuria is detected along with access of delirium, which, till then, may not have developed. One symptom is an almost certain sign, namely, the occurrence of sudden severe rigors late in the disease. During these attacks the patient seems on the verge of dissolution, and yet they are not necessarily fatal, particularly in young subjects. Free dosing with spirit of chloroform cuts the rigors short. In older patients the prognosis is worse, and in one case, that of a lady about fifty who soon died, the bacteriologist reported that he had never seen such a vast collection of the colon bacilli as there was in her urine. One patient with typhoid, a middle-aged physician, whom I saw in consultation, became actively delirious in the fourth week of the fever, and the urine was found heavily loaded with albumin and casts. The urotropin and benzoate soon caused a disappearance of both albumin and casts and entire cessation of the delirium, so that for a week he appeared convalescent, only to die afterwards from the sudden supervention of pulmonary edema.

Of subacute forms of this infection Case III detailed in my former article is a good example and in brief was as follows:

A physician of large family practice who had consulted me before for chronic ulcerative colitis, underwent an operation for excision of an ulcer high up in the rectum. In a very short time afterwards he became so delirious, though with only a moderate temperature, that he had to be watched constantly for four weeks. Meantime his urine was examined daily by a well-known expert, who closed his reports uniformly with the words, "acute parenchymatous nephritis with blood, albumin, and many casts." I was then called in consultation, and on examination of the patient, said that I did not agree with this laboratory diagnosis, that in my opinion he had no parenchymatous nephritis at all, for he had no edema anywhere, his pulse was soft, and moreover, prolonged active delirium was not common in parenchymatous nephritis, but that I wished his urine examined for *Bacillus coli*. Meantime I gave a favorable prognosis, which I would not have done if I thought that the laboratory diagnosis was correct, while I ordered the urotropin and benzoate every three hours. The first report from the laboratory was *Bacillus coli* in abundance, but two days afterward the remarks were, "astonishing improvement; no blood, albumin, nor casts." Six months afterwards this physician came to my office and reported that he was doing sixteen hours professional work a day!

In looking up the literature I have found several interesting papers dealing with different aspects of this subject, and all of recent date. The last is a paper in the London *Lancet* of October 30, 1909, by Dr. F. Charlton Briscoe, Physician to Kings College Hospital, London, in which he relates several instances of a matting together of the pelvic viscera by an exudate showing caseous changes which led to mistaken diagnoses of their tuberculous nature, but which proved on microscopical examination to be caused by the *Bacillus coli*. In each case colon bacilli were found abundantly in the urine. One patient was a woman with chronic hemorrhoids and rectal ulcer, who continued to decline in health for a year, losing weight, with a daily hectic fever and constant pain in her right flank. Upon laparotomy the pelvic organs were found matted together, the uterus being bound up with the posterior wall of the bladder along with a coil of the small intestine. Under treatment by vaccines she fully recovered. Another case in King's College Hospital was that of a young girl in whom on operation a large mass of caseous material was found attached to the small intestine, great omentum, left ovary, and tube. This was thought to be surely tuberculous, but on examination no tubercle bacilli were found, but instead a structureless material from which pure cultures of colon bacilli were obtained. In a third case the infection gave rise to a large tumor which was suspected to be malignant, in an Italian woman aged fifty-two. This tumor on laparotomy was found attached to the wall of the bladder and extended from the pubes to the umbilicus, of a dark red color, and covered by peritoneum with many large vessels coursing over the surface. On the supposition that it was malignant and inoperable, it was let alone. For three days after she showed a hectic condition, the temperature rising daily to 103° F., and then falling back to normal, until on the fourth day she passed a considerable quantity of pus with large flakes of lymph in the urine. The tumor was found to have disappeared, but from time to time it reformed and emptied itself, eventually disappearing entirely. From the urine a pure culture of *Bacillus coli* was obtained.

Dr. Briscoe refers to an interesting group of cases which have attacks of intermittent fever, the fever coinciding with the appearance of colon bacilli in the urine and the intermissions with their disappearance, and advises that the urine be examined for the colon bacillus in all cases of febrile attacks of obscure origin. It is worthy of note, also, how often ulcers in the rectum occur in his experience previous to the invasion of the kidneys and other organs. Along with other writers, he comments on the pale color of the urine, its milky haze, its acid reaction and relatively high specific gravity, along with the chronic persistence of the baccilli when once they appear in the urine, which also never decomposes with an ammoniacal odor. His treatment is mainly that of making the urine alkaline, giving frequent mercurial purges and when the symptoms persist, administering vaccines made from the baccilli of the patient himself, the initial dose being 50,000,000 of the dead organisms, according to the method of Sir A. Wright, and repeated every seven to eight days. This procedure he has found very effective.

Dr. Charles R. Box of St. Thomas Hospital, London, in an article in the *Lancet*, January 11, 1908, makes this important observation, that "it is a remarkable fact that in many cases when the kidneys are involved in typhoid fever, scarlet fever, measles, and diphtheria the organism found in the urine is the colon bacillus."

This observation is important because if the frequent affection of the kidneys in both scarlatina

and diphtheria is not due to the specific agents of those diseases, but to the colon bacillus, the treatment of their renal complications becomes comparatively easy, as a case reported by Dr. A. Seibert, of this city, well illustrates. Dr. Seibert, when first called to the patient, a girl, aged eleven years, in the sixth week of her illness, found universal edema, most marked in the face, some ascites, pulse forty-eight, intermitting every third beat; she was semi-conscious, with total blindness which had persisted for five days, nausea and incessant vomiting which had lasted for ten days, necessitating rectal feeding. The previous day she had had two severe uremic convulsions. Only four or five ounces of urine had been passed in the previous twenty-four hours, and this contained but a moderate amount of albumin. Five grains of urotropin were then administered, dissolved in an ounce of cold water with fifteen drops of dilute hydrochloric acid. This was not vomited and this dose of urotropin was repeated every three hours. As a result the headache disappeared first, and then marked diuresis set in so that 110 ounces was passed in the next twenty-four hours, and all edema disappeared within forty-eight hours. The amaurosis diminished in two days and finally disappeared in a week, after which she made an uninterrupted recovery.

Dr. L. C. Dudgeon, Bacterial Pathologist of St. Thomas' Hospital, in his Erasmus Wilson Lecture on Acute and Chronic Infections of the Urinary Tract (*Lancet,* February 29, 1908) says in the acute forms the onset may be very sudden with the temperature reaching 105°, kidneys tender, urine highly acid and loaded with colon bacilli, with, in some cases, pus and blood (a clinical picture which I myself have often met). These attacks sometimes occur with appendicitis. Finding the subsequent presence of the colon bacilli very persistent and prone to relapses, he recommends treatment with vaccines.

Finally, Dr. H. Batty Shaw, Physician to the University College Hospital, London, in an article in the *Clinical Journal,* February 12, 1908, gives a full bibliography of articles on this and cognate infections in Continental journals, all, however, of late years. Dr. Shaw gives the particulars of seven cases of his own and says that clinically such patients may be supposed to be sufferers from malaria, tuberculosis, mucous colitis, recurrent cystitis from unknown cause, dyspepsia, acute suppression, typhoid fever or pernicious anemia, and he recommends that every case of a chronic febrile affection of obscure origin should have the urine examined for *Bacillus coli.*

One hardly knows what the colon bacillus will not do when once it starts on its travels in the circulation. Dr. Robt. T. Morris, the eminent surgeon of this city, reports in the *New York Medical Journal,* January 1, 1910, the case of a patient, an elderly clergyman referred to him by Dr. John S. Kirchendall of Ithaca, N. Y., as a sufferer from choroiditis, which threatened to end in total blindness. In his letter to Dr. Morris, Dr. Kirchendall says that Dr. Stockton of Buffalo has asserted for years that the colon bacillus was the cause of most cases of choroiditis. Dr. Morris found that this patient had been suffering for years from intestinal troubles ascribable to a fibroid degeneration of the appendix, and on Dr. Morris' removing it the patient recovered, not only from his intestinal dyspepsia, but also from his choroiditis.

The *Bacillus coli,* however, is not the only micro-organism which can set up an acute inflammation of the kidneys. Both the *Staphylococcus aureus* and virulent forms of streptococci can do so with accompanying conditions very similar to those caused by the *Bacillus coli.* Thus, Dr. Geo. Emerson Brewer, Surgeon of the Roosevelt Hospital of this City, published an important paper (*Surgery, Gynecology, and Obstetrics,* Vol. II, No. 5) upon Acute Unilateral Septic Infarcts of the Kidney, in which, though the lesions were only in one kidney, yet caused very serious, and in some of the cases, fatal results, with symptoms of sudden onset and rapid rise of temperature from 105° to 106°. At autopsy the affected kidney was found riddled with small abscesses, the pus from which showed in some instances pure cultures of *Staphylococcus pyogenes aureus,* in others cultures of streptococci. In one of his cases the pyogenic organism was the *Bacillus coli.* Dr. Brewer cites a number of authors who describe such unilateral invasions of the kidney by different organisms, of which the *Bacillus coli* is mentioned as the most frequent form. Preceding lesions, such as the virtually traumatic irritation of a renal calculus, readily explain why the infection can be unilateral, according to the principle illustrated by the classic experiments of Dr. S. J. Meltzer who, by causing minute lesions by long needles in the liver, kidneys, and other organs, and even in the limbs, and then injecting a virulent culture in a vein of the ear, had abscesses begin in the body of the animal only at the seats of the traumatisms caused by the needle.

Some writers suggest that the origin of colon bacilluria is due to the introduction of these organisms from without, as by catheterization. Dr. Box, above quoted, inclines to this view mainly because among children he has found it much more frequent with girls than with boys, which he explains by the much shorter length of the female urethra. He says that there is no more common cause for enuresis among children than the presence of this bacillus. While there can be no doubt that these organisms may enter the bladder through the urethra instead of by descending from the infected kidneys, yet it is difficult to account for the persistent and enormous multiplication of these bacilli in the urine, when, unlike all urines decomposed by other bacteria, in colon bacillus cases it remains strongly acid and not alkaline and gives off no ammoniacal odor. Of course, in all the many cases which we have mentioned of organs other than those of the urinary tract being infected, the bacilli must have come through the blood.

As regards chronic infection by the *Bacillus coli,* an important paper was published in the *Journal of Medical Research* (Vol. VIII, No. 2), November, 1902, by Dr. A. Charlton, from the pathological laboratories of the McGill University, with the title, "On the Anemia Produced by Repeated Injections of Cultures of a Colon Bacillus of Low Virulence." Rabbits were used for experiments with the colon bacillus derived from their own intestines, the cultures therefrom being injected intraperitoneally or into a vein of the ear. The doses were always small and the period of experimentation extended over many weeks. The most striking results followed the intravenous injections and in brief were as follows: A very remarkable state of advanced anemia, in some respects strikingly like the conditions found in pernicious anemia, namely, great diminution in the number of red cells, marked poikilocytosis and the appearance of pear-shaped cells, crescents,

macrocytes, microcytes, and lastly nucleated red cells. On suspending the injections for some weeks, even when the fall in the erythrocytes was from five and a half millions to only one and a half millions, spontaneous recovery took place. Then when the injection of the bacilli was resumed, the injurious results were even more rapid and marked than on the first trial. But in addition to the effects on the blood very striking and progressive changes were produced in the spinal cord, consisting of diffuse degeneration in the columns of Goll, and in the antero lateral columns of the cord, closely resembling the conditions occurring in the spinal cord in certain cases of pernicious anemia.

The other bodily conditions were extreme emaciation, although the animals fed well and suffered from no gastrointestinal disturbances such as diarrhea, the animals in fact dying apparently from pure asthenia.

The whole paper is well worth study on account of its many suggestive analogies to numerous cases of human morbid conditions often of obscure origin, such as progressive anemia with emaciation and nervous weaknesses often grouped under that vague term, neurasthenia. In fact any such conditions if accompanied with febrile symptoms are doubtless ascribable to chronic infections. We also know that no visible lesion is necessary in the intestinal wall for bacteria to pass through into the circulation. Chronic constipation alone may suffice to allow the occurrence of chronic colon infection.

Finally, from my own experience I would regard chronic interstitial nephritis as most frequently caused primarily by slow infection of the kidneys by the *Bacillus coli.* Sudden terminations of cases of chronic interstitial nephritis characterized by great diminution or suppression of urine are nearly always preceded by acute indigestion of one form or another. I always dread an attack of so-called cholera morbus in an elderly patient and direct that the state of the kidneys be forthwith looked into. These cases are frequently attributed to an acute exacerbation of the chronic kidney disease, whereas I believe that I have saved a number of such cases by immediate recourse to urotropin and sodium benzoate, administered per rectum when the patients were comatose. It is suggestive how soon in the course of chronic interstitial nephritis symptoms of increased kidney affection develop after errors of diet.

Some writers are prone to minimize the role of the *Bacillus coli* in the causation of internal derangements, on account of its being naturally what they suppose to be a harmless denizen of the intestine. They might as well call the various virulent forms of staphylococci and of streptococci which constantly cover the surface of the skin as harmless, because while there they certainly are equally harmless so long as they stay there. The truth is that all these organisms are our mortal enemies, and will quickly prove themselves to be so if once they can penetrate through the thin barrier of the basement membrane, which membrane constitutes the external skin, or the internal mucous membrane, according to the different layers of epithelium which cover it. It is this basement membrane which is our chief protection, not only from the invisible foes of the external skin, but also against the large family of the colon group in the intestine.

In conclusion I would say that the advance of modern medicine is especially marked by the progressive elimination of the word idiopathic from our etiology. Whole classes of serious diseases which but lately we were content to regard as of unknown causation, we now know better than many of our most familiar old affections, with the further comforting assurance that the more we learn of their origin and nature the better we can treat them.

THE LIMITATIONS OF THE CALORIC METHOD OF INFANT FEEDING.

By HENRY DWIGHT CHAPIN, M.D.,

NEW YORK.

WITHIN the last few years attempts have been made to feed infants by the caloric method, and much is being written on this subject that is perhaps calculated to give a somewhat exaggerated idea of its place and value.

A calorie is the quantity of heat required to raise the temperature of one liter of water one degree Centigrade. The source of this heat is immaterial. It may result from the burning of coal, gas, wood, cereals, sugars, meats, or other food stuffs; or it may be obtained from electricity, chemical action, by friction, or from the rays of the sun.

It has been assumed that because all animals and human beings produce and give off heat that their food requirements can be determined by the quantity of heat they excrete. No animal or person could live more than a few hours unless the heat liberated as the result of the chemical activities of the body or metabolism was excreted. It is a waste product to a great extent, and in summer time there is more heat produced than is needed to maintain proper temperature of the body, and getting rid of it then is often such a serious problem that temporary abstinence from all food is sometimes necessary to reduce the production of heat as much as possible.

If an animal or person excreted enough heat to raise the temperature of one thousand liters of water one degree Centigrade in twenty-four hours, it might be assumed that food was needed which, when burned, would yield an equal amount of heat or one thousand calories. In cold weather, when all of this heat is needed to help maintain body temperature, and clothing is also required to prevent too rapid diffusion of heat, such an amount of food could be safely given. But in hot weather, when the heat produced is more than is needed to keep up the temperature of the body, the number of calories excreted is not an indication of the food requirements from the standpoint of heat value. Less heat is desired, and if it was practical to employ it, continual starving would be the ideal method of handling all cases in hot weather; and, in the tropics, no food at all would be needed if heating value was the sole factor that made food necessary.

From the heat producing standpoint, coal, gas, wood, meat, fat, sugar, and cereals are equally valuable, as all will burn and produce heat, but that the heat they are capable of producing is an indication of their food value, or that they are interchangeable according to heat values is at once seen to be absurd.

In selecting food a number of factors must be considered. First of all, is the food digestible by the *particular individual?* Food for a cow is entirely unsuitable for a dog, and the food of an adult will kill an infant. Yet such foods are nutritious and digestible in their proper spheres.

Fats, sugars, starches, meats, and other forms of protein will all produce heat, and all are digestible. If the heat or caloric value was all infants or adults

needed food for, it would be immaterial what article of diet was employed. But foods that are of equal heat producing value, and which are also digestible, are not interchangeable for different individuals, and growth and tissue repair do not depend upon the storage of heat, but upon the assimilation of protein. In infant feeding, particularly, where growth or the storage of protein is the chief phenomenon of nutrition, the main point to be considered is not, will the food supply heat, but, is it capable of causing growth?

TABLE OF CALORIC FOOD VALUES.

1 oz. Protein	yields	123 calories
1 oz. Carbohydrates	"	123 "
1 oz. Fat	"	288 "

KEY TO CALORIC VALUES OF PERCENTAGE MIXTURES.

1 oz. Food containing 1% Protein	yields	1.23 calories
1 oz. " " 1% Carbohydrates	"	1.23 "
1 oz. " " 1% Fat	"	2.88 "

EXAMPLE OF USE OF KEY.

What is the caloric value of 32 oz. of breast milk whose composition is protein 2 per cent., carbohydrates 7 per cent., fat 4 per cent?

32 oz. × 2% Protein	× 1.23 cal.	= 78.72 cal.	from Protein.
32 oz. × 7% Carbohydrates	× 1.23 "	= 275.52 "	" Carbohydrates.
32 oz. × 4% Fat	× 2.88 "	= 358.4 "	" Fat.
		712.64 cal.	

APPROXIMATE COMPOSITION AND CALORIC VALUE OF FOODS.

	Water %	Protein %	Fat %	Carbo-h'd't's %	Calories to 1 oz.
Human milk	87.0	2.0	4.0	7.0	22
Cow's milk:

Eggs (cooked)	65.0	11.7	10.7	.....	42
Round of beef (raw)	70.0	21.3	7.9	.....	45
Roast beef (cooked)	48.2	22.3	28.6	.....	100
Steak (cooked)	63.0	27.6	7.7	.....	52
Fish (cooked)	68.2	25.9	4.5	.....	42
Poultry (cooked)	53.6	21.2	10.3	.....	55
Vegetables:					
Potatoes (mashed and creamed)	75.1	2.6	3.0	17.8	32
Asparagus (cooked)	91.6	2.1	3.3	2.2	13
Baked beans (cooked)	68.9	6.9	2.5	19.6	37
Spinach	89.8	2.1	4.1	2.6	17

Again, heat or calories are not retained in the body, and if the amount of food needed is to be determined by the heat excreted, the quantity of food required will be that which when burned will produce exactly as much heat as is excreted. If only as much is taken in as is given off there can be no storage of protein or growth. The amount of food to enable growth to be made, therefore, can not be determined by the amount of heat excreted. It is self-evident then that the caloric method is not one that readily lends itself to successful infant feeding, whatever value it may have in the feeding of adults. But for roughly comparing the heat values of mixed diets, which prove to be suitable for the particular case from the digestive standpoint, when the composition and weights of the foods eaten are known, and also to act as a sort of check, the caloric values of the foods may serve a useful purpose, and to enable those who wish to become familiar with caloric food values the preceding key and table are given.

It should be remembered, however, that at the best the figures in the tables are but approximations, and that no exact figures are possible unless each lot of food is carefully weighed and analyzed. The data employed have been derived largely from Bulletin No. 28, U. S. Dept. Agric., Office of Experiment Stations, and the balance from other analyses and by calculation.

Heubner gives the following caloric requirements for infancy:

First three months, 100 calories per kilo of body weight; second three months, 90 calories per kilo of body weight; after that, until the end of the first year, 80 calories per kilo.

Langstein-Meyer gives the following caloric needs:

1- 2	weeks,	107	calories	per	kilo	of	body	weight.
13-14	"	91	"	"	"	"	"	"
25-36	"	83	"	"	"	"	"	"
37-44	"	69	"	"	"	"	"	"

The usual percentage system as applied in this country gives a very close approximation of the caloric needs as they have thus been worked out.

51 WEST FIFTY-FIRST STREET.

THE ECONOMICS OF STATE CARE OF THE INSANE.*

BY ALBERT WARREN FERRIS, A.M., M.D.,

NEW YORK.

PRESIDENT NEW YORK STATE COMMISSION IN LUNACY.

THE problem of the care of the insane is not simple, nor is it easy of solution. Its complexity is due in part to the fact that, while it is undeniably a medical matter, insanity is not a definite disease like malaria, to be treated successfully with a specific remedy like quinine. Rather it is a sociological problem resulting from heredity, food, occupation, education, and mental hygiene. Hence no narrow view, no easy self-satisfaction, no simple financiering, no mere utilitarian theory will avail in grappling with the situation.

So intricate is it in its correlation with psychology, nutrition of tissue, and development of function; with occupation, provision of environment, maintenance, and medical treatment of disease, that the care of the insane should be in the hands of a body of men who together will bring to the work not only prudence, thrift, judgment, and enthusiasm, but also expert medical and administrative training.

A former legislator of my own State gave utterance to the statement that all that the insane need is to be housed, clothed, and fed until they perish. This thought, though confessedly inhuman, he considered practical. It is not practical for it is not economic. Mere custodial care of the insane as a mass is wasteful and extravagant. It is wasteful of the lives and possible future usefulness of those whose mental integrity can be restored through proper nursing, treatment, and occupation. It is wasteful because it writes over the portal of the hospital for the insane the words, "Leave hope be-

*Delivered before the General Assembly, Annapolis, Md., February 9, and in part before the New Jersey State Conference of Charities and Correction, Camden, N. J., February 14, 1910.

mind, ye who enter here," thus making unnecessarily discouraging the matter of the diseased condition, creating in the minds of the near relatives and descendants a personal dread that robs these individuals of their social and industrial chance in life, and limits their effort and ambition. It also contributes toward perpetuating the unfortunate "stigma" that attaches to mental disorder.

Mere custodial care is extravagant because it assumes the burden of permanently caring for those who may become partially or entirely self-supporting, even after years of insanity. It is extravagant because it makes no provision for the study of the conditions of mental development, its arrest and retrogression; from which study by successive groups of physicians, teachers, and parents proper methods of rearing the young may be learned. Every pilot must personally study the charts of the stream, if he is to guide vessels past the rocks, beyond the whirlpools and around the shallows, and bring his ships in safety to the haven.

The importance of adequate provision for the insane is unquestioned. Whether or not insanity is on the increase we do not know. My own State of New York, which for many years averaged a net increase of the insane of 750 patients out of a gross increase of over 5,000, experienced a sudden augmentation of its net increase to 1,246 in the year before last, and one of 1,014 last year, with a total admission of 6,474 cases (of which number 5,146 were first admissions).

In contemplating the apparent increase of insanity, attention must be given to the fact that more of the population has become liable to insanity than was formerly the case, through the operation of an increased longevity. In 1840 the average age at death was about 28 years. In 1900 this average had increased to 34.5, thus bringing more people into the third decade of life, which is the most fruitful decade in insanity.

The question is often asked, "What is the proportion of insane to total population?" Fairly accurate figures are obtainable in several instances. In England and Wales (with an insane enumeration of 128,787) the proportion is 1 to 278, as compared with 1 to 277 in Massachusetts, 1 to 284 in New York, and 1 to 450 in the whole United States.

These figures suggest that a broad, comprehensive view be taken of mental unsoundness, and that all expedients be employed that science can devise to limit and restore, and that the most humane consideration be given to the subject. Past experience has shown that counties, with the rarest exceptions, have not taken such a view of the subject or employed such measures. Revolting and heartrending cases of neglect and cruelty toward even possibly recoverable individuals are too frequent. Abundant instances convince us that the only adequate and proper care of these unfortunates is State care.

It is difficult to compare the cost of county care with that of State care, as the latter is in operation in several commonwealths. The meager furniture, the coarse and common clothing, the revoltingly cheap food, the wretched housing, including bathing and toilet facilities, the insufficient lighting and heating, the infrequent medical attention, the total absence of nursing, the unskilled attendance and the absence of diversion or occupation, as existing or provided under ordinary county care, furnish no basis of comparison with even moderately intelligent provision. Were the counties separately to undertake to construct hospitals and provide properly in all these respects, the cost to taxpayers would be far greater than with one centralized board of administration and control, with an estimate system leading up to a central auditor and a central treasurer, and a single purchasing agency.

There is a widespread impression that the insane are recruited largely from the ranks of the ignorant, the idle, the vicious, and the generally useless members of society. This is most emphatically erroneous. The patients who suffer from attacks of insanity are of the valuable members of the community, in the largest proportion.

To illustrate this point the following statistics are taken from the Nineteenth Annual Report of the New York State Commission in Lunacy: "From October 1, 1888, to October 1, 1907, 104,013 patients (52,152 men, 51,861 women) were admitted to the New York State hospitals. Of this large number but 7,901 (3,052 men, 4,849 women) were not engaged in some legitimate wage earning occupation before becoming insane. In 2,715 the occupation, if any, was unascertained, and but 12,962 were classified as laborers only. Eighty thousand four hundred and thirty-five, over 77 per cent., were engaged in work above the grade of day labor, or were the wives, or in some cases the minor children of men so occupied. Nothing could show more conclusively that the State in aiding these people has given the aid to those who most deserve it, and to those who as wage earners and taxpayers have in the past contributed to the support of others in a similar condition, and that by restoring a considerable proportion to mental health it has made a definite and valuable contribution to the resources of the State."

The most economical method of caring for the insane is naturally the method by which as much as is possible is made of the remnant of life left to the incurable patient, and by which the greatest number of patients are rendered entirely or partially self-supporting, through cure or reeducation, the latter a very important agency.

Such a method is made complete only through State care. With a State properly districted for its hospitals, with hospitals built on the cottage plan for a capacity of about 2,000 patients each, with careful grouping and classification of inmates (socially as well as according to psychoses), with skilled medical officers and good laboratory and other medical equipment, with an organized nursing system radiating from each local training school, with facilities for amusement and therapeutic occupation and practical industries, true economy in care, in the lives of citizens and in the use of the taxpayers' money will be secured.

It is especially economical to make commitment simple and to encourage voluntary admissions. The insane should be placed under treatment without delay. The earlier you can institute care the more patients will recover, the sooner the recoverable cases will be returned to their homes, the earlier they will cease to be a burden upon the State. A close intimacy between State hospitals and families having an insane member will offer opportunity for warning and advice, and for early readmission in case of relapse. Cultivation of such intimacy will be progressed by the admission of voluntary cases.

Two important measures are inseparable from State care: First, prevention; second, after-care or "social service."

Simply to build hospitals in which to treat the insane produced within the State will not solve the

great problem. We must go to the fountainhead and limit the volume of the stream. We must instruct the people and the physicians of the State in the study of the avoidable causes of insanity. Our first preventive measure is instruction of children. As an aid in the instruction of children, we need the old family physician, modernized and versed in the psychiatry of to-day; the true "guide, philosopher, and friend." We need the physician who is wise enough to instruct the young parent and discreet enough to teach the youth important matters. There are certain truths which the parent should impart to the children very early. When the boys and girls are about to leave home for boarding school, the danger of certain diseases should be taught them, whatever their age may be. If children are living at home, and the parents share their complete confidence, these truths should be told the children at the age of fourteen or fifteen. Do not be misled by the old adage, "A young man must sow his wild oats." The harvest is not infrequently insanity. One indiscretion may result in an attack of syphilis which may in later life be followed by the insanity of general paresis. Of the 13,000 men in our New York State hospitals, probably 5,000 became insane as a result of self-indulgence or vicious habits, or sowing "wild oats." The perils of syphilis consist not only in temporary and present illness, but also in a breakdown in the prime of life, in diseased children, and in final insanity.

While the children's minds are being stored by their teachers with the studies of the day, do not neglect the training for the home. Better than free-hand drawing, better than clay modeling is training in correct habits of thought, common sense ideas, and an imagination stimulated along proper lines. Strength and breadth of mind, order, attention, concentration, frankness, sincerity, and avoidance of superstition are the traits that your child should acquire. Encourage your child to ask explanations; see that the children understand. You may recall the story of the examination paper written by a young child in a public school. His paper contained this sentence: "Every name of the Deity should begin with a caterpillar." Poor, little confused head! Not daring to ask what was meant, he had formed the habit of accepting and committing to memory, and thus "capital letter" and "caterpillar" were easily confused. Such a child readily develops a want of self-confidence as well as avoidance of others' help, and easily becomes a prey to doubt, suspicion, and alarm; and thus the dangerous "undercurrents of thought" become strengthened, to break through perhaps at some future time of stress and strain, with resulting insanity. I heard with amazement a public school teacher say that he, in an experience of twenty-five years, had never seen a school child so defective as to require separate or different teaching. Teachers should be psychologists. They should note not only if the conduct and behavior of their children is proper, but also if correct reactions to ideas and experiences follow normally. They should note the occasional weakening of the "upper current of thought" and build up a protective personality. They should encourage the fullest enthusiasm for health, strength, and beauty, and for doing right for right's sake. Nature studies among the bees and birds, the ferns and flowers, the shells and pebbles, or the rocks and trees, will fill the children's minds with interests of great value and will provide the change of occupation that rests the mind.

The second preventive measure is instruction in the dangers of alcoholism. The greatest single factor in the avoidable production of insanity is alcoholism. Of the insane of New York State 28.9 owe their lunacy to alcohol; of Massachusetts, 30.6 per cent.; of three asylums in England, 26.3 per cent.; of Munich, 30 per cent. of the male patients, while in 44.9 of the male Bavarian patients alcohol was the important factor. In a series of 961 New York cases, in which the causation was accurately known, the use of alcoholic stimulants was the precipitating factor in 55 per cent. of the men and in 22 per cent. of the women.

Syphilis is the next important avoidable cause of insanity. It is the cause of insanity in from 14 to 20 per cent. of the men and in from 2.5 to 3.5 per cent. of the women. In the prevalent disease general paresis, commonly termed "softening of the brain," syphilis is the cause in 85 per cent. of the victims. Communities must be investigated, teachers must be informed, youths must be taught plain truths in vigorous language, families must be educated.

Deportation of insane aliens with mental defect is necessary. All States should combine in assisting the United States government in preventing the admission into the country of immigrants who are insane, who have been insane on more than two occasions, or within five years of entering this country, or who, within three years, become insane from causes existing previous to landing. The immigration laws are clear and forcible and will afford ample protection with cooperation of State authorities. When found, such aliens should be deported forthwith, and when discovered within the three years' period, after slipping through the port in some way, they should be returned to their own countries at once. About 45 per cent. of the 30,000 insane people in New York State are of foreign birth, against about 35 per cent. of the population. To use the words of the former president of Harvard College, Dr. Eliot, "we should not water the blood" of our people in this way.

The second great adjunct to State care of the insane is providing after-care. The most practical work and that which will most quickly result in the prevention of the recurrence of attacks in certain cases, and prevention of any attacks in relatives of patients, is the work done by the after-care committees. Some call this important and valuable work "social service." It consists in cooperating with a State hospital and visiting the convalescent patients in their homes. Under a long parole period, patients may be sent to their homes in the care of a relative, when convalescence begins, for a trial. The after-care consists of the following duties: (a) Securing from the hospital information concerning the precipitating factor of the attack of mental trouble, the stress and strain of the patient's life, the undermining features of his environment and the hereditary influences in his case. (b) Securing from visits to the patient in his home additional facts concerning surroundings and conditions, and gaining his confidence and that of his family. (c) Suggesting and providing agencies which will improve his environment, explaining away his remaining doubts, reassuring and encouraging him, and teaching him and his relatives how to avoid future illness. (d) Providing occupation and employment for him and raising up friends for him; giving him a mental and moral prop.

Philanthropic men and women are needed to volunteer for this work who will attach themselves to the after-care committees and familiarize themselves with the common manifestations of the diseases called by the collective name of insanity. There is no more imperative duty, and there is no nobler service one can render humanity, than to care for the insane wards of the State.

SOME FACTS THE GENERAL PRACTITIONER SHOULD KNOW REGARDING THE TREATMENT AND CARE OF THE INSANE.*

By WILLIAM MABON, M.D.,
NEW YORK.

SUPERINTENDENT AND MEDICAL DIRECTOR, MANHATTAN STATE HOSPITAL, WARD'S ISLAND.

It is the prevailing, but erroneous, belief that insanity, one of the most fearful afflictions that besets humanity, is in all cases a hopeless condition. It removes from the family the wage earner, the housekeeper, the parent or the child, for an indefinite period of time. You, as physicians in general practice, first come in contact with this condition in its incipiency, and my purpose to-night is to bring to your attention the progress recently made in the treatment of that group of diseases classified under the general term "insanity," and the steps to be taken by you to secure the advantages of modern scientific treatment for your mental cases. I hope to help you, and through you your patients, to a better understanding of the means provided by the State for the care of these unfortunates. We believe that the good accomplished in the State hospitals can be much augmented by securing the active co-operation of the medical profession and the public in our work, both with the idea of preventing attacks of mental disease whenever possible, and with shortening attacks by early treatment.

In this great city, the second largest in the world, where practically all the public charitable and correctional agencies are under municipal control, it is not realized by the people generally that the insane are, and have been for many years, State charges, and that the institutions for their care and treatment are entirely under State supervision and control.

I shall explain briefly the method of commitment and the essential legal points to be observed; the provision for voluntary admissions; how a patient is examined and cared for at the hospital; the forms of treatment; the methods of discharge, the parole system, and the work of after-care.

There are three essential points to be observed in the commitment of the insane patient, viz., the petition, the certificate, and the order.

First, the petition must be made by certain near relatives, the poor authorities of the town or county, or the person at whose house the patient may be residing. In Greater New York the petition may be made by the Commissioner of Charities or his deputy.

Second, the medical certificate. This must be made after a joint examination by two qualified examiners in lunacy, must state what the patient said and did in the presence of the examiners, and any other facts indicating insanity, and must be sworn to. A qualified examiner must have practised at least three years, be a licentiate of the State and a graduate of an incorporated medical college. These qualifications must be certified to by a judge of a court of record, filed in the County Clerk's office, and a certified copy filed in the office of the State Commission in Lunacy in Albany.

Third, within ten days from the date of the medical certificate an order must be had from a judge of a court of the judicial district in which the patient resides, approving the findings of the physicians and committing the patient to the designated institution.

The law also provides that a notice of the petition must be served upon the person whose commitment is sought, unless in the opinion of the judge the service should be dispensed with, and in this event, the reason for dispensing with the service must be noted on the certificate.

In the case of voluntary patients, Section 99 of the Insanity Law provides as follows:

"Pursuant to rules and regulations established by the State Commission in Lunacy, the superintendent or person in charge of any State hospital for the care and treatment of the insane, except the Matteawan and Dannemora State hospitals, may receive and retain therein as a patient any person suitable for care and treatment, and who voluntarily makes written application therefor, and whose mental condition is such as to render him competent to make such application. A person thus received at such hospital shall not be detained under such voluntary agreement more than five days after having given notice in writing of his intention or desire to leave such hospital."

This comparatively new provision of the law makes it possible to receive borderland, incipient and recurrent cases, as the general hospital receives its cases, and does away with the loss of time required in the ordinary procedure for admission to an institution. In our experience we have found that those who take advantage of this provision are largely former patients, or their relatives. The regulations of the State Commission in Lunacy governing this class provide that alcoholic and drug habitués must not be received, and case history and records must be kept the same as for a committed patient.

When a committed patient is to be received directly from his home the physician should notify the institution that a certificate in lunacy has been completed and the patient is ready to be removed. The hospital on its part will send a physician and nurse, who will bring the patient by carriage or ambulance. If the physician finds the certificate defective, it is necessary to have the required corrections made and the case will have to be deferred until the law in all particulars has been complied with. The institution is always glad to furnish any information as to the procedure to be followed.

It is expected that the relatives, whenever they are able, will reimburse the State for the maintenance, and if the case is one requiring extra care and attention and the relatives are financially able, they are expected to pay a higher rate than the reimbursing one. Furthermore, relatives who are able to pay the rates charged at private institutions are expected to do so, on account of the great number of indigent insane who must be cared for. At the present time all the State hospitals are overcrowded and preference is always given to the indigent class. In order to ascertain the facts as to the financial responsibility of the family, and to protect any property interests the patient may have, the State has special agents who investigate and report to the State Commission in Lunacy, and each hospital has an attorney to assist in this matter. In all cases

*Read before the East Side Medical Association, February 24, 1910.

relatives of patients are expected to provide them with clothing, but when this is impossible clothing is furnished by the State.

The method of examination and keeping case records at the hospital is of a thorough and comprehensive character. There thus results a mass of records, which, valuable as they are in further elucidating psychiatrical problems, are none the less of the greatest value as a guide in directing intelligent therapeutic effort.

Every patient on admission is at once placed in bed, there to remain until the physical examination is completed, the result of which determines the necessity for further rest in bed. Immediately after arrival a superficial examination is made for marks of identification, injuries, and any serious disorder requiring immediate attention, all of which is duly recorded, as is the treatment instituted. Later, more extended physical examination is made, following a general outline, which embraces all necessary points of inquiry in the ordinary case, but which at the same time calls for the most detailed examination of any abnormal condition. While such outline is closely followed, the record of the examination is typewritten upon blank sheets, thus avoiding printed forms which tend to mere routine work. The examiner is thus allowed all latitude in expressing his findings, while, following the outline as he does, no point is overlooked.

A brief survey of the outline shows its comprehensive character. With a paragraph for a description of the general type, appearance, and condition, including anthropological makeup, general state of nutrition, evidence of acute or chronic disorders, the neurological examination is first undertaken following the segmental development of the nervous system. Thus, after a paragraph devoted to general and subjective sensations, the special senses are first examined in their segmental order. Then the condition of the cutaneous sensibility is determined, including subjective complaints, stereognostic sense, sense of position, etc.

The examination of the vasomotor and trophic conditions follows, and in turn the various motor functions are examined, both deep and superficial reflexes are tested, the presence or absence of fibrillary twitchings is noted, while tremors and conditions of speech are made objects of special inquiry. In aphasic conditions a special detailed outline is followed, which is, of course, unnecessary in the majority of cases admitted. The condition of the organic reflexes and their control is determined, the question of convulsions is inquired into, and a paragraph is devoted to the matter of sleep and dreams, respectively.

Following the above, the ordinary physical examination of the thoracic organs is made, the condition of the digestive and abdominal organs ascertained, while a paragraph is devoted to the urinary and genital apparatus, respectively. After the completion of the whole physical examination it is customary to summarize the essential findings, thus avoiding the necessity of searching the detailed record for the most important abnormalities.

The mental examination is then proceeded with, when there are no physical contraindications, likewise following a detailed outline. An effort is first made to obtain an idea of the spontaneous mental activity, and the nature of the stream of thought when uninfluenced by the examiner. Thus, when the patient is spontaneously productive, a sample of the talk is recorded without questions being addressed, but when it is necessary to use questions only the simplest ones are employed, such as inquiries as to the patient's name, occupation, etc., special attention being given to any indication of acceleration or retardation in the stream of thought. As it is of great importance to form an idea of the setting in which the talk is produced, the motor reactions are set forth under this heading showing whether the patient be in a restless, retarded, rigid, or other unusual motor condition when speaking.

The next division of the mental examination is the general mental attitude, which includes inquiry into the emotional reaction and special moods, with a detailed analysis of delusional and hallucinatory states.

Orientation and mental grasp are next determined, this being a special inquiry into the condition of the sensorium as regards the patient's knowledge of time, place, and personal relations.

Memory of the recent past is determined, and then as the patient is induced to give data of his life, one is able to judge as to the memory of the remote past. Under the heading of personal data the examination is extended to all matters occurring throughout the patient's life which may be deemed to have any bearing upon the situation.

Retentive power is determined, the patient's grasp on school knowledge and general information is ascertained, and the latter is then compared with the educational opportunities afforded the individual in question. The same is done regarding the ability to count and calculate, read and write, a specimen of the writing being filed whenever possible.

An idea of the patient's insight regarding his own condition and his general judgment is sought, and the mental examination is then concluded with a paragraph detailing the general attitude and manner. A summary paragraph is made similar to the one following the physical examination, wherein the important diagnostic points are grouped together and where it is possible to find the more important deviations from the normal. Of course, if the patient be in a delirious, stuporous, or mute state, we have to content ourselves by limiting this detailed examination, and in such instances the attitude and manner are more fully described, including the motor reactions, every effort being made to obtain differential diagnostic points in this matter.

While the above general outline is followed whenever possible, the rule is invariably observed of fitting the examination to the individual patient, so if a patient is weak, the mental examination is conducted in brief interviews, but at intervals, until all the various points have been inquired into. In addition, it may be stated that a woman physician makes a gynecological examination of all female patients, while the usual laboratory tests are employed whenever indicated, an urinalysis, of course, being always performed.

Staff meetings are held for two hours daily, at which every patient admitted is presented in turn by the physician making the initial examination, he incorporating in the record such information as has been obtained from the patient's friends, other hospitals, or any other source. A free discussion takes place, from both a diagnostic and therapeutic standpoint. Such discussion is recorded by a stenographer present and is later typewritten, forming a part of the case record. The tentative diagnosis and therapeutic suggestions thus represent the opinion of the whole staff and not of any one physician.

With the typewritten records thus obtained, treat-

ment can be intelligently inaugurated with the view of alleviating the mental as well as any physical disorder that may exist. At frequent intervals additional notes are made as to both mental and physical condition, including also a record of the treatment, with the results observed from day to day.

In addition to this original presentation, every case is presented a second time, usually two or three months after admission, when a summary is read embodying the essential features of the entire clinical record, including the result of treatment. The physician writing the summary makes a differential diagnosis, and the final diagnosis is then determined. As a commentary upon the thoroughness of the original examination, it may be mentioned that the final summary diagnosis agrees with the tentative diagnosis made on the original presentation in approximately 90 per cent. of the cases, the remainder being obscure and anomalous cases, in which prolonged observation is necessary to arrive at a correct understanding of the condition.

At the time of summary, if the patient's condition admits, the question of discharge or parole is considered, likewise after a free discussion by the staff. Suggestions are made, conclusions reached, and all circumstances pertaining to the patient thoroughly expounded. Thus every patient entering the hospital appears at the staff meeting twice, while cases which have not sufficiently improved to warrant their leaving the hospital when summarized are presented for the third time before they are discharged or paroled. In this manner no patient leaves the hospital until all the conditions attendant upon the case have been thoroughly analyzed, and it is thus possible to intelligently advise the patient as to the future.

When the case is to be presented for summary, the following letter is sent to the family physician wherever possible:

STATE OF NEW YORK—MANHATTAN STATE HOSPITAL, WARD'S ISLAND, NEW YORK CITY.
WM. MABON, M.D.,
Superintendent and Medical Director.

.....19....

DEAR DOCTOR—It is strongly felt by many of those engaged in the care and treatment of the insane that a closer cooperation between the family physician and the hospital physician would do much toward developing more effective measures for the prevention and management of mental disorders. Some of the most common psychoses develop slowly out of conditions which might be recognized and dealt with by the general practitioner long before hospital treatment becomes necessary.

It is unfortunate that the practitioner nearly always loses track of the case after the patient is admitted to the hospital. The family physician can frequently supply the Hospital physician with many facts helpful for the understanding and treatment of the case; furthermore, his continued interest will do much to inspire confidence in the patient and secure more ready acquiescence in the necessary detention in the hospital.

A former patient of yours.....was admitted to this hospital on..... At the regular staff meeting to be held..... this case will be presented for discussion as to the diagnosis and treatment.

I beg to enclose for your information a summary of the clinical history of the case, and to express the hope that you will be able to attend the staff meeting, which will be called at 8.30 A.M., and last until 10.30 A.M. If you are unable to attend, we would be glad to have any suggestions from you in reference to this clinical summary.

The most convenient way of reaching the hospital is by way of the surface, elevated, or subway trains to 116th street and the 116th street crosstown car to within one block of the East River. The hospital boat leaves its dock at the foot of East 116th street on the even and half-hour.

Will you kindly notify us if you will be able to attend? Very truly yours,

SUPERINTENDENT.

As a part of the medical work, autopsies are held in approximately one-third of the deaths and once a week at a meeting of the entire staff the clinical facts are discussed in connection with the pathological findings.

As regards specific medical and surgical treatment, it may be summed up in the statement that the insane require the same treatment for like conditions as do the sane. It is our contention that the State hospitals provide as good hospital care for the various physical disorders presented as do the general hospitals. While, of course, it is generally known there is no specific treatment for any form of psychosis, the general hygienic treatment is of the utmost importance, and in this connection one may speak of the open air camps which have been established at the Manhattan State Hospital. Here certain selected patients improve much more rapidly than in the closed wards, simply as a result of their out-door life.

The value of the open-air treatment has always been recognized in institutions for the insane, and it has been the practice to keep most of the patients out of doors during the greater part of each day, but it is only during recent years that its specific value has been appreciated and suitable plans adopted for its special use.

In 1901 the late Dr. A. E. Macdonald introduced tent life for the care of the tuberculous insane at Ward's Island. Following this experiment, it was found that this life had a remarkably good effect on feeble and untidy patients and later on the convalescent class also. In 1904 the late Dr. Emmet C. Dent, superintendent of the Manhattan State Hospital, West, inaugurated this treatment for the acute insane and fully equipped camps were erected for those suffering from acute delirious conditions, anemia, insomnia, and the various physical ailments coincident with the acute insanities. Dr. Dent began his work with tents built on wooden platforms, each accommodating twenty-five patients. These tents were heated with iron stoves and were supplied with closets and running water. It was found, however, that during wet and stormy weather the tents had to be kept closed when ventilation became difficult. As a result of this experiment, a structure was built of wood and glass, in size twenty by seventy feet, and accommodating twenty-five patients. The sides are movable so that if desirable there need be absolutely nothing operating in the nature of an enclosure. These structures proved so satisfactory that they have been greatly extended, particularly in the women's part of the hospital. They are lighted by electricity, have steam heat, steam tables for warming food, water closets and baths, in fact every sanitary requirement. The more robust patients take their meals in the adjacent dining-room, while food is brought to those who are weak and

feeble. The last of these buildings erected was for the tubercular women. It has a sitting room attached and a special dining-room easy of access, and separate from the other classes of the insane. In selecting patients for the camp, aside from the tubercular, no discrimination is made because of violent or suicidal tendencies, and through the six years that these camps have been occupied, only one calamity has occurred, although their proximity to the water would naturally appear to be dangerous. After the acute cases have been under treatment sufficiently long to improve the general health, we notice that the insanity is either well on toward recovery, or we are in position to make a more accurate prognosis. In a certain group of cases there is no more important restorative that a sufficient amount of sleep. Under treatment in the camp, the constant exposure to fresh air and sunlight tends to bring about a normal amount of rest and oftentimes the patients reach in the course of a month an average of six to eight hours sleep out of the twenty-four. Aside from the hygienic advantages derived from these camps, the moral effect upon the insane has considerable influence toward their recovery. The freedom from the restraint of bars and locked doors, together with the wide open windows, is appreciated to such an extent that vacancies in the camps are eagerly sought by the more intelligent class of patients.

Of any single therapeutic agency, however, in the treatment of the insane, it is scarcely to be denied that hydrotherapy is of the first importance. Both hot and cold packs are extensively employed, the hot air bath is important as an eliminating procedure, while the various showers and douches all have their special indications.

The disturbed insane have hitherto formed one of the most difficult groups of cases to treat successfully, but with the introduction of the continuous bath, we now cure approximately 95 per cent. of acute maniacal conditions. The patient lies upon a canvas sheet in a large tub, through which the water is constantly flowing at body temperature, and here a patient will sleep when unaffected by ordinary hypnotics. It may be said that scarcely any form of excitement exists but that is favorably influenced by this treatment. Of course, in senile cases with arteriosclerotic changes and in individuals suffering from gross cardiac or pulmonary lesions care must be exercised, but even such patients undergo prolonged bath treatment much better than might be anticipated, and with benefit in no other way. Indeed, such patients show less adverse symptoms than was formerly the case when their excitement was controlled by powerful hypnotics, with their attendant depressing effect upon the cardiovascular and muscular systems.

Manic depressive excitements are thus favorably influenced, although they usually respond less promptly than do the infective exhaustive and toxic conditions, in which improvement is usually shown within twenty-four to forty-eight hours. In fact this form of treatment is now regarded as absolutely essential in the care of the latter.

By means of the continuous bath, it may be said that the use of hypnotics has been largely reduced and drugs are never employed as a substitute for the prolonged bath, although they have their value in certain cases.

The hospital has two fully equipped operating rooms and the necessary sterilizing apparatus in connection with them. With a population of nearly five thousand, we naturally have a large amount of surgical work. Some minor operations are performed by members of the staff, but this work is largely done by visiting surgeons from the city, members of our board of consulting physicians and surgeons. Active clinics are held by different members of this consulting board and I wish here to express my appreciation of the work of these gentlemen who give freely of their time and skill for the benefit of those committed to our care.

The institution is provided with facilities for the administration of electrical treatment and in certain selected cases this proves of much value. An oculist and dentist visit the institution regularly for work in their respective fields. A trained masseur is employed by the institution. Extra diet is part of the routine treatment in all cases where it is indicated. A training school for nurses is maintained and is under the immediate charge of a Bellevue graduate. This school is registered with the State Department of Education at Albany and gives a very thorough course, especially in mental nursing. There is a considerable demand for our graduates to take charge of private cases.

In the treatment of mental diseases, amusement, diversion, and occupation deservedly occupy a very important place. Perhaps in no particular is the difference between the new and the old régime more marked. Formerly the insane were locked in wards with nothing to do and no opportunity for exercise, except possibly in a barren yard surrounded with a high fence. The bare walls, heavily barred windows, and heavy, crude furniture fastened to the floor were in marked contrast to the modern open-air camps, for instance, photographs of which I have distributed. We strive to interest our patients in some form of industry or amusement—anything to prevent the brooding and introspection so common and so harmful to the insane. Many of the women work in the sewing rooms, others in the laundry, the kitchens, the dining-rooms; some will show an interest in caring for the ward. Some will take up fancy work, embroidery, tatting, Mexican drawn work, and the like. Work in raffia and in brass has recently been introduced in the wards. For the men there is the work on the grounds, in the gardens, in the various mechanical shops, in the tailor and shoe shops, making mats and mattresses, the bakery, kitchens, clerical work, and running errands. These patients work an average of five or six hours a day. The work is assigned by the physicians as a part of the treatment and the nurses make every effort to interest their charges.

For amusement and diversion there are games, such as cards and checkers in the wards, dances and concerts in the different wards, in the amusement hall and out of doors in summer where we have a large platform for this purpose. Two bowling alleys are maintained for patients' use. In the summer four excursions a week are given on the hospital steamer, about two hundred patients going on each trip. We have recently introduced folk dancing and singing games and these have proven of value. The women have shown much interest in this diversion. A baseball team of employees plays exhibition games with visiting teams from the city and the patients themselves occasionally play. Field day sports are held Decoration Day and Labor Day in which patients compete for prizes; these events are greatly enjoyed. Through the kindness of theatrical friends of the hospital, vaudeville entertainments by high-class artists are given frequently dur-

ing the season. On the various holidays throughout the year some of the wards give entertainments, the different numbers on the program being given almost entirely by patients. Every Friday afternoon a party is given by the women, who are convalescing and an informal programme is rendered. These parties arouse much interest and started originally by a nurse reading to some convalescent patients while they were doing fancy work. From this simple beginning the work has developed until now in point of attendance and quality of program given these meetings will rank with some of the women's organizations in the outside world. The hospital has two libraries for patients' use and these are added to from time to time. The Hospital Book and Newspaper Society furnishes newspapers and magazines for the different wards. One of the Jewish papers furnishes ten copies daily for the benefit of those reading that language. Many of the wards have pianos and each ward has its musicians to play for them. The hospital maintains its own orchestra and there are a number of phonographs in use, some purchased and others provided by friends of the institution.

For the religious instruction and comfort of its inmates, the hospital provides three chaplains, one for each faith, Catholic, Protestant, and Jewish. The ministrations of these clerical gentlemen afford much solace to our patients.

When a patient has improved to such an extent that it seems wise to give him a trial outside the institution with his friends, it is the usual custom to grant him what is known as a "parole." This means that he is still carried on the hospital records and can be returned any time within the parole period without the formality of a recommitment. Paroles are from one to six months, most of them for the latter period. During this time the patient reports frequently to his former ward physician and his progress is noted. If he does well outside, his formal discharge takes place at the end of six months. About 10 per cent. of all cases paroled return within the time, many of them of their own volition. In order to bring home to the friends so far as possible the importance of this period in the patient's life, the following letter of advice has been prepared and is handed to them when he leaves the hospital:

State of New York—Manhattan State Hospital, Ward's Island, New York City.

To the Friends of Patients:

The superintendent begs leave to offer the following advice for the benefit of the patient who is leaving the hospital, with the view of preventing, if possible, a return of the mental attack:

Those conditions and surroundings which operated in bringing about the first attack should be avoided and, as far as possible, remedied. Where the surroundings were objectionable, a change should be made in residence. Bad associates should by all means be avoided. In order to effectually change the surroundings and associates, it is frequently necessary to move to another section of the city, or even leave town and take up life in another community.

Oftentimes it is embarrassing to the patient to have the subject of the former residence in the hospital discussed. See that the patient avoids all forms of dissipation; endeavor to keep the patient occupied and establish regular hours for meals and retiring. During the summer months, where it is possible, it is well for the patient to go to the country for a short time at least. The home life should be made as pleasant as possible and friends should endeavor to encourage and help in every way.

Inasmuch as it is the practice of this institution to parole for a period of six months before discharging a patient, it should be considered a duty on the part of relatives to encourage the patient to return to the hospital once a week during the parole period to consult with his former *ward physician* in reference to the progress of his convalescence, and to seek from him advice as to the best mode of living. The patient, at the same time, should have instilled into his mind that the idea of these regular visits to his physician is not for the purpose of his possible return to the institution, but rather to prevent a recurrence of his disease, and hence the necessity for a recommitment.

Whenever a paroled patient declines to return to the institution, it is well to keep him under careful observation, and in case of any illness, or a suspicious symptom of his former malady, the family physician should be immediately consulted, and then if advice is desired, a letter addressed to the superintendent will receive a prompt answer.

William Mabon, M.D.,
Superintendent and Medical Director.

In connection with discharges, I would state that we frequently have much difficulty in persuading friends to allow the patient to remain until fit for a trial outside. In many cases as soon as he has shown a slight improvement, and while still in a very unstable mental state, the relatives become insistent for discharge, overlooking the obvious fact that a return to the environment in which the breakdown occurred, at such a time, would be about the worst possible thing for the patient. The law provides two ways for the possible discharge without the consent of the superintendent. One is by writ of habeas corpus. Quite a number of these are issued during the year, but in nearly all cases the courts have denied the writ and remanded the patients back to the hospital. The other method of discharge is by bond guaranteeing good behavior and maintenance provided the relatives can satisfy the court that the patient will receive proper care. Our experience is that the courts are usually reluctant to discharge an insane person against the advice of the superintendent and require definite assurance as to the provision the relatives propose to make.

For patients with no friends able to assist them, there has been developed, through the cooperation of the State Charities Aid Association, a system of after-care, to look after and see them through the critical weeks of their parole. The Manhattan State Hospital After-Care Committee was formed early in 1906, being the first organization of its kind in the United States. About one hundred cases a year are referred to this committee and its agent makes an average of five visits in behalf of each patient. Employment is secured for about thirty each year and supervision in all cases is continued until they are doing well and have become self-supporting. Some are assisted with clothing or money, some sent to the country, others have board provided until employment is secured. Where home conditions are unknown and thought to be of rather a low standard, the agent makes a visit and reports her observation to the physicians. Many cases referred to the After-Care Committee are turned over to existing charitable and relief organizations and receive help in this way.

I consider this work of after-care of vast im-

portance from the economic, the social, and the humanitarian point of view, as well as that of a superintendent. It fills a need we have felt for years and for which there was no adequate provision before the After-Care Committee was appointed.

Prophylaxis is the keynote of modern medicine, and the old proverb, "An ounce of prevention is worth a pound of cure," is nowhere more true than in the realm of psychiatry. The principal exogenous factors in the production of insanity are those twin scourges of humanity—alcohol and syphilis, both avoidable causes.

In the prevention of insanity, there are two fields to cover, the first being to make the most of the recoveries and avoid relapses, and in this we receive valuable aid from the After-Care Committee. The second, and more important by far, is to prevent, or at least abort, the initial attack. This, gentlemen, is largely in your hands. Persuade your mental cases that the institution should not be considered the last resort, but the first. Tell them that many forms of insanity, if taken right at the beginning, are amenable to treatment; that there is nothing to gain and everything to lose by delay. As in physical diseases, so with mental, there are certain forms in which the prognosis is unfavorable, but even in these early treatment may do much to relieve the patient's distressing symptoms.

The deep-rooted prejudice against the hospital for the insane dies hard, but we hope and believe the time is coming when the person mentally unwell will turn to the institution as freely for help as he now does to the general hospital for treatment of his physical diseases. When that shall occur, and it is recognized that insanity is a disease and not a disgrace, then the medical profession will have achieved another great triumph for humanity.

NONDETENTION AN ALL-IMPORTANT FACTOR IN THE TREATMENT OF THE DRINK HABIT.*

By CHARLES A. ROSENWASSER, M.D.,

NEW YORK CITY.

ATTENDING PHYSICIAN TO THE PRESBYTERIAN DISPENSARY, NEWARK, N. J.; MEMBER OF ADJUNCT STAFF OF ST. JAMES' HOSPITAL; VICE-PRESIDENT OF THE DEPENDENCY AND CRIME COMMISSION OF THE STATE OF NEW JERSEY.

In an article entitled "The Drink Habit and Its Treatment," read before the Medical Society of The State of New Jersey,† and before the Eastern Medical Society of New York City, the writer called attention to the possibility and great importance of the treatment of the drink habit without requiring the detention of the patient. At that time I said: "In most cases, the treatment of the drink habit resolves itself into nothing more or less than the treatment of an aggravated case of neurasthenia, a condition which will tax your skill to the utmost, and exhaust your patience, but, nevertheless, one in which you can achieve success in a gratifyingly increasing number of cases if you will go about it in the right way. Treatment in order to be effective, must be conducted systematically, and must cover a period of months. It consists essentially in thoroughly studying the patient and applying in each case the remedies called for. There is no remedy or plan of treatment which will cure all cases; there is no specific for this condition; each case must be studied and treated as an individual. Your first step in dealing with the patient is to win his confidence. Without having succeeded in this you can do nothing, but having succeeded you can accomplish marvels. The patient demands prompt action without hesitation. You must convince him from the very start that you can promptly and effectively destroy his craving for alcohol, that you can put him in such a physical condition that he will not suffer for the want of alcohol, and will indeed get along better without it; that the nausea and vomiting will promptly subside; that the restlessness will give place to calm; that the sleeplessness will be replaced by peaceful slumber, and that you will leave no stone unturned to help him to get well, and then will show him how to stay well. You must make him feel that your entire aim in life for the time being is to help him win his way back to health. Having won your patient's confidence, and having succeeded in getting him into the proper frame of mind, you must proceed to make good your promises. This you can do with the aid of remedies available to every physician, and without resorting to any secret remedies or secret systems of cure, and what will be news to many of you, you can do this in a surprisingly large number of cases without requiring the detention of the patient, he being able to go about and attend to his business."

That statement was based upon four years' experience with the method advocated. The result of another year's experience has strengthened my earlier convictions. The successful treatment of the drink habit without detention is an accomplished fact. It holds out the greatest hope for the greatest number. Its possibilities are clearly demonstrated in the results obtained in the cases hereinafter cited, to which attention is called in the hope of securing for this subject the thoughtful consideration which its vast and far-reaching importance merits. When such consideration is accorded this subject, physicians everywhere will study and treat victims of the drink habit scientifically, humanely, and hopefully, and then the inebriate will turn to his physician for relief and not to the so-called "cures" and secret remedies, which are exploited solely for gain and are of little or no value. The cure of the drink habit and the restoration of the inebriate lies in the physician and not in the physic.

Viewed from the practical standpoint, the results of the treatment of the drink habit, irrespective of the method employed (whether by the use of drugs or without, whether by detention for a long or a very brief period, or without detention), are as follows: Some patients are cured; some are improved, and some are incurable.

By cured I mean that the patients are leading sober lives. They are cured in the same sense that a patient suffering from gout is cured. The manifestations of gout may disappear under treatment, but the predisposition to attacks remains, and the individual is still "gouty." The manifestations of inebriety may disappear, but the individual is still predisposed to the pathological manifestations of alcohol; using the term pathological to describe the behavior of alcohol in individuals predisposed to the development of the drink habit or drunkenness.

The following are examples of cured cases. They were all treated without detention:

Case I.—A. H., a button maker, married, aged 45, began the use of alcohol at the age of 21 and was

*Read at a meeting of the American Society for the Study of Alcohol and Other Narcotics, Philadelphia, April 7, 1910.

†*Journal of the Medical Society of New Jersey*, February, 1909.

drunk at 23, and has been a steady drinker ever since. He takes beer and whiskey in quantities depending upon his purse, and is drunk almost every day. He came under treatment July 21, 1905, stopped drinking at once, and has remained sober and steady to date.

Case II.—J. S., painter, married, aged 51, has been a hard, steady drinker for 30 years, drinks as much beer and whiskey as he can get, and is drunk every day. He began treatment March 15, 1905, and has been a total abstainer ever since.

Case III.—M. J. W., a fish dealer, married, aged 48, began the use of alcohol socially at 19 years of age; at 30 was drinking very hard, but was able to stop for a time; at 40 got drunk occasionally and since then has been a constant hard drinker, with periodical sprees. Since about one year is almost always drunk, taking a quart of whiskey daily. He came under treatment August 22, 1905, in the midst of a spree, responded very promptly, and has remained abstinent ever since.

Case IV.—J. J. T., a plumber, married, aged 37, began the use of alcohol socially at 17 and was drunk at 25. For the past eight years he had been drinking to excess, being a hard, constant drinker, with occasional sprees lasting two to three weeks. He took from 30 to 40 drinks of whiskey daily when on a spree. This patient came under treatment September 7, 1905, having been on a spree for about two weeks, and was taking about one quart of whiskey daily in an effort to reduce his daily consumption. The results of treatment were very prompt. This was one of the worst cases I ever saw. He is to-day a sober, steady, hard-working man, a property owner, a good father and husband.

Case V.—H. R. C., a restaurant keeper, married, aged 45, has been subject to periodical sprees for twenty-five years. Lately they have been coming more frequently, are of longer duration, and harder to get over than formerly. The present attack began a few days ago. He was taking a quart of whiskey daily. He came under observation November 10, 1905, reacted very promptly to treatment, and has remained well ever since.

However, the number of cases that are cured is small as compared with the number of those in whom improvement is the best that we can obtain. Unfortunately the condition is prone to relapse regardless of what is done in the way of treatment. There are many reasons for this. There is nothing, so far as I have been able to determine, which will remove the predisposition to the development of drunkenness, and there is no alcoholic concoction or beverage, however weak in alcoholic content, which an alcoholic can take without manifesting the pathological effects of alcohol. Occasionally one encounters a man, who, having once been a drink addict, is now a moderate drinker. Though this is the exception which proves the rule, such a man is walking on thin ice, and it is merely a question of time before he will fall and be submerged.

Most inebriates have rather a hard time to remain abstinent. The drinking of alcoholic beverages is a universal custom. Most everyone takes alcohol in some form or other. Physicians use it themselves, and prescribe it, though much less frequently than formerly. I would remind you that in 1889 the London County Asylums, with a population of about 8,100, consumed about 255,000 gallons of malt liquors, while in 1905, with a population of about 19,450, they used only about 1,280 gallons (Sir Victor Horsley). Alcohol is used in the kitchens of most noble housewives, and hence we encounter it in our foodstuffs and table delicacies. Almost all fluid medicines contain it. But little of it is required to arouse the craving for more in the predisposed. A half-ounce of whiskey is usually more than enough. The little which is contained in a wine or brandy sauce, or in a glass of hard cider, will often suffice. "The down-and-outs" will tell you that it is easier to get a glass of whiskey than it is to get a piece of bread. The inebriate must live the life of his environment, hence you see that the road before him is rough and rugged. To err is human, and so is the inebriate. Beset with danger on all sides, cursed with a disease-breeding disposition, misunderstood and, therefore, misjudged, is it any wonder that he so often succumbs to temptation, and that the number of those who remain totally abstinent forever under any plan of treatment is small, as compared with the number of those for whom the best that we can secure is improvement. Improvement insofar that the days of inebriety will be fewer. In this connection we must also remember that relapse is not infrequently due to the fact that inebriety in a certain number of cases is merely an expression of mental disease. This applies especially to periodical dipsomania, which I am inclined to believe is often a manifestation of manic-depressive insanity.

Attacks of gout, as you all know, are not infrequently due to indiscretions in diet. The same is true of some forms of epilepsy. When the victim of gout, or the epileptic, who has disobeyed your orders and is suffering as a result of his indiscretions summons you, do you drive him from your doors or refuse to respond to his call? Do you have him arrested and sent to the workhouse or jail? Of course not. Why, then, should you adopt a different code of ethics in dealing with the inebriate? The drink habit is a manifestation of a chronic disease. Relapse calls for treatment, not for condemnation.

The following case serves to illustrate that improvement is sometimes obtainable even in apparently hopeless cases, and that even in these cases detention over a period of a few days will sometimes suffice after prolonged detention has failed.

Case VI.—J. P. A., a playwright, single, aged 46, has been a hard drinker for many years, being at first constant, but for the last few years has been subject to periodical sprees, which would last weeks or months. He drank enormous quantities of any alcoholic beverage obtainable, and also used narcotic drugs at times. He had been treated at Bellevue and other hospitals for alcoholism innumerable times. Was an inmate of Bloomingdale Asylum on two occasions, and had also been an inmate of the State Hospital at Poughkeepsie on two occasions; the first time for three months—the second for seven months. Concerning him the superintendent wrote me as follows: "While here Mr. R. had a parole to the hospital grounds on several occasions, but each time violated it and went to the city, returning in an intoxicated condition. His word was found to be entirely unreliable and he could not be depended upon to restrain his appetite for drink." He had also been an inmate of the Chester Crest Home and the Inebriate Asylum at Fort Hamilton. He had taken the Keeley cure and the Oppenheimer cure on several occasions, and had also gone through several so-called gold cures. He came under my observation July, 1905, acutely drunk and in a de-

plorable condition. He responded to treatment and remained abstinent about four months. He left me at midnight after an enjoyable evening at the theater, perfectly sober, and an hour later was blind drunk. He did not go back to the gutter, however, but returned to me, for he was making a hard fight to overcome his affliction. No other place being available, I placed him in the Essex County Hospital for one week, and then continued treatment and observation. Following this he remained totally abstinent for about eight months. Then he relapsed. I again placed him in the Essex County Hospital for one week. Following this he remained abstinent about two months. Then came another attack, which was very severe. In order to try the effect of prolonged detention he was placed in the New Jersey State Hospital at Morris Plains, where he remained eight months. He left the hospital on a Saturday afternoon and was drunk the following day. I placed him in St. James Hospital for one week, following which he remained well about six months. During the past two years he has had three attacks, all of them being of very short duration, only a few hours, before he voluntarily returned for help. In the interval between his attacks he has done good work. He is to-day sober and well, and I am pleased to number him among my closest friends. A gentleman by birth and breeding (his grandfather was one of the founders of the New York Hospital), it is his misfortune to be afflicted with periodical dipsomania. I firmly believe that he has no more control over his attacks than an epileptic has over his fit. Under treatment he has been greatly improved. I am hoping that in time his attacks will die out, instances of that kind being on record. Unfortunately, most of these cases are unrecognized, the victim is sent to jail, goes from bad to worse, and dies before his disease does.

Prolonged detention in cases of this type, is insofar as curability is concerned, unwise and usually futile. Almost invariably the patient is kept under restraint during his abstinent period, and is liberated shortly before the onset of his drinking period. Hence disaster follows.

Of incurable cases there are a host. I know hundreds of them. They should be cared for in custodial colonies, both for their own protection and for the protection of society. While such labor is, of course, a very doubtful quantity, there is no doubt that under a skilled manager such a colony could be conducted along lines which would make every man earn his bread by the sweat of his brow. However, no case should be considered incurable, however gloomy the outlook, until treatment has been tried. We sometimes get astonishingly successful results in apparently hopeless cases, as well as we get failures in apparently hopeful cases.

I am of the opinion that in almost every case there is a period in which cure is possible. As a rule this period is early in the disease, but occasionally in young inebriates, those around nineteen years of age, we get very poor results until, after two or three years of indulgence, the youth comes to his senses and gives us the assistance we so much need.

It is clear that the army of incurables is recruited from the army of mild cases. Men in the early stages of the drink habit will not as a rule consent to place themselves under restraint in a sanatorium. They usually will consent to undergo treatment for "neurasthenia," if the treatment will not interfere with their vocations. Herein lies one of the greatest advantages of treatment without detention.

Sanatoriums are, of course, necessary asylums in some instances, but, as a class, they are not adapted for curing inebriates. The patient is thrown into contact with other patients, and being very susceptible, readily learns new tricks. The last cocaine case I saw told me that he learned the use of cocaine in an asylum which he entered for the purpose of getting away from alcohol. Almost all the sanatoria I have in mind are in reality insane asylums, and the atmosphere is certainly not helpful for an inebriate.

The first step in attempting to cure a victim of the drink habit is to remove the alcohol, and to keep it away. If the patient is desirous of overcoming the habit he will give you his assistance. If he is not desirous of overcoming the habit, treatment is futile. Inebriates are sent to sanatoria so that they will be unable to get alcohol, except as ordered by the attending physician. Do they obtain alcohol without the knowledge of the physician? I fear that they do in most sanatoria, for isolation is as a rule imperfect and many alcoholics who have been inmates of sanatoria will tell you the tale of the tree which is hollow and of the attendant who is crooked. A father whose son I had placed in a sanatorium in a neighboring State, wrote me as follows: "The discipline is very lax. I have good reason to believe that drinking, gambling, and drug taking are carried on continually without the doctors' knowledge. My son went to town with attendants who got 'full.'"

In my experience, those patients who really want to be cured of the drink habit can, provided the condition has not gone too far, be cured, or improved by the judicious use of remedial agents and moral support, without detention or with but a few days' detention during the acute stage. That will power plays an important part in the cure is of course self-evident. Under treatment the weakened will can be strengthened in various ways, but best of all by exercise. When the patient resists the desire to take the drink which is within his reach he exercises his will power, and under the exercise it grows stronger. Under restraint, the will power is not exercised and consequently it grows weaker, not stronger, as a rule.

All things considered, the treatment of the drink habit without detention holds out the greatest hope for the greatest number. I commend it to your earnest consideration.

510 West End Avenue.

STRYCHNINE IN PNEUMONIA OF THE AGED.

By WILLIAM FRANCIS WAUGH, A.M., M.D.,

CHICAGO, ILL.

DEAN AND PROFESSOR OF THERAPEUTICS, BENNETT MEDICAL COLLEGE.

The fatality of pneumonia in the elderly and aged subject is well known. No newspaper case ever recovers, and these are always men who have lived long enough to make their demise a matter of public interest. When pneumonia attacks a man of sufficient note to have his condition bulletined, the journals put his obituary in type, for he is sure to die. This inevitable ending may be due in part to the distraction of the medical attendants, who have one eye on the patient and one on the press, but it is largely to be explained by the peculiarities of this class of patients.

In the aged the vital forces are ebbing; the digestive functions grow weaker, the hematopoietic apparatus becomes less capable of supplying extra

demands. The limitless possibilities of youth have passed away, and the shrinking forces are capable only of supporting the steadily contracting activities. There are also to be reckoned with the pathologic relics of the active period of life, the dregs of disease, the results of abuse, and the influence of habits. The most important consideration usually is that the reserves of vitality have been spent.

Disease taken in its broadest sense is essentially debilitant. No malady increases the vital forces or enhances the faculties. Every illness is destructive, constitutes a drain on the powers, and lessens the stock of vitality that must suffice to carry the individual to the limit of his viability. The difficulty with which the aged recuperate from losses of the body fluids was known even to the mighty bleeders of the school of Bouillaud. The value of normal saline solution, as employed to swell the volume of the circulation, is appreciated by comparatively few to-day. While the loss of elasticity in the arterial coats may be an obstacle sometimes, there are many instances in which the pulse communicates to the finger the sensation of a half-empty vessel, where an increase in the bulk of the blood is feasible, if not rashly pushed beyond the capacity of vessels to receive and heart to propel. The evanescent glow following a generous imbibition of hot toddy is not due directly to the alleged stimulus of alcohol, but to relaxation of the vascular walls and the addition to the nutrient stream. Better nutrition of the heart and the cerebral centers is the consequence of the fuller blood current.

These considerations point to the truth of my proposition, that the occurrence of pneumonia in the aged is a formal indication for the administration of strychnine. We need not wait for debility, low vascular tension, or any other of the indications pointing to the need for strychnine in the young; we have an imperative call for this potent helper in the simple fact of pneumonia in the aged. Strychnine arouses the dormant powers and energizes them. It awakens the sensibility, restores the elasticity, the spring of a younger age, and enhances every vital function. The bases of physical power, the digestion, the respiration, and the nervous organization on which all depend, are restored to activity and power by this most potent agent. The presence of secretion is felt in the pulmonary tract, and it is removed by the patient's efforts. The pulmonary tissues are vivified, and the blood serum does not transude the vessel walls, nor do the tissues lose their vitality. The heart shares in the general toning, and the circulation is sustained. The eliminants are likewise energized and the toxemia naturally reduced to safe limits.

Despite the tendency of recent teaching I can not look on fever as altogether beneficent. It is a fire that here threatens to become a conflagration. With Juergensen I look upon it as the chief element in the causation of that cardiac debility that constitutes the most serious danger to the patient's life. While fever represents the patient's reaction against the onslaught of the disease, it is not in itself salutary, or is so only when restrained within salutary limits. It is a combustion that rapidly consumes the tissues, the fluids, the red blood corpuscles, and whatever reserve forces the patient may still possess.

But it is obviously desirable to repress the fever with as little general sedation as possible; and here we have another indication for strychnine, since this drug notably enhances the antipyretic action of the heat-reducers when administered with them. Give a certain dose of veratrine or aconitine, and whatever reduction of temperature they may effect alone, this will be notably increased by the simultaneous administration of strychnine. This remarkable fact was first announced by Oliveira Castro, and has been confirmed by many observers. So marked is the antipyretic action that, to account for it, Biechy was led to claim that strychnine is essentially a sedative and not a stimulant.

The true explanation is different. Drugs do not act directly of themselves, but through the intermediation of the vital functions which they incite or depress. Drugs do not act on a dead body, but only on and through the living, acting functions. Strychnine enhances the sensibility of all these, through its influence over the cerebrospinal centers; and therefore these respond more readily to the power of other remedies, such as aconitine and veratrine, which enhance inhibition and elimination in smaller doses when thus aided by strychnine.

Of the salts of strychnine the preference should be given to the arsenate. Arsenic favors fatty degeneration. Acting more powerfully on the forming, unorganized products of disease than on the healthy tissue cells, it tends to disintegrate the former and facilitate their removal, thus limiting the destruction caused by the disease and shortening the period of repair, or convalescence. It is now held that in malaria arsenic acts beneficially by imparting to the red corpuscles a power of resistance or repulsion against the plasmodia. If so, inferentially we may assume that these cells, and presumably others, may thus be protected against other microorganisms. We need scarcely add that while the pneumococcus belongs in an entirely different category from the malarial plasmodium, the damage wrought by infectious diseases is not solely due to the leading causative germ, but this opens the door to many others, that profit by the opportunity offered by the general lowering of the vital defense. Hence my preference for strychnine arsenate.

In this advocacy I am referring to the scientific use of this remedy, as properly dosed. The man who gives a bulky dose of strychnine once in 4, 6, or 8 hours, never learns to use it. The solubility of a drug regulates its absorption, the manifestation of its activity and its elimination. Strychnine arsenate may be administered in doses of half a milligram every quarter hour, half hour, or hour, repeated until exactly the desired tonicity has been secured, then often enough to maintain this. Employed in this manner, with a clear idea of what it will do, one need not be incredulous of the reports of its efficacy. A given dose of strychnine always exerts exactly similar activity to any other dose of the same size, as to quality and quantity of effect; but the reaction of each patient differs. We may therefore find cases in which three doses *per diem*, of ½ milligram each, suffice for the need; or we may find that a grain a day or more is requisite. There is no such thing as "a dose." The true dose is what suffices to produce the desired effect.

In the treatment of pneumonia in the aged we should hold to this routine:

Clear the alimentary tract and eliminate from the case the factor of fecal toxemia. Free the emunctories, and see that the toxins are passing out freely by every channel. Sustain the vitality and the vital organism from the beginning. Moderate fever to salutary limits and keep up nutrition. In-

crease leucocytosis. Meet each undesirable symptom with the appropriate remedy. Treat in each case the pathological conditions presenting rather than seek an illusory specific for the malady viewed as an entity.

CEREBELLAR ATAXIA — WITH REPORT OF A CASE.*

By CHARLES ROSENHECK, M.D.,

NEW YORK.

NEUROLOGIST TO THE HARLEM HOSPITAL, O.P.D.; PHYSICIAN TO THE METHODIST EPISCOPAL DISPENSARY.

Although our knowledge of cerebellar function is at present meager, we have learned to recognize disturbances in the cerebellum with varying success. This is due to the well-known association of the cerebellum with maintenance of bodily equilibrium. Disease processes in this part of the cerebrospinal axis primarily produce disturbances of gait and station, thus affording a valuable diagnostic aid. The associated symptoms, such as vertigo, nystagmus, reflex phenomena, ocular and auditory disturbances, are by no means conclusive of cerebellar affections—merely corroborative, for they may occur in a variety of cerebral affections in which pressure of circulatory disturbances inhibit or disturb brain function.

Cerebellar ataxia had been observed and described by the older writers, who were unaware of the true pathological condition and considered these cases as anomalous forms of hereditary spinal ataxia. Fraser in 1880 described the first case and accurately pointed out the cerebellum as the seat of the affection. Nonne described three cases later, thus placing cerebellar affections as distinct clinical entities. Since then a fairly voluminous literature testifies to the interest the condition has awakened. In reviewing the literature, however, one is impressed by the great number of cases of Friedreich hereditary ataxia described as cerebellar. This is at variance with the pathology of Friedreich's disease. Although ataxia of a cerebellar type is present, the cerebellar fibers are not often affected. The ataxia is due mainly to a sclerosis of the posterior and lateral columns. On this account we should exclude these cases from the true and well recognized affections of the cerebellum, viz., tumors, abscesses, inflammatory processes, sclerosis and atrophy, softening and hemorrhage. Thus the following cases from the literature represent fairly accurately the various aforementioned pathological processes:

Under the title of "Acute Ataxia" (Encephalitis Cerebelli) (Transactions of the Clinical Society of London, 1907, XL., 276) Batten reports the case of a child who, after an attack of measles, vomited, had a convulsion, and passed into a comatose condition. After return of consciousness, an ataxia of the trunk and extremities was present which showed no improvement at the end of three years. The left extremity was incoordinate. Sensation and knee-jerks were intact, and the mental condition was slightly impaired.

Porot (*Bulletin Société Medical de Hôpiteau de Lyon*, 1906, V., 369-374) reports a case coming under observation with marked ataxia and dimness of vision. Examination revealed a right hemianosmia and hemiamopsia. No ptosis or diplopia. No pupillary disturbances or paralysis. A moderate dysarthria was present, and before death there were increased blindness and marked psychic disturbances. Autopsy showed extensive softening of the cerebellum, with destruction of the right hippocampal convolution.

Bacon (*American Journal of Medical Sciences*, Aug., 1895) reports the case of a male patient, aged 31, with a chronic suppurative otitis media of five years' duration, who sought relief for an intense vertigo and a staggering gait. A radical mastoid operation was followed ten days later by severe headache, vomiting, extreme vertigo, difficulty in speech and swallowing, and a right facial palsy. Autopsy revealed an abscess in the right cerebellar hemisphere.

Horsley (*British Medical Journal*, 1887, I., 865) (quoted by Starr) reports a case in a male, aged 18, who had suffered from headache, vomiting, optic neuritis, increasing weakness of all limbs, especially of the left arm and leg, vertigo, and a typical staggering gait of cerebellar disease. He also had epileptoid attacks with turning of head and eyes to right. Mental state good, but he was emaciated and bed-ridden. Operation revealed a tubercular tumor of the right lobe of the cerebellum.

Anderson (*Intercolonial Medical Journal*, Austral., 1906, II., 439) reports a case in a man aged 80, with marked arteriosclerosis, who after a partial loss of consciousness, felt giddy and in a few days developed marked ataxia of legs and left upper extremity. No paralysis was noted. Reflexes were intact. There was thickness of speech at times. No aphasia or amnesia. He regarded this case as one of hemorrhage into the cerebellum.

Under the title of "Defect of Cerebellum Occurring in a Brother and Sister" (*Glasgow Medical Journal*, p. 90, 1880) Fraser describes the first cases observed in a brother and sister, aged 30 and 20 years, respectively, who developed, within a short time of each other, a gradually increasing reeling gait, a "slow, gutteral, and hesitating" speech, with moderate ataxia of the upper extremities. Hearing and vision were undisturbed, and there were no psychic alterations. The brother dying of an acute tuberculous infection gave Fraser the opportunity to study the affection post mortem. He found the cerebellum considerably diminished in size, the cortex shrunken and atrophic and the cells of Purkinje contorted and shrunken.

A résumé of the above reports confronts one with the unalterable fact heretofore stated, that the *sine qua non* for cerebellar diagnosis is the ataxia, and to attempt a diagnosis of cerebellar disturbance on the associated symptoms alone would be rather difficult and unjustifiable. Apropos of the above I can do no better than to quote Collins ("Twentieth Century Practice") who states, "The disturbance of gait or locomotion is the symptom of grand importance, and, although absence of the characteristic gait has been noted in a number of cases of cerebellar disease, particularly of tumor, this in no way militates against the truth of the statement that cerebellar gait is by all means the most important diagnostic symptom."

The subject of my report first came under my observation about a year ago, with the following history: She is a female domestic, 34 years of age, the only child of parents who were considered unusually robust and healthy. She is positive that no similar trouble existed in any of her relatives. The demise of her parents was rather sudden, the father dying of cerebral hemorrhage, the mother of

*Patient presented at a meeting of the Harlem Medical Society, April 7, 1909.

pneumonia. The patient never had any serious illness, with the exception of the usual diseases of childhood. She menstruated at 15, and had a miscarriage at 23. There are no living children. Promiscuous relations were admitted prior to her marriage. About nine years ago, when she was 24 years of age, she noticed a feeling of weight in attempting to use the right leg. This was followed by a gradually increasing ataxia, which the patient interpreted as a staggering gait. On this account she was unable to obtain employment, her reeling gait being always eyed with sinister significance. Up to two years ago she had been able to use her hands for finer movements, then noticed some difficulty in handling small objects and using fingers for complicated movements, such as sewing, buttoning clothes, etc. Has never had any difficulty in using tongue or in swallowing. Vertigo is present at times, but of a transitory character. No headaches. Patient is able to do anything when in a sitting posture or standing still, but is afraid to walk about for fear of stumbling. For past two years there has been an inability to hold bladder or rectal contents for a short space of time.

Examination showed a well nourished and healthy looking woman, appearing none the worse for her malady, of fair intelligence, and with no alterations in the psychic sphere. The pupils react promptly to light and accommodation. The fundi oculi are normal in every respect (Dr. Martin Cohn). There is no true nystagmus, but fairly continuous oscillations of the eyeball can occasionally be observed. There are no ocular or cranial nerve palsies. The speech is somewhat slow and hesitating, but enunciation is quite distinct. A slight ataxia of the upper extremities is present, but no intention tremor. The gait is typically cerebellar, with no particular tendency to forced movements. At times she staggers to the right and at other times to the left. Propulsion quite marked, but no retropulsion. The sensory and motor sphere are intact and there are no vasomotor disturbances. The electrical reactions and superficial skin reflexes are normal. Conjunctival and pharyngeal reflex present. The biceps, triceps, and wrist jerks are present and normal. The patellar and tendo Achillis reflexes are markedly exaggerated, but there are no Babinski, Oppenheim, Kernig, or Romberg phenomena. Ankle clonus is absent. No labyrinthine or auditory disturbances. Wassermann-Noguchi reaction negative. (Kaliski, Mt. Sinai Laboratory).

That the cerebellum is the seat of the trouble admits of no doubt, but the exact pathological process at work is somewhat problematical. In view, however, of a certain luetic infection, and the continuation of the symptoms these many years, it is quite safe to surmise a primary sclerosis of the cerebellum due to syphilitic virus.

247 West One Hundred and Thirty-fifth Street.

THE THERAPEUTIC POSSIBILITIES OF THE JUICE OF THE FRESH PINEAPPLE.

By B. G. R. WILLIAMS, M.D.,

PARIS, ILL.

In undertaking the study of this subject two years ago, I considered only its possibilities in the treatment of certain throat conditions. But the field of usefulness of the vegetable proteolytic enzymes has been so enlarged and so much is being said on the subject that several months ago I saw my way clear to overlook entirely its employment in pharyngeal diseases and investigate its value along altogether different lines.

The pineapple (*Ananasa sativa*) is a native of the West Indies. It is found in other tropical countries, but the finer varieties come from the British hot houses, the wild pineapples being fibrous and with but little flavor. After a careful inquiry as to the chemical nature of the pineapple, I find that more work is possible along this line. Several authorities have acknowledged as much in personal letters. Older botanies and materia medicas state tersely that analysis of the juice shows the following: sugar 2 per cent., free acid 1 per cent., albuminous and pectinous substances 3 per cent., and water 94 per cent.

Some years ago Señor V. Morcano discovered that the juice had the power of digesting proteins. Professor R. H. Chittenden (*Journal of Physiology*, XV, p. 249) studied the pineapple more thoroughly. He showed that the juice in a fresh condition contained an enzyme, or enzymes of a proteolytic nature, active either in acid or alkaline carbonate media. Concerning the temperature, he stated that it was most active between 122° F. and 140° F., still digested at 86° F., but was destroyed at 158° F. He showed that since leucin and tyrosin, as well as proteoses and peptones, were formed, this new enzyme was more nearly related to trypsin than to pepsin. This active substance (or if there be several) has been termed tentatively bromelin (from *Bromelia*—latin for pineapple).

Careful comparison of the digestive powers of the proteolytic enzymes of certain plants will show that, while those from the pawpaw are more powerful beyond a doubt, bromelin offers so many advantages that it is safe to predict that it will eventually replace the last few months' reign of the *Carica papaya* preparations. With the question of the therapeutic indications of all enzymes in its infancy, we can expect any statement like the previous one to mean merely, "Lo here!" And as the crowd starts coming, some new truth leads a fellow observer to cry, "Lo here! Over here, not there, is the truth."

The various pharmaceutical houses have made such extravagant claims for each new enzyme as it has been isolated that we sometimes are inclined to pass by the entire subject and search no further. Some time ago an advertisement came to my notice claiming that the pawpaw ferments were indicated in all diseases of the stomach.

Before assuming that there is any use whatever for the juice of the fresh pineapple in medicine, we must recognize certain facts: Fresh pineapple juice is always obtainable, pawpaw is not, but must be supplied by pharmaceutical houses in a preserved state, which means, if we know anything of the nature of enzymes, in a more or less, generally less —to say the least, very variable—active condition.

As a matter of course we must look to bromelin for our chief therapeutic results from pineapple juice administration. Yet we must not overlook the presence of other substances in the juice. For example, there is some acid present. The Bureau of Chemistry of the U. S. Department of Agriculture informs me that the principal acid seems to be citric and that it occurs in varying quantities, usually from 8 to 9 per cent. It is well to note the presence of sugar, and likewise certain albuminous substances, in case it is desired to add preservatives to the juice.

In experiments with the juice of the pineapple,

I have found that large amounts may be taken from one apple by the aid of the fruit press. When this is collected it is of a dirty, greenish color, and is translucent. It is filtered with difficulty, the filtrate being clear. All of my experiments have been carried out with the unfiltered juice, it being passed through cotton merely to take out the larger pieces of fiber.

The specific gravity varied considerably, but averaged 1054 from several dozen apples. The reaction was acid, but was capable of being neutralized, or at least overclouded by small amounts of inorganic alkalies. The acidity persisted in old samples of the unpreserved juice, in preserved samples, and in media where digestion of the proteins by bromelin had occurred.

Concerning the requirements for the action of the enzyme to take place, I have found that Chittenden's experiments were easily duplicated. At ordinary temperatures digestion took place with astonishing rapidity the presence of leucin and tyrosin being easily demonstrated in short periods of time and solution occurring rapidly. A small amount of pineapple juice was capable of digesting much protein. For example, piece after piece of steak added to but a few cubic centimeters of the juice disappeared within a few hours, and yet the enzymes seemed capable of further action when more meat was added. The temperature variations and reaction requirements I found to agree with other investigators. Boiling killed the enzymes, so that after canning, the pineapple loses its digestive powers.

The fresher the juice the more success I have had. Pineapples may be kept for long periods and bits of the fruit eaten as food form an ideal method of administering the enzymes internally. For external application, I generally use the crushed pulp or lint soaked in the juice. The expressed juice may serve if it is desired to disguise it. A few drops of caramel will render filtration unnecessary. Spearmint or other flavoring agents may be deemed advisable in certain cases to hide the taste. But, after all, whenever possible, I prefer the fresh pineapple unexpressed, uncolored, and unflavored.

At various times I have attempted to prepare a permanent preparation of the juice which I might keep upon my shelf in a bottle in order to avoid the annoyance attendant upon obtaining and prescribing the fresh juice. The result has been failure, invariably. I would not from these few experiments have any person believe that such a preparation is an impossibility, but rather would point out the difficulty of obtaining it and expecting at the same time no diminution of digestive powers. I avoided the more poisonous preservatives, though, of course, they might find a place in preparations not used for internal administration. Among such I would name thymol, borax, benzoate of soda, etc. Those which I tried were glycerin, alcohol, chloroform water, and spirits of chloroform. The results of these investigations are clearly shown in the table just below. In general, it is evident that as safe preservation from fermentation of the sugars is attained by the addition of certain chemicals, the proteolytic enzymes are rendered inactive, and that this inactivity is in direct proportion to the degree of preservation. Large amounts of aqua chloroformis may serve to preserve small amounts of the juice but render it unfit for internal administration. The amount of fluid used in each test was two drams. So that, if we keep in mind that equal volumes were used at all times the apparent discrepancies in the recording of the amounts of precipitate are easily explained.

THE LEAST POISONOUS PRESERVATIVES AND PINEAPPLE JUICE

No.	Test	Carbohydrate Fermentation	Precipitation	Protein Digestive Powers
1	Aqua destillat (control)	.....	.....	.....
2	Fresh juice (control)	.....	.....	Marked
3	Unpreserved juice	3rd day	Small	Fairly good
4	Chloroform water, 5%	4th day	Small	Fairly good
5	" " 15%	4th day	Small	Fairly good
6	" " 30%	5th day	Small	Fairly good
7	Alcohol, 10%	.....	Moderate	Poor
8	" 20%	.....	Large	Very poor
9	" 30%	.....	Very large	None
10	" 40%	.....	Fairly large	None
11	Spirits, chloroform, 5%	7th day	Moderate	Very poor
12	" " 15%	.....	Large	None
13	" " 25%	.....	Large	None
14	Glycerin, 5%	4th day	Small	Fair
15	" 25%	.....	Small	Poor
16	" 50%	.....	Very small	None
17	Canned juice	.....	.....	None

Note.—All samples except the fresh juice and the canned juice wer kept for two weeks in my laboratory at about 80° F. All sunlight was excluded from the test tubes. In all tests, fibers of roasted beef were used.

The therapeutic possibilities of pineapple juice were brought to my notice some years ago in a case of pharyngeal diphtheria by its administration in the hands of men who, I feel certain, did not understand how it acted, but were sure that it did have some advantages over ordinary gargles. Personally, I have never seen a diphtheritic membrane extensive enough to indicate its use. But the circumstances brought to my mind its possible value, not only in certain cases of this disease, but in several other fields. This value would depend, to be sure, upon the selective action of bromelin, upon its power to pick out nonliving proteins and rapidly digest them, leaving behind all living tissues, thus differing from the action of salicylic acid and other tissue solvents. As I have stated, I have yet to come across a case of diphtheria in which this treatment seemed to be indicated. However, in cases of quinsy, suppurative tonsillitis, and pharyngitis my experience has been different. Here, because of objections by the patient, or because of my inability to see the exact pointing of the abscess, surgical intervention has often been disappointing. I shudder when I recall some cases of needless butchering which I have seen inflicted upon some of these patients. Quinsy and pineapple juice have been synonymous terms with me for some time. The bromelin never makes a mistake, but digests off the necrotic tissue, giving very often a quick relief. To be sure, such an action is impossible early in the disease, though several hours or days of suffering may be avoided after the pus has once by its presence rendered the overlying tissues bloodless and necrotic.

Several months ago I was called to see a lady who had broken both thighs in a fall. As she was eighty-three years old and in poor condition physically, I did not apply extension, but limited movements of the member by bran bags alone. Gangrenous areas developed promptly over the sacrum in spite of alcohol as a rub. It seemed to be a question of a few hours until I should be called upon to sign a death certificate. However, one month later she was walking about with the aid of crutches. I then applied pineapple juice in small amounts to the bed sore. The reaction was prompt, healthy granulations taking the place of digested necrotic tissue, and at the present writing all signs of the sore have disappeared. Caution was necessary in this case to keep the juice within the margins of the decubitus, as the skin was drying rapidly.

While in furuncles the ideal treatment is incision, sometimes this is forbidden by the patient, as he prefers to suffer rather than have the knife used. Thus I have seen a yellow cap remain upon a boil for hours without solution and hold back the pus. Though the man was suffering agonies, he hesitated to face the bistoury. The application of pineapple pulp shavings invariably establishes free drainage within a short time. The yellowish and desiccated necrotic head is often digested promptly.

A peculiar case of aphonia came under my attention some time ago. The man could whisper but could not speak aloud. No pathological changes were noted, although some mucus was raised which evidently came from the trachea and larynx. There was a slight cough. After four weeks of vain medication, pineapple juice was tried. Its action was so satisfactory that I never fail to try the juice where the so-called mucosolvents containing borax and soda do not act properly. However, there are limitations to its use in the mouths of sick persons, as I learned in a case of aphthous stomatitis following measles. Here the use of the fresh apple led to prompt bleeding and great discomfort.

Recurrent urethral gonorrhea, where there is a copious discharge, may yield promptly to injections of the juice. Here dilution is preferable in beginning the treatment, increasing the concentration gradually and cautiously day by day. In cleaning up wounds pineapple juice will dissolve clots and render them more easily removed by the peroxide of hydrogen.

I have yet to see good results from pineapple collodion on corns, though I have tried it in several cases. I have had no experience with it on indolent ulcers and sinuses. It is not only useless, but dangerous to apply it to abdominal suture sinuses commonly termed fat necroses. These tissues are of low vitality, and are easily destroyed.

It is indeed with hesitation that I attempt to offer the fruit of the *Ananasa sativa* as a therapeutic agent in gastric conditions. There has been so much said and yet so little proven concerning the relations of enzymes added or presumably added to the contents of the human stomach. Again, what I would say presumes no finality. Be that as it may, let us consider its theoretical possibilities as an artificial gastric juice in the achylias and hyposecretory conditions. We have both the enzymes and acids; it lacks the disagreeable odor of pepsin, affording rather to the full grown dinner a delightful portion, and, finally, it can be obtained thus in its active and palatable condition when the other vegetable enzymes of a like character are unavailable. No; it is not of use in all gastric disorders, but in very few, if any. In fact, I think that I can see its disadvantages, theoretically at least, in carcinoma ventriculi, where gangrenous tissue is present—we are dealing with enzymes much more powerful than pepsin. But it seems to me that the stomach can use pineapple juice under certain conditions. And this I would point out to be a prevention rather than a relief of symptoms. Pineapple juice cannot quickly neutralize an acute indigestion, but it may prevent one. I recall at least one patient who, though sound physically in every respect, knows that when he sits down to the Thanksgiving dinner a most painful sick stomach is certain to follow. There could be no better addition to the meal than a piece of pineapple eaten now and then. To be brief, I convinced myself long ago that pineapple is a Godsend to the one who dissipates. The midnight chop-suey and lobster lose their terrors, and he retires confident of dreamless sleep even after mince pie or fruit cake, where once he would not have dared. Possibly no encouragement of this kind should be given to such habit; nevertheless, such knowledge is of value to the medical man in his consultation with the one with whom the ordinary meal is as much a dissipation as the midnight banquet. Those who cannot bear the taste of the fruit must search elsewhere—there are stomachs and stomachs. The healthy individual does not need the pineapple except as an adjunct to the especially large dinner. He should avoid permitting his gastric glands to suffer atrophy of disuse by depending continually on an unnatural digestant. I hesitate at this time to give a general rule for dosage of this fruit.

In a brief summary I shall omit the general therapeutic indications, pointing out the advantages of bromelin over the other proteolytic enzymes used in internal medication: (1) To pepsin, in that it is not nauseating, is more easily obtained and administered, and acts promptly in most any kind of media and variation of temperature. (2) To trypsin and vegetable proteolytic enzymes, in that it is more palatable, serving as a dessert rather than a drug, but chiefly in the fact that it is so readily obtained in its most active condition.

Malignant Diphtheria in an Infant.—Rolleston reports a fatal case of diphtheria in an infant six weeks of age. The membrane appeared on the tonsils, anterior pillars, uvula, pharynx, epiglottis, anterior nares, buccal mucosa, labia majora, and anus.—*Proceedings of the Royal Society of Medicine.*

Meat Diet in the Tuberculous.—F. Vandeputte says that the tuberculous subject loses in weight because of increased waste and deficient nourishment. The increased waste results from the fever, the profuse sweats, and the expectoration, as well as the inability of the digestive organs to assimilate foods. The results of meat diet are not brilliant; tolerance fails before a sufficient amount has been taken to feed the body. Man is not a carnivorous animal in the normal state, and cannot become so in a pathological state. If too much protein be taken we get bad digestion, flatulence, and diarrhea due to intoxication from poisonous materials ingested. When the meat is replaced by vegetables we get absence of these symptoms. A mixed diet has these advantages; it keeps up a good appetite; continues the normal function of the digestive tract, and facilitates assimilation. This is necessary for the cure of the individual. If the action of the liver be not good the whole organism suffers.—*Le Nord Médical.*

Relations of Acute Polioencephalitis with Infantile Paralysis.—A. Delearde and André Paquet consider that infantile paralysis and acute polioencephalitis are identical diseases with different localizations. The etiology of these diseases is not established as yet, but they give every reason to believe that they are similar to the other infectious diseases. Both begin with a febrile stage; a stage of paralysis follows in which the paralysis develops quickly; then comes the stage of regression of paralysis and permanent deformity. In polioencephalitis there is an inflammatory process affecting the bulbar motor nuclei, while in infantile paralysis the motor nuclei for the muscles of the limbs are affected. Both involve motor nuclei. In polioencephalitis we may have the eye nuclei involved, with fixity of the globe, ptosis, strabismus, and inequality of the pupils. When the hypoglossus is affected we get troubles of deglutition. When the recurrent laryngeal nerve is involved there is failure of the voice; if the pneumogastric is affected we have failure of respiration and rapid pulse with sudden death. The paralysis is flaccid, with atrophy of muscle, and failure of osseous development. The faradic contractility is lost in permanently paralyzed muscles, and galvanic reaction of degeneration is present. Postmortem there is found inflammation of the bulbar nuclei. All these symptoms are common to both the diseases under consideration.—*L'Echo Médical du Nord.*

AMERICAN MORTALITY STATISTICS.

THAT the death rate of the country is high is surmised, but not definitely known. At least, such is the statement of Mr. Edward Bunnell Phelps, who has been writing on the matter in the *American Underwriter*, December, 1909. However, Mr. Phelps says that since 1900 the Census Office has compiled approximately accurate vital statistics which, after all, is the best that can be expected. The South, with its unusually large percentages of both the colored race and native born Americans, is still without the fold of the registration area, Maryland being the only Southern State of which reliable mortality statistics can be obtained. The object of Mr. Phelps is to analyze available statistics, and by means of tables he makes a comparison of the annual death rates from various leading causes in the registration area in the nine years 1900-1908, inclusive. The death rates are calculated per 100,000 population, and the urban and rural death rates are set down separately. We are unable to refer here to the rates in detail, but it may be noted that in the last four years of the nine-year period the general death rate of the entire registration area dropped from 1,656.2 to 1,600.6, a satisfactory decrease of 55.6 per 100,000 population. Most of the decrease occurred in the urban districts. No doubt Mr. Phelps is correct in his hypothesis that the causes of the large fall of the mortality rate of cities are various, but that they are due to improvements in sanitation, hygiene, and medical and surgical methods. As a matter of fact, sanitation and hygiene are far superior in town than in country, and, of course, the facilities for obtaining medical and surgical care are much better in urban than in sparsely settled rural districts.

Mr. Phelps draws attention to the fact that the Census Bureau since 1907 has initiated uniform methods for the collection and publication of vital statistics in the United States, and in other respects has greatly improved upon former modes of performing the work, so that probably the death returns of the past two or three years may be more exact than those previous to 1907; but in most cases, at least, the returns for the nine years are fairly comparable. As to comparative figures for the various classes of diseases, as shown by the Census Office statistics, the conclusions to be drawn are both interesting and of a conflicting nature. Typhoid fever apparently shows a pronounced decline in the nine years under survey, although the record of the cities in the registration States seems to have increased from 25.9 to 28.1 per 100,000 since 1904. This is a matter difficult to explain. There has been a decrease since 1900 in the death rate from tuberculosis, but the decrease was not so large as might have been hoped or even anticipated. The mortality rate of other forms of tuberculosis than pulmonary shows an increase; this is, however, probably more seeming than real, and may be largely owing to the method of classification. In any event, the decrease in the death rate from tuberculosis hardly exhibits the decline that might be expected when considering the money expended and the efforts put forth to check its spread. The increase in the death rate from cancer is a sad reflection on the inability of modern science to cope successfully with the disease. Until, perhaps, the cause of the malady is discovered little can be done in the way of eradication. The most hopeful feature of the fight against cancer is that in every civilized country, money and brains are being devoted lavishly to the attempt to solve the mystery of its origin. Diseases of the digestive system, diseases of early infancy, and Bright's disease not only show no decrease of consequence, but in most cases indicate a decided increase. The death rate from diarrhea, enteritis, and diseases of early infancy exhibits a very slight decrease in cities, but a heavy increase in rural districts and a net increase of 5.1 deaths per 100,000 population in the whole registration area. The campaign against infant mortality has been carried on with great vigor in some American cities, and especially in New York, where its good effects have been evident. However, it may be stated as an undoubted truth that, until American mothers generally will feed their children at the breast, the death rate among infants must be high. If possible, it would be interesting and instructive to gather data as to the number of breast-nourished infants in this country.

A most disquieting portion of Mr. Phelps' figures is that which relates to the death rate from violence. If it cannot be said that the death rate from this cause is increasing by leaps and bounds, it can be stated that its decided increase is sinister and alarming. Mr. Frederick Hoffman has shown that the suicide rate has manifested for many years a continuous upward tendency in practically all cities of the first or second rank in this country. The figures of the Census Bureau indicate that in city and country alike suicides have been more frequent since 1904. The increase was approximately 37 per cent. in 1905-1908, as compared with 1900-1904. This seems to prove that we are becoming yearly more and more victims to our environment, to the strain and stress of modern life. The record of other deaths from violence provides sorry reading, for our railway accidents, mining disasters, factory accidents, etc., are mainly pre-

ventable. Good service has been done by Mr. Phelps to the cause of medical science and of humanity by the publication of the statistics on which comment has been here made. Reforms, sanitary or otherwise, will never be introduced so long as the general public is ignorant of the true condition of affairs. The death rate throughout the country is decreasing, but there are many phases of the situation which require scrutiny with a view to improvement. Infant mortality and deaths from violence are the most conspicuous of these.

THE RESEARCH DEFENCE SOCIETY.

A SOCIETY in defence of research work was recently established in Great Britain under the presidency of Lord Cromer. The so-called antivivisectionists of Great Britain have advertised their objections to animal experimentation with such clamor that the ordinary individual has been dazed by the noise and has taken part in a movement of the merits of which he has been profoundly ignorant. His ignorance has been played upon by the specious arguments of fluent partisans. No doubt there are those who thoroughly believe in the propaganda against vivisection which they advance, but it may be stated without fear of contradiction that those are little conversant with the scientific aspects of the case. The society in denfence of research work which has been founded in Great Britain has been established for the purpose of explaining to the public the objects of animal experimentation and in order to dissipate the myths and rumors which have gathered about and which have been spread concerning the modus operandi of these experiments. Anyone who cares to take the trouble can thus easily investigate the matter, and whoever does this will find that the origin of many of the most dreadful diseases to which man is liable has been found by animal experimentation, and as a natural corollary a discovery of the means of eradication, of prevention, and of treatment has followed.

The antivivisectionists of Great Britain are now greatly concerned because the Bishop of North Queensland, Australia, has allowed himself to be enrolled as one of the vice-presidents of the Research Society. Of course, his action has aroused a storm of protest in England and he has been written to by the chairman of the Church Antivivisection League imploring him to reconsider his determination. However, the bishop is not to be moved by these entreaties, and in his reply he stated that he deemed it his duty to join a society which was founded "to make known the facts as to experiments on animals, the immense importance to the welfare of mankind of such experiments, and the great saving of human life and health directly attributable to them." Moreover, he remarked that he could judge of the ignorance of the public in England only by the "rhetorical license" of those who essayed to represent them. Furthermore, the bishop stated that he had stronger reasons for his advocacy of animal experimentation, in that he had seen something of those dreadful tropical maladies of which the public knew nothing in England. He himself had been largely instrumental in establishing an Australian Institute of Tropical Medicine, and in its laboratories, as in others of a like nature, animal experiments were necessary, needless to say carried out with humanity and due regard to animal life. The British Research Defence Society has commenced its work under favorable auspices, and the fact that a bishop has been sufficiently courageous and broad-minded to act as a vice-president should give some of the sentimental enthusiasts who declaim so noisily against experiments on animals food for thought.

NUTRIENT SUPPOSITORIES.

A FEW years ago the use of the nutrient enema was somewhat more in vogue than at the present day, partly due to the fact that it has recently been found by physiological and metabolic experiments that but a small portion of the food given by this method is absorbed into the system. Adding to this the frequency with which the oft repeated injections of fluid into the rectum not only excite peristaltic unrest and thus defeat their purpose by causing their premature expulsion, but even by their irritant action set up various degrees of colitis and proctitis, the growing prejudice against nutrient enemata is sufficiently explained. There are, however, many cases in which complete gastric rest is to be desired, or a temporary obstruction to the upper alimentary tract makes feeding *per os* impossible, while not of sufficiently long standing to make gastrostomy necessary, in which it is desirable to get some food into the body, be it ever so little. To meet these cases Boas, in an article in the *Berliner klinische Wochenschrift* for April 4, 1910, suggests the use, instead of nutrient enemata, of nutrient suppositories. Those which the author has used for over three years consist of crystallized egg white, which Ewald showed twenty years ago to be as easily absorbed as albumose, provided a little salt is added, carbohydrates in the form of the nonirritating dextrin, and fat, for which the usual cocoa butter is used. Each suppository, which is two and one-half inches long, and one-half inch thick, contains approximately 20 per cent. of water, 2 per cent. of salts, 20 per cent. of fat, 33 per cent. of carbohydrate, and 23 per cent. of protein, and has an energy value of 46.2 calories. Such suppositories Boas administers four times a day, if necessary, with five drops of laudanum. He irrigates the bowel morning and night with saline solution. While not claiming that this small amount of nourishment is sufficient to sustain life for any length of time, he finds that such suppositories are better borne by the patients than nutrient enemata, that a much larger proportion of the food is absorbed, and that the patient's general condition is distinctly better.

THE VISCOSITY OF THE BLOOD.

DURING the past decade the procedure of viscosity estimation of the blood and its relation to disease has received more or less attention from various observers. This physical characteristic of the blood, as estimated by measuring the time required for it to flow through a glass tube of a definite bore and length and comparing this with the time required for distilled water to make the same journey, depends upon such various factors that uniform results have been rare, and the ascribing to them of chemical significance has been diffi-

cult. Not only do changes in the red blood count and hemoglobin content alter the viscosity, but variation in the blood plasma, in its globulin, and its salts, and the amount of absorbed water, all influence it in one way or another. Sex, age, constitution, diet, exercise, baths, and drugs are influencing factors in the determination of the viscosity. In the *Berliner klinische Wochenschrift* for March 28, 1910, Oehlecker reports a series of investigations into the significance of viscosity variations in acute surgical diseases of the abdomen, especially in appendicitis. His cases are divided clinically into three groups, simple appendicitis, appendicitis with localized peritonitis, and diffuse purulent peritonitis. In the first class of cases the author has found that the viscosity shows no especial variation from the normal, that it is 4.5 times that of distilled water; in the second class of cases it was moderately raised, averaging 5.3; while in the cases of general purulent peritonitis, the index was distinctly above normal, varying in the cases which recovered from 5.0 to 6.3, and in two fatal cases being 7.0 and 7.1. From these findings it would appear that while the viscosity will be of but little value in the diagnosis of simple acute appendicitis, it may be of use in determining the extent of peritoneal involvement when the appendix has ruptured. The fact, too, that in hemorrhage the viscosity is rapidly reduced below normal, may make the test an aid in the differentiation between appendicitis, adnexites, and ruptured ectopic pregnancy.

Thirst Fever in Infants.

Variations in the temperature of the young infant, as the result of the most insignificant causes, are common occurrences. What in the adult would be a hardly noticeable gastrointestinal disturbance is capable in the baby of producing a temperature as high as 104° or 105°. A troublesome tooth about which there is but slight congestion may well cause a fever sufficiently high to result in a panic in the mind of the watchful mother and in a hurried call for the physician. A child, too, apparently desperately ill with hyperpyrexia may be seen four hours after a thorough catharsis playing happily in its cot. Recently the German pediatrists have called attention to another cause of sudden fever in the infant, the so-called "salt fever", produced by subcutaneous or rectal injection of saline solution, in which a few hours later the temperature rises rapidly, remains so for a few hours, and then as rapidly falls. In the *Berliner klinische Wochenschrift* for April 11, 1910, Erich Müller reports two cases of a condition first described by Crandell in 1899, but as yet not widely appreciated, which is closely related to the "salt fever", but is due to concentration of tissue salts, not by the administration of salt, but by withholding of water. In his cases, a few hours after withdrawing the child's food, for one reason or another, a rapid pyrexia appeared, lasting until either milk or some other fluid was given. First considered to be cases of fever from hunger, they were soon shown to be prevented if the milk was replaced by weak tea, and it was conclusively proven that the important factor in causing the fever was thirst. The possibility of such cases of "thirst fever" should be borne in mind by the physician when ordering starvation in the gastrointestinal affections of childhood, or when suddenly confronted with an inexplicable case of fever in the young infant.

News of the Week.

The Illinois State Medical Society and the A. M. A.—At the annual meeting of the Illinois State Medical Society, held May 17, some important resolutions, introduced by Dr. G. Frank Lydston, were adopted. After a preamble to the effect that the present organization of the American Medical Association was radically defective and fundamentally illegal, and that the methods of election and government now in operation were inequitable and undemocratic, it was resolved to offer a number of recommendations to the House of Delegates. Among these were recommendations that the offices of secretary, editor, and general manager be separated; that officers whose positions involve financial responsibility should be required to give bonds; that the financial condition and business affairs of the Association should be presented in more detailed form than at present, thus maintaining the confidence of the membership at large; that there should be more than one trustee in the town where the central office of the Association is situated, the burdens of the present lone trustee being too great; that provision be made in the by-laws for the initiative and referendum for safeguarding the interests of the membership at large; and that the Association should conform to the corporation laws of the State of Illinois by holding its election within the State, the Association, under the present system, being liable to attack on the ground of illegality.

New York State Vital Statistics for the month of March show a net gain in the State population of 3,538 and in New York City of 4,914. Tuberculosis caused 1,409 deaths; pneumonia 1,405; heart disease 1,015, and Bright's disease 934. There were 131 suicides and 30 homicides. The total deaths from violence were 689. Under the classification of heat and sunstroke was recorded one case, and under that of cold and freezing 4 cases.

Yellow Fever Commission Memorial.—On May 2 Senator Owen introduced into the U. S. Senate a bill providing for an appropriation of $50,000 for a monument in honor of the Yellow Fever Commission, composed of Major Walter Reed, Dr. James Carroll, Dr. Jesse W. Lazear, and Dr. Aristides Agramonte. The bill provides that the monument be erected in Washington under the supervision of a commission composed of the President of the American Medical Association, the Secretary of War, Major-General Leonard Wood, the Surgeon-General of the Army, and Colonel William C. Gorgas.

Health in the Canal Zone.—The report of the department of sanitation of the Canal Zone for March 1910, shows an annual mortality among employees of 8.91 per 1,000, as against 8.75 for February, and 8.76 for March, 1909. The total death rate including Panama and Colon was 18.33 as against 17.50 for February, and 17.07 for March, 1909. The annual average per 1,000 of employees in hospital for malaria was 125, as against 85 for February, and 182 for March, 1909. No case of yellow fever, plague, or smallpox originated on the Isthmus during the month. One case of yellow fever died at the Culebra Island quarantine station, having originated in Guayaquil and taken off from a Guayaquil boat at the quarantine station. The general health of the Canal Zone continues excellent.

King Edward's Illness.—The *Lancet* of May 14 publishes an authorized report of the last illness of King Edward VII. According to this it appears that for some years his Majesty had suffered from emphysema and bronchial catarrh, the signs of which were permanently present. His reaction to various minor ailments recently had shown to his attendants that his power of resistance was rapidly diminishing. On March 7, while in Paris on his way to Biarritz for a rest, the King had a severe attack of acute indigestion accompanied by dyspnea. Though he fulfilled his social engagements in Paris, he developed, on arrival at Biarritz, an attack of acute bronchitis which confined him for ten days. On April 27 the King returned from Biarritz greatly improved, and on April 30 went to Sandringham for the week-end. On Sunday he caught cold while inspecting some work in the gardens and returned to London on Monday, May 2, feeling "chilly and out of sorts." He was seen that evening by one of his physicians, who found him suffering from dyspnea with slightly raised temperature and quickened pulse. Bronchial crepitations were heard at the basis of both lungs. Tuesday morning, though feeling better, he suffered much from cough and expectoration and considerable dyspnea. Against professional advice he attended to his duties that day, and Tuesday night was quite ill and distinctly dyspneic, the attacks for the first time coming on even without exertion. On Wednesday morning the temperature was 99° F., the pulse 90, and there was some irritation of the throat, which showed a catarrhal condition. That evening the air entry of the lungs at both bases was poor, and the right side of the heart was embarrassed. The temperature was normal and the respirations 34 per minute. Though his condition was not improved Thursday morning, the King gave several audiences. The dyspnea and cyanosis increased. That evening the first bulletin as to the King's illness was issued. Thursday night he seemed to be better and passed a comfortable night until 4.30 A.M., when the dyspnea returned, and in the morning the second bulletin was issued to the effect that his Majesty's condition was causing grave anxiety. From then on his condition grew rapidly worse; dangerous dyspnea developed on the slightest movement, consciousness began to fail at 3 P.M. and never completely returned. The end came at 11.45 P.M. after a long period of perfect calm. The report is signed by Drs. Francis Henry Laking, James Reid, and R. Douglass Powell.

A Characteristic Misstatement.—The silly and unveracious antivaccinationists of London had the impudence a few days ago to distribute a leaflet about the streets declaring that King Edward's death was due to a vaccine treatment which he underwent prior to his trip to Biarritz and which was designed to avert influenza and pneumonia. This having been brought to the attention of Queen Alexandra, she has issued a statement in which she expresses herself as deeply grieved at the false report and asserts that the late King's fatal illness was not due in any way to the treatment. She adds that, on the contrary, he was kept in excellent health for fifteen months by the doctors who attended him.

The Standard of Milk Lowered.—On May 21 Gov. Hughes signed the Baumes bill lowering the standard of milk so that it shall be deemed adulterated when it contains less than 11½ instead of 12 per cent. of milk solids.

Care of Insane Convicts.—Gov. Hughes has signed the bill introduced by Senator Bayne, providing that when a convicted murderer appears insane, the Governor may appoint a commission of three to examine him and report to the Governor, whereupon, if found insane, the Governor may order his removal to the State Hospital for Insane Convicts, where he shall be kept in custody until cured of insanity, when, upon an order of the Justice of the Supreme Court, the convict is to be returned to the custody of the warden of the State's prison to suffer the sentence given him under the law.

The Etiology of Pellagra.—A dispatch from Rome from Dr. Sambon of the Field Commission, which has been investigating pellagra, states that the committee has proven that the conveyor of the disease is the *Simulium ripens,* a species of black fly. A simultaneous dispatch says that Professor Alessandrini of the University of Rome has found the etiological factor in water.

Plague at Amoy.—On May 16 the bubonic plague was officially declared to be epidemic in Amoy.

Pure Milk Decision.—In a test case recently on the question of the right of the New York City Department of Health to exclude from the city milk from dairies which do not meet the sanitary requirements of the board, Judge Coman held that the New York City Health Department had absolute jurisdiction without as well as within the city lines, could impose whatever rules and regulations its officials wished, and compel their observance under penalty of prohibiting the sale of dairy products shipped to New York City for consumption as food.

Bequest to Hospital.—By the will of the late Justus P. Jones of Philadelphia, the sum of $25,000 will revert to the Germantown Hospital on the termination of certain trust bequests.

The New York Postgraduate Medical School and Hospital has commenced work on the new $600,000 addition which is to be erected adjoining the present building on the east. The basement of the new addition will be devoted to diseases of the nose and throat, the first floor to medicine and surgery, and the second floor to the eye and ear. The third, fourth, and fifth floors will contain public wards accommodating 180 beds. Research laboratories, an *x*-ray room, eight small operating rooms, and extensive roof gardens and porches are included in the plans.

The New York Polyclinic Medical School and Hospital.—Work was begun early in May raising the houses on West Fiftieth street preparatory to the erection of the new hospital. The new building will be ten stories in height and will have a frontage of 95 feet. The ground floor will be occupied by the out-patient department. The second floor will be devoted to teaching rooms, and the third to laboratories. The fourth and fifth floors will contain the free wards, and the remainder of the building will consist of private rooms and staff accommodations. Lower building to the east and west of the main building to be used for ambulance service and nurses' home will insure light and air to the wards. The hospital, when completed, will accommodate 350 patients.

The Coney Island Branch of the Kings County Hospital was formally opened recently. The hospital will accommodate 100 patients.

Tulane University.—The medical department of Tulane University recently inaugurated the custom of holding an "Alumni Week", at which clinics and demonstrations were held for the benefit of graduates of the school and other medical men. The custom is to become annual. The school will this summer give regular summer courses to post-graduates.

The Metropolitan Life Insurance Company has withdrawn its application to the State Commissioner of Health and the local health officer of the town of Somers, in Westchester, for permission to build a sanatorium for the treatment of its tuberculous employees, in deference to the sentiment expressed by the people of the City of New York in opposition to the construction of such a sanatorium within the watershed of New York City. The company is now looking for a site to which the present objections cannot be raised.

Cocaine Seller Sentenced.—A cocaine seller was sentenced recently to two years in the State Prison by Judge Mulqueen of New York City. This was the offender's fourth arrest and second conviction. The sentence is said to be the heaviest ever handed down under the cocaine act in New York.

The Medical College of Virginia held its seventy-second annual commencement exercises on May 18, 1910. The speakers included Dr. Lyon G. Tyler, president of the College of William and Mary, and Dr. Simon Baruch of New York. The subject of the latter's address was "Therapeutic Lessons of Half a Century in Medicine."

Dr. George Howard Monks has been appointed professor of oral surgery in Harvard University.

Dr. William Colby Rucker of the United States Public Health and Marine-Hospital Service has been appointed Health Commissioner of Milwaukee by Mayor Seidel.

The American Society of Tropical Medicine will hold its seventh annual meeting at the Medical School of the St. Louis University, St. Louis, Mo., June 11, 1910. The president of the society is Dr. Wm. C. Gargas.

The Fifth Congress of the Association of French Physicians of North America will be held in Sherbrooke, August 23, 24, and 25, 1910. The president of the society is Dr. P. Pelletier of Sherbrooke, and the general secretary Dr. F. A. Gadbois of Sherbrooke.

The Nurses' Associated Alumna held its annual convention in New York City May 18 and 19, 1910. The officers elected were: *President*, Miss Jane A. Delano of Washington, D. C., and *Secretary*, Miss Agnes Deans of Detroit.

The National Association for the Study of Epilepsy held its ninth annual meeting in Baltimore May 7, 1910, as the guests of the Maryland Psychiatric Society. The more careful study of individual epileptics, their classification, and the indications for operation were the chief subjects discussed. The following officers were elected: *President*, Dr. H. L. Perry of Parsons, Kan.; *Vice-Presidents*, Dr. W. T. Shanahan of Sonyea, N. Y., and Mr. Chas. H. Grasty of Baltimore, Md.; *Secretary and Treasurer*, Dr. J. F. Munson of Sonyea, N. Y.; *Editor of the Transactions*, Dr. W. P. Spratling of Maryland.

The American Climatological Association.—At the 27th annual meeting of this association in Washington, May 3, 4, and 5, 1910, the following officers were elected: *President*, Dr. John Winters Brannon of New York; *Vice-Presidents*, Dr. W. H. Swan of Colorado Springs, and Dr. J. H. Lowman of Cleveland; *Secretary and Treasurer*, Dr. Guy Hinsdale of Hot Springs, Va. The meeting in 1911 will be held in Montreal.

The Nebraska State Medical Association met at Lincoln May 3-5, 1910. The following officers were elected: *President*, Dr. J. P. Lord of Omaha; *Vice-Presidents*, Dr. H. M. Hepperlin of Beatrice, and Dr. C. A. Anderson of Stromsburg; *Delegate to the American Medical Association*, Dr. P. H. Salter of Norfolk; *Alternate*, Dr. W. J. Birkoffer of Gothenburg. The *Secretary* of the association is Dr. A. D. Wilkenson of Lincoln, and the *Treasurer* is Dr. A. S. von Mansfelde of Ashland. The next meeting will be held at Omaha.

The Connecticut Society of Social Hygiene was organized at a meeting in Hartford on May 16, at which the following officers were elected: *President*, Dr. Phineas H. Ingalls; *Treasurer*, Dr. Charles S. Stern of Hartford; *Secretary*, Dr. Thomas H. Hepburn of Hartford.

The New Hampshire Medical Society, which met at Concord May 12 to 14, 1910, elected the following officers: *President*, Dr. Alonzo S. Wallace of Nashua; *Vice-President*, Dr. G. W. McGregor of Littleton; *Secretary*, Dr. D. E. Sullivan of Concord; *Treasurer*, Dr. D. M. Currier of Newport; *Councilors*, Dr. P. T. Haskell of Concord, Dr. E. Bralock Atherton of Nashua; *Trustees*, Dr. J. M. Gile of Hanover, Dr. J. W. Parsons of Portsmouth; *Delegate to the American Medical Association*, Dr. F. A. Stillings of Concord; *Alternate*, Dr. John C. Shedd of North Conway.

The Ohio State Medical Association held its annual meeting in Toledo and elected the following officers: *President*, Dr. G. A. Skeel of Cleveland; *Vice-Presidents*, Dr. S. P. Filler of Portsmouth, Dr. E. J. Marsh of Canton, Dr. A. V. Spear of Newark, and Dr. A. C. Starr of Pittsburg. The next meeting will be held in Cleveland.

The Missouri State Medical Association meeting at Hannibal, May 6, elected the following officers: *President*, Dr. Herman E. Pearse of Kansas City; *Vice-Presidents*, Dr. W. T. Lindsey of Hamilton, Dr. George Harmon of St. Louis, Dr. Hume Armstrong, and Dr. A. W. Camp of Springfield, and Dr. Ashley of Bloomfield; *Secretary*, Dr. E. J. Goodwin of St. Louis; *Treasurer*, Dr. J. Franklin of Salisbury.

The Worcester (Mass.) District Medical Society, in a meeting at Worcester May 11, elected the following officers: *President*, Dr. A. C. Getchell; *Vice-President*, Dr. C. A. Church of Millbury; *Secretary*, Dr. Roy J. Ward; *Treasurer*, Dr. George O. Ward.

The Hampshire (Mass.) District Medical Society meeting at Northampton, Mass., May 12, 1910, elected officers as follows: *President*, Dr. D. M. Ryan of Ware; *Vice-President*, Dr. N. C. Haskell of Amherst; *Secretary*, Dr. A. G. Marshall; *Treasurer*, Dr. J. G. Hanson; *Librarian*, Dr. F. L. Burnett; *Censor*, Dr. J. S. Hitchcock; *Councilors*, Drs. F. H. Smith of Hadley, J. S. Hitchcock, and E. D. Williams of Easthampton.

The Walker County (Texas) Medical Society was organized May 6 at a meeting held at Huntsville. The following were elected: *President*, Dr.

W. E. Fowler; *Secretary and Treasurer,* Dr. L. H. Bush.

The Fort Bend County (Texas) Medical Society was organized at Richmond, Texas, recently with the following officers: *President,* Dr. J. C. Johnson; *Secretary and Treasurer,* Dr. J. B. Turner.

The Webb County (Texas) Medical Society met at Laredo May 6 and elected the following officers: *President,* Dr. Sauvignet; *Secretary and Treasurer,* Dr. Hamilton.

Dr. Byron Robinson.—A memorial meeting in honor of the late Dr. Byron Robinson was held in the Whitney Opera House in Chicago May 22, 1910. Prof. Charles R. Van Hise, president of the University of Wisconsin, presided, and Dr. William A. Evans delivered the address.

Obituary Notes.—Dr. Frank Monroe Tiffany of Stamford, Conn., died at his home May 18, 1910, aged 41 years. He was a graduate of the University of Pennsylvania in 1896 and a member of the Fairfield County Medical Society, the Connecticut State Medical Society, the American Medical Association, and the American Academy of Medicine. Dr. Tiffany was physician to the Stamford Hospital, the Children's Hospital, and St. John's Church Home, and consulting physician to the Day Nursery.

Dr. Daniel Mayer of Charleston, W. Va., died in Cincinnati May 21, 1910, aged 73 years. He was a graduate of the Eclectic Medical Institute of Cincinnati in 1859, was a surgeon in the Civil War, and was Consul-General to the Argentine Republic.

Dr. James E. Blaine of St. Louis, Mo., died suddenly May 11, 1910, aged 59 years. He was a graduate of the Bellevue Hospital Medical College in 1872. Dr. Blaine was associated with Dr. Keeley in the formation of the Keeley Institute at Dwight, Ill., and at the time of his death was physician in charge of the Keeley Institute of St. Louis.

Dr. Martin Cagle of Adairsville, Ga., was killed by a train in Atlanta May 6, 1910. He was a graduate of the Georgia College of Eclectic Medicine and Surgery in 1894.

Dr. Oliver P. Rex of Abington, Pa., died at sea on May 13 at the age of 64 years. He was graduated from Jefferson Medical College in the class of 1867. He served a term as resident physician in the Philadelphia Hospital, and he was for a number of years physician to Jefferson Hospital and lecturer on diseases of children. He was for twenty-five years Medical Director of the Penn Mutual Life Insurance Co. During the Civil War he served as hospital steward in the Thirty-third Regiment Illinois Volunteers, rising to the rank of Major.

Dr. Walter C. Jackson of New Orleans, La., died at his home, May 11, 1910, aged 30 years. He was a graduate of the medical department of Tulane University in 1900.

Dr. Elijah W. Jay of Marshalltown, Iowa, died in that city on May 5, 1910, as a result of an accident to an ambulance. He was 47 years of age. Dr. Jay was a graduate of the University of Wooster in 1893, and was a member of the Marshall County Medical Society, the Iowa State Medical Society, and the American Medical Association. Dr. Jay was coroner of Marshall County.

Dr. Michael Brinkman died at Philadelphia on May 19 at the age of 83 years. He was graduated from the University of Marburg in the year 1848 and he served during the following two years as surgeon in the German Army.

Correspondence.

TREATMENT OF CARCINOMA WITH THE BODY FLUIDS OF A RECOVERED CASE.

To the Editor of the Medical Record:

Sir:—I was unable to get a copy of the Medical Record of February 26 until a few days ago, but I am very pleased to have seen it, however much belated, on account of the important communication with the above reference which it contains. The article, with your own note referring to it, cannot fail to prove of highest interest not only to those who are specially engaged in cancer research, but also to the ordinary practitioner who is anxious to get some method of dealing with cancer other than by the knife. With commendable scientific reserve, Dr. Hodenpyl does not claim conclusively to have made out a cure, but he is certainly on a live trail. The case he described bears a very striking resemblance in most points to one I had to deal with over three years ago. In mine there had been large recurred growths in both breasts, both axillæ, and in the neck. A spontaneous cure took place and this was complete in that the disease, so far as it could be made out clinically, had absolutely disappeared. The attendant circumstances were such that there was positive proof that the result was due to a sudden and rapid absorption of a large pleuritic cancerous effusion. I was so much impressed with what took place that in a paper which I wrote on the subject (*British Medical Journal,* July 20, 1907) I suggested that in similar cases i tmight be possible to imitate artificially what took place spontaneously in this one. I found no opportunity in my own practice of trying the direct transference of a serous exudate into the system, but I have repeatedly recommended the method to medical men who asked my advice in reference to such cases. I have often tried an alternative method on the same principle. This consisted of taking the patient's blood by a venesection, partially defibrinating it, and then injecting this fluid into the tumor or into its near vicinity. In four patients in which this has been done the results could not be claimed as cures, but the growths were retarded in all. Three patients improved very much in health, the fourth I have not seen for two years, but she is still living.

The interpretation I put upon the phenomenon I had seen was, that the active agent, whatever it be, was in the serum (in this case sanguineous), and in effect had power to dissolve cancer cellular tissue, which, so dissolved, became absorbed. Wells of Chicago, who was pleased to take notice of my paper (*Journol Amer. Med. Assoc.,* May 29, 1909), thought it more probable that the serum had acted as a stimulant to the body tissues and thus led to the development of cytolysins for the cancer cells, and he referred to Ribbert as supporting this view. Whether the action is indirect as the weighty authorities I have named regard it, or direct as I judged, may have importance on theoretical grounds as to how and where immunity arises, but the point of greatest practical importance is that whatever cancer be there certainly is a defence against it in the system, and in consequence exudates, pleuritic, ascitic, or other, arising secondarily to, that is, as a result of, the cancer, contain bodies that bring about immunity, and are there curative agents. The point has a scientific basis and is supported by clinical experience.

Charles G. Mackay, M.B., C.M.
Lochcarron, Rossshire, Scotland.

PITUITARY EXTRACTS IN HAYFEVER, ASTHMA, ETC.

To the Editor of the Medical Record:

Sir:—The period of so-called "rose cold" or "vernal hayfever"—*i.e.* vernal, pollen-caused, angioneurotic edema of the air passages—is approaching, or with certain patients, here. Referring to my observations in 1898 concerning the use of adrenal preparations in this disorder and in asthma (since confirmed throughout the world) I wish now to ask physicians to use preparations of the pituitary gland, and more especially of the infundibulum or posterior lobe. There are at least two, and possibly several, good commercial preparations now available. From the recoveries which I have observed to follow their use in Quincke's edema, asthma, recurrent erythema, and other angioneuroses, as well as their effects in "opening" the nasal passages, I should expect them to be superior to the adrenal preparations in all varieties of hayfever. The action is slower, but more persistent. The pituitary extracts may be used both topically and systemically. While more

effective by hypodermic injection, they also produce clinical results when administered by the mouth—another advantage over the adrenal extracts. I shall be much obliged for reports by letter or publication of the experience of those adopting this suggestion.

Solomon Solis Cohen, M.D.
1525 Walnut Street, Philadelphia.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

CANCER HOSPITAL MEMORIAL—GASTROPOSIA—RISK OF INFECTION IN HOSPITALS—ANTHRITIS — POST-OPERATION HEMORRHAGE—TROPICAL SCHOOL—BRITISH COMMITTEE FOR DRESDEN HYGIENE EXHIBITION—OBITUARY.

London, May 6, 1910.

H. R. H. the Princess of Wales has appointed July 14 next as the date on which she will lay the foundation stone of the Barnato Memorial Hospital. You will perhaps remember that Mr. H. Barnato left a quarter of a million sterling to found a charity in memory of his brother and nephew. The trustees decided to devote the money to an addition to the cancer charity of the Middlesex Hospital. They secured a site adjoining that hospital to enlarge the wing in which so much work has been done and equip it for every kind of treatment and research known to science. The ground has been cleared and the plans accepted, but the contract for the erection of the building has not yet been settled. It is believed, however, that all will be ready for the ceremony on the date fixed by the Princess. The estimate for the cost is about £50,000, and the remainder of the bequest will be invested for endowment of the memorial institution.

Gastroptosia is not of frequent occurrence; indeed, many practitioners have never met with it, and some are disposed to deny its existence as an ailment. Others regard it as a definite disease. Mr. F. S. Eve last week read a paper on its surgical treatment at the Medical Society of London. He had to acknowledge that the symptoms were so like those of other gastric diseases, especially ulceration, that a diagnosis could only be made by the process of exclusion, often culminating in an exploratory laparotomy. He had had twenty cases; in nine hematemesis was present, in seven of these to the extent of a teacupful or more. A great point with him was that acidity was rarely increased; in fact, it was sometimes decreased. He favored gastropexy when medical measures failed, and gave results of eleven cases. He had done gastrojejunostomy in seven cases, but his later experience led him to avoid it, though it might be necessary in certain cases of dilatation with atony or for the relief of hematemesis.

A paper from the medical side was then read by Dr. Robert Hutchison, who could not admit gastroptosis to be a disease. It was common enough, he held, in routine examinations to find displacement in patients who did not complain of gastric symptoms. Neurasthenia was the underlying condition in most cases, and required rest and improved nutrition. Those who had much digestive disturbance while going about lost their symptoms on remaining recumbent and could then take full diet. In the neurasthenic state bromide was perhaps the most useful drug. Strychnine, often prescribed, was frequently injurious. Iron might be of use if anemia were present, but that was seldom the case, and even if it were iron was apt to disagree, and arsenic might be substituted. He had a poor opinion of hypophosphites, glycosophosphites, and such like. Massage of the stomach stimulated its motility. Evidence was wanting that electricity was any use. No doubt patients with any enteroptosis derived comfort from effective support, but it did not follow that the result was due to actual pushing up of the viscera. But the best belt was a firm abdominal wall and a rest cure tended to improve this by increasing the natural packing of fat. His conclusion that these patients should be well fed, but not over-dieted; their stomachs should not be washed out, nor should they be operated on.

Dr. Scanes Spicer held that gastroptosis was brought on when the diaphragm did not act centrifugally, and that physical exercises would suffice to remedy the condition.

Dr. Hertz said gastroptosis was very rare as a sole condition, but common as a part of a general ptosis of the abdominal viscera.

Dr. Parkes Weber said these cases were relieved at once by the recumbent position; so were some of albuminuria. He would like to know why.

Dr. West, in the chair, remarked that the utility of washing out the stomach had been denied, but these cases were benefited by getting rid of accumulated fluid.

The risk of infection, if any, incurred by residence in a consumption hospital has been an occasional topic of medical conversation ever since the discovery of the bacillus. Some statistics, too, have been collected, but it cannot be said they were of a kind to secure much confidence. So that discussion, if it may be so called, has been rather the statements of general impressions than well-founded convictions. The question has been revived by Dr. Edward Squire in a paper submitted to the Royal Society of Medicine on the 26th ult., based on the records kept by him of fifteen years' experience at the Mount Vernon Hospital. At this institution it is the rule that every nurse and every man or boy employed in or about the hospital shall be examined before being definitely engaged, and again on leaving, by one of the physicans. Dr. Squire, now senior physician, has undertaken this duty for fifteen years. It is obviously an advantage that the same person should examine all the applicants, and a nurse who feels indisposed during her employment will be naturally more willing to consult the physican who has already examined her than the resident medical officer, who is in daily contact with her. The tables give information as to 420 individuals, among them 235 of the nursing staff, to which I must restrict my remarks. Some 14 per cent. had been infected before application, and it appears some of these, having quite recovered, were engaged. It may be questioned whether they should have been employed in the wards. Excluding those rejected, or who did not stay above three months, there were 215 nurses of whom nine developed tuberculosis during residence, giving a percentage of 4.18. Some nurses stayed in the hospital for years, but the average period was only eighteen months, a figure due to the large number who only entered as probationers for a part of their training. Notes of the cases which developed signs of tuberculosis, definite or suspicious, were given in tabular form, and Dr. Squire added further details of half a dozen illustrative cases.

The discussion on arthritis, about which I wrote to you on April 1, was resumed on the 20th, but less interest seemed displayed in the speeches than at first. Dr. Garrod agreed that several distinct diseases had been included under the same or similar names. Osteoarthritis should be distinguished from rheumatoid arthritis, as the prognosis and treatment differed. Dr. Latham held still to the hypothesis he put forward in 1901, that rheumatoid was due to lesions in the spinal cord, and he recommends blistering and cupping. Mr. Anderson of Buxton supported Dr. Latham and said he had found good results. He had not found serums and vaccines of any use. Dr. Sunderland thought that the greater prevalence of arthritis deformans in the female sex might be due to germs lurking in the reproductive passage. He had several years ago stated that, contrary to the common opinion, gonorrheal arthritis was more common in females. Dr. L. Canney contributed a paper on the climate of North Africa, in which he maintained that chronic arthritis was best treated in Egypt. The driest health resort in the world, he declared, was Assouan.

The prevention of hemorrhage in major operations is a question of importance to every surgeon, as shown by the many devices that have been used to secure it. In many cases a small loss of blood turns the case against the patient. Hemorrhage and shock are the twin dangers and may even be considered as one. To interrupt the blood supply is the aim of tourniquets and a multitude of other appliances, of which Esmarck's band is perhaps most in vogue. To ligature the main artery before amputating at the hip or shoulder is a recognized practice, and Mr. Lockwood of St. Bartholomew's Hospital is disposed to extend this plan to other operations, notably of the leg or arm. Not long since he gave an address at a northern medical society in which he advocated this practice and supported it by a number of cases. He is distrustful of digital compression, which he has known to fail, and serious loss was always the consequence. Esmarck's clasp bandage, too, seemed distasteful to him, for he called it crude and said its pressure could not be good for the vessels beneath. He asked why skin flaps sometimes die so mysteriously. The risks of amputating the leg

at the upper third when the vessels are calcareous are well known, and in such cases Mr. Lockwood would tie the tibial and peroneal vessels before completing the flaps. Another objection to Esmarck's band is the troublesome bleeding which follows its removal, as if the small arteries had been paralyzed by the pressure. No surgeon cares to amputate the thigh for diabetic gangrene, the mortality being so high. Mr. Lockwood related a case which appeared quite hopeless in which he exposed the vessels at their exit from Hunter's canal, tied the artery and vein, which were closely adherent, in a single ligature, and completed the operation leisurely without moving the patient. The relief, if only temporary, was very great.

The dean of the London Tropical School (Sir F. Lovell) has returned from his tour in the West Indies on behalf of the school. He has been promised subsidies from the governments of the different British possessions.

Yesterday a British committee was formed to carry out arrangements for the British section of the International Hygiene Exhibition at Dresden next year.

Dr. Vaughan Holberton died on the 4th inst. aged seventy-seven. He had practised at Hampton-on-Thames for above forty years and retired about sixteen years ago. He succeeded his father (at Hampton), who was surgeon to Queen Adelaide.

Dr. Alonzo Henry Stocker died on April 24, aged eighty-one. He was a distinguished student of the London Hospital, carrying off a number of gold medals and prizes. He qualified at the age of 21-22 and was soon after appointed medical superintendent of a private lunatic asylum. Thus the way was open for him to become a specialist, at which he for many years held a high position. He retired several years ago.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

TUBERCULOSIS IN BERLIN.

BERLIN, May 1, 1910.

IN the Society for Social Medicine, Hygiene, and Medical Statistics a lecture has been held which, though it applies directly to Berlin, has a general interest, as its results are of value for many large cities. I refer to A. Kayserling's lecture upon the incidence of tuberculosis in Berlin. In the first place, the lecturer presented some statistics on the course of the tuberculosis mortality in Berlin from 1880 to 1908. These statistics are of especial value because in the city the number of the inhabitants is registered very carefully and for every fatality the physician must make a certificate of the cause of death. The statistics show that in 1885 for every 10,000 inhabitants 34.63 died of tuberculosis, while in 1908 19.93 succumbed to this disease. The fall in the intervening years is not absolutely regular, as there are many variations, but the descent in the curve has been continuous. The objection may be raised that this fall is only apparent, in that owing to better diagnosis the mortality of other pulmonary diseases has increased. This objection is easily controverted by the statistics, as there has been a falling off in the mortality from all pulmonary diseases. In 1886 of every 10,000 inhabitants 32.8 died of pulmonary diseases, while in 1907 23.7 died of such ailments. The cause of this fall in mortality from tuberculosis lies in the discovery of the tubercle bacillus, and the measures which have been directed against it. Among these are the work of the sickness insurance, which makes early diagnosis and treatment possible. The growth of the "homestead" movement in Berlin has been especially valuable. Since 1892, when the first tuberculosis "homestead" was founded in Malchow, near Berlin, the movement has grown with such rapid strides that now there exist 1,500 beds in the city of Berlin. That comprises one-seventh of all the beds open to adult tuberculosis patients in the German Empire. In relation to the population in Berlin there are 75 beds to 10,000 inhabitants; in the rest of the German Empire there are 19 per 10,000. The forest convalescence resorts of Berlin, which were opened in 1900, have up to date cared for 30,000 persons, the greater portion of which were tuberculous.

The statistics of tuberculosis mortality, calculated for men and women, show, in the class between 20 and 25 years of age, a reduction of fatalities among men and an increase among women. In the next older class the mortality among men is also reduced; among women it is stationary. As an explanation of the increased mortality among women may be mentioned the increased number of women who have gone into business and the lack of a sickness insurance among household servants. The results of the institutional treatment will be more striking during the next decade. The significance of the sanatorium treatment in Berlin has become evident only since 1907. Furthermore, it is only recently that the method has been introduced of repeated sanatorium cures, which has proved to be especially beneficial. The increase of tuberculin therapy is also a hopeful feature.

That the battle against tuberculosis is not entirely satisfactory is the result of the especially unfavorable conditions in Berlin in relation to the number of the sick. In Berlin 4,000 persons die annually of consumption. The mortality rate from tuberculosis in the city is 21 per 10,000, in the remainder of Prussia 16. The main reason for this is the unhygienic mode of living, as the following statistics demonstrate: During the past three years 40 per cent. of the deaths from tuberculosis among those dying at home occurred in people living in single-room dwellings, and 41 per cent. among those in two-room dwellings. The single roomers must be considered as the main source of contagion. With these single roomers who died from tuberculosis there lived 8,229 persons, so that exposure to contagion was extremely great. Furthermore, the tuberculosis cases which died in the hospitals averaged a residence in the institutions of but 45 days, so that the greater part of their illnesses were spent in their homes.

In the condition of home life, therefore, lies a point of attack for further activity in the campaign against tuberculosis. The nursing depots, with their educational work, accomplish much good in this matter. The national insurance statistics work even more effectually, for they control through their single district branches the entire city, and carry out their measures systematically. These measures include regulation of the renting of rooms, disinfection of dwellings on removal to a new home or admission of the patient to an institution, periodic disinfection of the house during the patient's occupancy, and supplying of sputum cups. The city of Berlin seems also to be about to realize a long-standing need. This is a special hospital to care for a great number of advanced cases of tuberculosis. The organization of this hospital is of such importance that it will be taken up on another occasion for special discussion.

THE FAR EASTERN ASSOCIATION OF TROPICAL MEDICINE.

(From Our Regular Correspondent.)

MANILA, P. I., March 17, 1910.

AT the close of the eighth and last scientific session of the Far Eastern Association of Tropical Medicine, which was held at Bagnio, March 14, a business session was held which commenced at 11 A. M.

An invitation from His Excellency, the Governor-General of Hongkong, asking that the next meeting, which will take place in 1912, be held at Hongkong was read. The invitation was supplemented by a further invitation from all the medical men of Hongkong. On motion the invitation was unanimously accepted.

Resolutions upon beriberi, opium, plague, quarantine, tuberculosis, and leprosy were then presented to the association by the different committees which had been named to prepare suitable resolutions upon these subjects.

After considerable discussion, the following resolutions were passed:

Beriberi: Resolved, "That in the opinion of this association sufficient evidence has now been produced in support of the view that beriberi is associated with the continuous consumption of white (polished) rice, as the staple article of diet, and the association accordingly desires to bring this matter to the notice of the various Governments concerned."

Quarantine: Resolved, "That the Far Eastern Association of Tropical Medicine, appreciating the benefit which would accrue from concerted sanitary action on the part of Eastern Governments, be empowered officially to approach the following governments, namely: Philippine Islands, Japan, Hongkong, French Indo-China, Siam, Netherlands-India, Straits Settlements, and Ceylon, with the view, if possible, of obtaining their official support on the following lines:

"1. To have a common standard for the term "epidemic" when making reports to or imposing quarantine against each other. We suggest the following definition for consideration: 'Plague, cholera, small-pox, or yellow fever, shall be considered to be epidemic, when, after the first telegraphic report of its occurrence, any weekly report thereafter, shall show the occurrence of an average daily number of three cases.'

"2. To agree to notify each other's territories as infected, only when the infectious disease shall have assumed epidemic proportions as defined above; and automatically to withdraw such notification when the average number of cases for three successive weeks has fallen below the status epidemicus as above defined.

"3. To circulate weekly returns of plague, cholera, small-pox, or yellow fever among each other, and also a telegraphic report on the first occurrence of any of these diseases in a clean port or territory.

"4. To insist on a bill of health being carried by all ships leaving a country declared to be infected, which intend to proceed to the port of another signatory, such bills of health to include a return of infectious disease for the previous 48 hours.

"5. To report by telegram to the country concerned the departure of an infected or suspected ship (as defined by the Paris convention) which may intend to proceed to any port in the territories of another signatory; and to endorse the bill of health of the said infected or suspected ship with a full account of measures taken to disinfect or otherwise deal with the said vessel."

Opium: Report.—"Your committee appointed to consider the opium question regret that the time at their disposal precludes the possibility of giving the subject adequate consideration. They have reviewed the work done and the resolutions agreed on by the International Opium Commission, Shanghai, 1909.

"With these resolutions your committee are in agreement, but it is to be regretted that the paucity of medical commissioners prevented the question being dealt with fully in its medical aspects.

"Any measures which are introduced for the control of opium must be adequate to guard against the danger of secret remedies containing opium and opium derivatives being substituted.

"They would suggest that the delegates from the various countries represented at this conference should be asked to arrange that the regulations controlling the sale of opium in their respective countries, as well as any observations they may care to make on this subject, be submitted to the next meeting of this association in 1912."

Plague: Report.—"In our opinion the only practical measure concerning plague that we can recommend is the advisability of each country represented agreeing to notify to the other countries the occurrence of plague within their borders, the first case by telegram and afterward by weekly returns."

Tuberculosis: Resolved, "That the Far Eastern Association of Tropical Medicine should use its influence to cause the formation of a national anti-tuberculosis society in each political entity represented in the Far Eastern Association of Tropical Medicine. These societies to be formed along the lines of existing anti-tuberculosis societies in other parts of the world, yet revised to facilitate the work under local conditions."

Leprosy: Resolved that. "1. Leprosy is to be regarded as a dangerous communicable disease.

"2. Compulsory notification of all cases of leprosy to the authorities is essential.

"3. Compulsory segregation of all cases of leprosy is necessary and preferably in special colonies constructed for the purpose.

"4. The entrance of aliens afflicted with leprosy into a country must be prohibited."

The election of officers was then held and Dr. John M. Atkinson, principal civil medical officer of the Government of Hongkong, was unanimously elected president. Dr. Francis Clark of Hongkong continues in the position of secretary-treasurer of the association. Dr. Victor G. Heiser was elected vice-president for the Philippine Islands. Sir Allen Perry was elected vice-president for Ceylon. Dr. Vassal was elected vice-president for Indo-China. Dr. Stanton was elected vice-president for the Straits Settlements.

The convention then adjourned *sine die.*

Federal meat inspectors have shown that 2 per cent. of the 56,000,000 hogs in this country a year ago, and valued then at $339,000,000, are affected with tuberculosis.

Progress of Medical Science.

Boston Medical and Surgical Association, May 12, 1910.

Circulatory Failure in the Acute Infections of Children; Causes and Treatment.—J. Howland gives an admirable summary of the literary on this question. In a general way he states that the cause of death is a paralysis of the centers in the medulla; that this is confined primarily to the vasomotor center, and secondarily the respiratory center; that the circulation shows striking symptoms earlier than does respiration, but that respiration ceases first; that paralysis of the vasomotor center is the cause of the circulatory symptoms and that the heart is comparatively unaffected. The author then passes in review the action of the remedies commonly employed. Alcohol when given in large enough doses to produce any effect on the heart causes a lessened efficiency and a weakness of the contractions, and it causes also an inhibitory effect and finally a paralysis of the vasomotor center, exactly what we wish to avoid. Ether is absolutely contraindicated, as it is accompanied by a rapid fall of blood pressure. Strychnine is without effect in circulatory collapse unless enough is given to cause convulsions, and it is denied that it has an effect in the treatment of the low blood pressure in shock. Digitalis has no effect on the vasomotor center. For use on human beings in circulatory failure this drug has the great disadvantage of slowness of action. It takes hours for its effects to follow if it is given by mouth, and we have no reliable preparation for hypodermic use. If the condition for which it is to be given can be foreseen, it may tide us over an emergency. It is to be considered an adjuvant to other remedies. Caffeine is probably the best vasomotor stimulant we have. Camphor is also useful. We may raise the pressures also by increasing the peripheral resistance. For this purpose we may employ infusion of salt solution and the injection of adrenalin. Infusion will act only as long as the increased amount of fluid is contained in the arteries and the pressure sinks when the abdominal veins still further dilate. From the knowledge at present available it seems that the continuous use of cold air, the use of caffeine and camphor reinforced by digitalis, with infusions of salt solution and the careful, not too often repeated, use of adrenalin are our best methods to combat this dangerous condition.

Some Observations on the Late Results Obtained by the Submucous Resection of the Nasal Septum.—O. A. Lothrop has reported on the late results of 59 cases of this operation. He considers it as beneficial in almost every case. The greater the septal deflection, the more definite will be the improvement. To ensure the best results the operation must be thorough and complete and all thickened and deflected portions of the septum must be removed, particularly the vomer ridge and the perpendicular plate of the ethmoid high up opposite the middle turbinates. If careful attention is given to these points the flaps of mucous membranes will approach nearer the middle line. Drainage from the middle turbinate region is facilitated and greater space on the convex side is obtained. If turbinectomy is indicated it can be then limited to the larger turbinate on the concave side. If there is insufficient space between the septum and the larger turbinate when the septum is brought to the median line, a judicious trimming of the turbinate will prove efficacious. This may be done either before the operation on the septum and allowed to heal, coincidently with it or subsequently. If there is any laceration of the septal mucosa on that side it should be allowed to heal before the turbinate is trimmed or cauterized lest synechia form later. The operation should not be attempted before the nose has obtained full development. However, trimming of the turbinates and plastic operations in children may not be contraindicated. An incomplete operation renders subsequent attempts difficult and unsatisfactory. Perforations are undesirable and they may cause crusting. No whistling was found in the author's cases. Crusting is not relieved in cases of atrophic rhinitis. Correction of external deformities may be combined with the resection operation.

New York Medical Journal, May 14, 1910.

Molluscum Contagiosum.—F. D. Knowles reports ten family epidemics and forty-one cases in children. He says that in reviewing the literature and taking into account his own cases there seems but little doubt but that the disease is contagious. In approximately 25 per cent. of the patients, a history of contagion can be elicited, in the direct family, the household, or from intimate friends.

Children are more frequently attacked by the disease than adults. In a great majority of the cases the face is attacked, especially in the vicinity of the eyelids, either alone or in combination with other portions of the body. Most cases have but a few lesions. In those cases in which there are a large number of mollusca the trunk and the extremities are the areas usually attacked, frequently exclusive of the face.

Caloric Method of Infant Feeding.—S. A. Blauner says that the percentage method finds its widespread support in the fact that it attempts to make the proportions of the three important elements of cow's milk, correspond as closely as possible to that of breast milk; and that it succeeds in this important phase of the problem, there can be no doubt. But, unfortunately, it has missed one other important truth of infant feeding, in that it does not consider the child's actual volume requirement; and it is this element that the caloric method tries to supply. The percentage method recognizes the importance of making cow's and breast milk as similar as possible, and insists upon its absolute necessity, in order to preserve the child's digestive powers. But, in doing so, it seems to feel that the child lives only for its digestion, and not that the digestion is only a means of supplying the child's energy value. The caloric method recognizes and adopts the value of diluted milk, and also, like the percentage method increases the carbohydrates of this diluted milk to equal that of mother's milk. The percentage of sugar of mother's milk being 7 per cent., in a liter there will be 70 grams, and to increase the sugars of the diluted artificial milk to contain that amount, it will be necessary to add to the diluent of one-third milk, 8 per cent.; of one-half milk, 10 per cent., and of two-thirds milk, 12 per cent., and their respective caloric value will be: One liter of one-third milk, 400 calories; liter of one-half milk, 500 calories; liter of two-thirds milk, 600 calories. This may appear rather complex, but if simplified to a system, all that is necessary to be remembered is: (1) Age of child and its weight, and the computation of its caloric need by multiplying its weight by either 80, 90, 100 calories, depending, of course, on its age. (2) To remember that a liter of one-half milk with 8 per cent. addition equals 400 calories; one-half milk with 10 per cent. addition equals 500 calories; two-thirds milk with 12 per cent. addition equals 600 calories, and full milk equals 650 calories. Is the administration of milk by this method any more difficult than by the percentage method? Surely not. In fact, it is a saving of both time, labor, and expense to both mother and physician, and once we get into its routine, it is surely surprising how quickly we can prescribe any strength of milk for any infant, and how quickly the mother comprehends its execution. An illustrative computation is given.

Acute Anterior Poliomyelitis.—J. W. Cokenower considers this disease from the standpoint of etiology and the best treatment to prevent deformities, that result. He says that a faulty milk supply, period of dentition, hot weather, etc., suggest autointoxication following gastro-enteric disturbance as a possible cause. The disease is undoubtedly contagious. The conclusions to be drawn as to etiology from the literature of the disease do not warrant the statement that any one cause produces the disease, but many, because various degrees and kinds of illness often precede the attack, such as malaise, headache, loss, of appetite, varicella, measles, scarlet fever, cholera infantum, otorrhœa, and many other diseases incident to child life. Hence, the disease may be the clinical expression of the reaction of the spinal cord to one of the several causes, of which infection may well be considered one. At present we must observe, study, and collect material, remembering that we may be dealing (1) with a specific infectious disease, (2) with an infection due to one of several organisms, or (3) with a disease of more than one origin, not always necessarily infectious. The physician perceives plainly that his patient is suffering from an acute infectious process of some kind, but he is surely to be pardoned if he fails to appreciate its true nature, for until paralysis makes its appearance no pathognomonic symptoms are seen. Disability from this disease is seen almost ten times as often in the lower as in the upper extremities, and yet in the early stage the paralysis is found in all parts of the motor system, and in the recumbent position we find it absolutely favorable to spontaneous recession of the paralysis. The arms and hands retain this advantage when the patient is erect, but the impaired muscles of the legs and feet give way at once when they meet the weight of the body, and become attenuated and elongated, and could not be put in a position more damaging to them, and the result is plainly seen in all kinds of club foot, short tendo-Achillis, anterior muscles of the thigh, and flail joints. Therefore, if in acute anterior poliomyelitis we can by means of a recumbent position give to all the muscles alike the same opportunity for spontaneous recession of the disease in them, we will not see ten times as many deformities in the lower extremities, as we do in the upper, and the number of deformities from this disease will be materially reduced. Another treatment in this disease, when it has taken on the chronic form and the deformity is well marked, which has proved very satisfactory in his practice, is repeated plaster casts at short intervals, while the patient is under an anesthetic and muscles and tendons easily stretched.

Journal of the American Medical Association, May 14, 1910.

Acute Visceral Perforation.—B. B. Davis advises prompt treatment in any case of visceral perforation or in which there is strong suspicion of its existence. In every acute abdominal pain the possibility of perforation of some part of the alimentary canal should be considered and the patient should not be dismissed until the possibility of such an accident can be definitely excluded. If the symptoms point rather definitely to perforation, but there is still some doubt as to diagnosis, an exploratory operation is safer than delay. Shock is no contraindication to operation, which should be as expeditious as possible, only necessary work being done and artistic ideals being left for less urgent conditions. Davis thinks that appendiceal perforation is more frequent than is generally supposed, but, as in gall-bladder perforations, there is some protection by adhesion, though unfortunately these are not always life-saving.

Acid-Fast and Semi-Acid-Fast Tubercle Bacilli.—L. J. Tint and L. Breskman say it has been questioned by some whether acid-fast bacilli demonstrable in the sputum are always significant of tuberculosis of the respiratory organs, and ask, if not, of what are they significant. They give their experience and the difficulties they have encountered in the examination of an average of 2 sputa a day for a year past in the Pennsylvania Hospital, describing the methods and technic employed, and tabulate their results as regards the proportions of resisting, semi-resistent, and decolorized forms found with each acid or reagent used. Inoculation experiments on guinea-pigs were also performed with the cultures and tuberculosis produced. The following points are enumerated by them as worthy of further investigation: "1. The acid-fast property of the tubercle bacillus increases with the age of the culture. 2. In old cultures, isolated bacilli are found which are non-acid resisting, and these bear a relationship to the acid-resisting forms. 3. The number of acid-non-resisting forms and the acid-semi-resisting forms are relatively increased in young cultures. 4. In very young cultures, mostly acid-non-resisting, more semi-resisting and very few acid-resisting forms are present. 5. The semi-resisting forms when removed from the decolorizing fluid, and placed in a solution of methylene blue of definite strength, will gradually assume that color in proportion to the time that the slide was left in. 6. No single decolorizing agent, at present employed will stain uniformly all bacilli that cause demonstrable tuberculous lesions. 7. No decolorizing agent at present employed in tuberculous lesions of the examination of any tuberculous material is efficient enough to bring out the presence of acid-non-resisting forms. This is brought out by the work of Much, Terebinsky, Michaelides, Ferran, Duval, and others. 8. Acid-non-resisting forms have been demonstrated in tuberculous lesions of the lymphatic system by Much, Terebinsky, and Duval; also in cavities of lung, and in sputum by eminent observers. Such forms were demonstrated by cultural methods when they were not demonstrated by staining methods."

Tuberculous Adenitis.—C. L. Leonard recommends the Roentgen-ray treatment as the most effective method of treating tuberculous adenitis in all its varieties, affording the best cosmetic as well as permanent results. If taken early, scars are completely avoided, which is an important consideration, especially in young women who are often subject to the disease. The treatment is harmless and painless but must be adapted to the individual. If too weak there will be no progress and if pushed too far it may be hurtful. It also has an effect, he thinks, in raising the opsonic index and in producing an autogenous vaccine or antibodies which pass through the patient's system and effect tuberculous lesions at a distance and produce an immunity. The treatment is not confined to the earlier stages though it is in these that the best cosmetic results are obtained. Old scars, however, can be softened and reduced and recurrence after operations of persistent

ulcerations or sinuses can also be thus treated. Medical measures, tonics, etc., tending to increase the bodily vigor and resistance can also be used at the same time. Two cases are reported.

Transurethral Operation.—H. A. Kelly advocates the use of the cystoscope in removal of calculi from the bladder in women, and reports a case of operation on calculus impacted in a diverticulum of the viscus. He thinks that it will be possible in the future to treat almost all calculi found in diverticula in this way, *i.e.*, (1) by exposing the diverticular orifice through an open speculum; (2) by cutting the sides, so as to open the cul-de-sac, with an electrocautery; (3) by extracting the calculi with forceps; (4) by examining thoroughly the interior of the cavity through the cystoscope. He says that there is no reason why a variety of operations should not be done in a simpler manner through the open tube of the cystoscope instead of through a bloody suprapubic or transvaginal incision. The method is applicable to the male as well as to the female bladder.

Heat Spasm in Cooks.—L. Clendening writes of the occurrence of muscular spasms, similar to those described as occurring in persons exposed to intense heat, observed in cooks employed on Pullman dining cars. His patient was a negro, aged 64, who had worked considerably on such cars and said that the condition was familiar to him and to all others in like situation. The heat in the kitchens of these cars during hot weather sometimes rose to 150° F. and he had known of one death from this cause. On inquiry, while Clendening finds that the condition is well-known among Pullman chefs, it is not familiar to those who work in the better ventilated kitchens of hotels, restaurants, etc. He has not seen it mentioned as occurring in cooks in the literature of the subject which he has examined.

The Lancet, May 7, 1910.

The Bacillus Influenzæ and Symbiosis.—R. W. Allen refers to his studies of the last few years, noting that as he has previously stated, the great majority of cases of influenza (so-called) are not really such, but instances of infection by the pneumococcus. He finds that so long as the infection remains in a truly chronic condition no dissemination by means of contact seems to occur, but as soon as the climatic conditions determine the lighting up of an acute attack, the carrier becomes a source of infection to all around him. With regard to a vaccine therapy under the circumstances, the author says that the establishment of an immunity against this disease is very difficult. Large doses are necessary before the patient begins to improve. In such cases would the better way be to attack the symbiotic bacteria and exterminate them? The author is satisfied in his own mind that the good results reported as having been achieved in some cases of pyorrhea alveolaris have been brought about in this way, and he cannot help feeling that a thorough investigation of the relationship, one to another, of the *Bacillus tuberculosis* and the secondarily infecting organisms in pulmonary tubercle will point the way to a more satisfactory method of treatment.

Cerebellar Abscess and Acute Suppurative Labyrinthitis; Differential Diagnosis.—J. Harper refers especially to the matter of nystagmus and says that there are three chief tests on the labyrinth by which the nystagmus is brought about, the caloric, the rotatory, and the galvanic. He regards the caloric as the most valuable. It is practically the only one which can be applied to bed patients. Let us imagine, says he, a strong rotary nystagmus to the right and that it is the right ear that is diseased. With the patient lying on his back, sterilized water at 21° C. is allowed to flow in through the external meatus. If after a lapse of from 12 to 60 seconds we do not get a nystagmus to the left and the nystagmus to the right is not lessened, this nystagmus to the right must be due to some intracranial condition. The absence of the right caloric reaction shows that the right canals must be already destroyed, and that they are no longer capable of sending impulses, and again, if all this spontaneous nystagmus were due to the destruction of the right canals, it would be to the left and not to the right, and thus we can settle the point that the nystagmus is not due to any labyrinthine condition. But should the patient have rotary nystagmus to the left and not to the right, we can again apply the caloric test, but in this case the water must be at a temperature of 39° C., since we wish, if possible, to create a nystagmus to the right. If we find the function of the labyrinth remains, even though it is impaired to some extent, we must diagnose suppuration of the labyrinth and not cerebellar abscess, but should this spontaneous nystagmus not become less after four or five days we must diagnose cerebellar abscess in addition. Indeed, we may say, as a general rule, that should the patient have a strong rotary nystagmus to the right or left, and if on application of the caloric test the right canals are found capable of being irritated and if this nystagmus does not get less as time goes on, then it is evident that the case must be intracranial.

The Use of Solid Carbon Dioxide.—E. R. Morton gives his personal experience with this remedy. His statements contain nothing new to American readers. Most of his cases were nevus cases, of which he has treated 208 growths occurring in 167 patients. Of these 134 were capillary, 121 being cured by a single application; 51 were cavernous, 33 being completely cured; with port wine mark cases the results were less satisfactory. Results were good in seven cases of lupus vulgaris, and in moles and warts success should always result. Care must be taken to avoid sepsis after extensive applications.

Berliner klinische Wochenschrift, April 18 and 25, 1910.

The Function of the Hypophysis and the Action of the Extract on Animals.—Franchini, as the result of animal experimentations with the hypophysis and its extracts, finds that administration of an extract of ox and horse hypophysis produces marked metabolic changes, especially in the inorganic elements, causing particularly a decrease of calcium, magnesium, and to a lesser degree of phosphorus. In the circulating blood it causes an increase of calcium and magnesium. The extract administered to rabbits only exceptionally causes glycosuria. Besides its toxic action on guinea-pigs and rabbits, the extract has an especial influence upon the intestines, producing ulcerations and hemorrhages, which appear to be due partly to changes in the vessels and partly to alterations in the trophic nerves. The greatest toxicity is produced by intravenous injection, but is also present following subcutaneous or gastrointestinal administration. Digestion *in vitro* to a certain degree weakens its toxicity. The anterior lobe, isolated from the epithelial covering produces, even in large doses, but slight lesion, but causes death if the epithelial layer which covers the posterior lobe is attached to the anterior lobe. The posterior lobe, isolated, has a special action on metabolism and on the vessels and organs of the abdomen and pelvis. In the isolated posterior lobe there is a substance which produces mydriasis in the frog's eye, but gives no other adrenalin reaction. This is not present in the isolated anterior lobe, but appears to be in the epithelial layer, but to a lesser degree than in the posterior lobe. The serum of animals which have been injected with the extract of the posterior lobes produces mydriasis, a phenomenon obtained very rarely with the extract of the isolated anterior lobes, but somewhat more frequently when the latter is combined with the epithelial layer.

The Prophylaxis and Therapy of Caisson Disease.—J. Plesch discusses the theory of the causation of caisson disease on the premise that it is due to the absorption of nitrogen in proportion to the increased pressure following physical laws. He says that the chief factor in prophylaxis, besides slow decompression, is the proper selection of the workers. There are six groups of individuals which it is of especial importance to exclude from the high pressure work: (1) Fat Men; (2) men with heart weakness, vasomotor weakness, as hysteria and neurasthenia, or arteriosclerosis; (3) chlorosis, primary or secondary anemia; (4) persons with disease of the central nervous system; (5) edematous individuals and nephritics without edema; (6) persons with ear affections.

Feeding Experiments in Tumor Rats.—F. Medigreceanu calls attention to a previous finding that mice and rats who had either spontaneous or inoculated tumors had livers somewhat larger than normal animals of the same weight. On the theory that this might be due to an increased amount of food eaten as a result of the nutriment requirement of the growing neoplasms he undertook a series of experiments on normal and tumor rats to see whether the latter ate more than the former. The method consisted of careful weighing of the animals before and after meals of a constant quality. He was unable to demonstrate any increased ingestion of food on the part of the inoculated rats in comparison to the normal. The total weight of the animals during the early period of tumor growth increased more rapidly than in the controls, but during the later periods of the disease it decreased. There was a decrease in the appetites of the tumor rats during the later period. From these findings it may be stated that the hypertrophy of the liver in tumor rats is not rue to increased ingestion of food.

Münchener medizinische Wochenschrift, April 12, 19, *and* 26, 1910.

The Treatment of Peritonitis with Camphor Oil.—Hirschel reports nine cases of advanced purulent peritonitis treated with a 1 per cent. solution of camphor in oil, of which five recovered and four died, a mortality of 45 per cent. The operation consists in making an incision, searching for the seat of perforation, and sewing it up. Then the pus is sopped up very carefully with dry or moistened gauze throughout the entire abdomen, and removed as far as possible. This may be accomplished with the hand or with a sponge stick. Douglas' sac is carefully dried out. The whole cleaning process must be done rapidly. After this superficial cleansing of the peritoneum from 100 c.c. to 300 c.c. of the warmed 1 per cent. camphor oil is injected, and, with the hand covered with gauze, is spread over the whole peritoneum, between the intestines, and in Douglas' sac. As a rule a counter incision is made in the left lumbar region, the peritoneum is drained by numerous drains the size of a finger, the root of the appendix or the neighborhood of the perforation is packed off, and the incision partially closed.

An Albumin Reaction in the Blood in Psychoses.—Geissler has found circulating in the blood serum of patients with melancholia and catatonia, a material which is not present in the healthy. This material is apparently an albuminoid substance, and is antagonistic to the serum of those of normal mentality. The substance which circulates in the blood of melancholia is only in part similar to that found in catatonia. The material may be recognized by the precipitative reaction. Normal sera and sera of bodily diseases and other psychoses do not supply the antigen for the reaction. The hemolysis reactions make possible the diagrams of these two psychoses only. Further investigation is desired.

The Influence of Acute Febrile Processes Upon the Tuberculin Reaction.—A posthumous report of the work of H. Krannhals upon this subject is given. The first set of observations were of the opthalmoreaction during typhoid fever in 158 cases. In all there were 251 instillations, of the 140 during the fever 16.4 per cent were positive while of the 111 during convalesence, 43.3 were positive. Of the 93 cases tested both during the fever and during convalescence, 13 were positive during the febrile period, and 40 during convalescence. The cutaneous test was made in 133 typhoid cases, 202 times. Of the 111 vaccinated during the fever, 32.5 per cent. were positive; of the 91 during convalescence 82.5 per cent. Of the 69 cases vaccinated both during the fever and afterwards, 24 were positive in the febrile period, and 56 during convalescence. In 154 conjunctival tests made in cases of relapsing fever, 29.2 per cent. were positive during the attacks, and 32.0 per cent. during the intervals. Of 189 of cutaneous tests made in 130 cases of relapsing fever, 35.3 per cent. were positive during the attacks, and 76.2 per cent. during the interval.

The Value of Fulguration in Gynecology.—Richter reports his results in using the Keating-Hart method of fulguration in 45 cases of pelvic cancer. Twenty-eight cases were treated once, 11 were treated twice, 3 were treated three times, and 3 four times. The first cases were treated under chloroform narcosis, later with lumbar anesthesia, and finally without anesthetics. The immediate effect of the fulguration was relief of the pain, explained by loss of blood and reduced pressure, control of hemorrhage, from the hemostyptic action of the spark, and cessation of suppuration. The final results of the experiments warranted the following conclusions: (1) From fulguration one cannot hope for lasting benefit, but the palliative effects are excellent. (2) As the spark may be used in breaking down cancer of the uterus without an anesthetic, the method is an improvement over cauterization. (3) The fulguration relieves the pain for a considerable time, stops the hemorrhage and prevents the discharge. For these purposes it is best to combine it with the acetone treatment.

The Means by Which Mercury in the Treatment of Syphilis Acts on the Serum Reaction.—August Brauer says that there are theoretically three possible ways in which mercury may act to prevent the occurrence of the Wassermann reaction; the mercury may act to make the serum hemolytic; it may destroy or paralyze the complement binding substance in the serum, or it may prevent the production of the complement binding substances by acting directly upon the virus. As a result of a series of experiments the author finds that there is no relation between the amount of mercury excreted in the urine, which may be taken as a measure of the amount absorbed in the tissues, and the serum reaction; the reaction may be positive when the mercury excretion is high and negative when it is low or even nil. A previously negative reaction may become positive in spite of a moderate or even large amount of mercury in the blood. A reaction which has become negative as a result of treatment may again become positive although mercury is continued. The mercury present in the serum of a syphilitic under treatment is not able to destroy or paralyze the complement binding substance in the serum of an untreated syphilitic. Clinical experience shows that both in early and late syphilis the effect of mercury treatment upon the Wassermann reaction is most variable. The mercury content of the organism has no direct influence upon the serum reaction. Mercury has only an indirect influence upon the Wassermann reaction because its action is directly upon the virus of syphilis and not upon the complement binding material.

Deutsche medizinische Wochenschrift, April 14 *and* 21, 1910.

The Shape of the Pathological Stomach.—Groedel, as a result of *x*-ray examination of the human stomach, says that one is not able to determine the character of the disease by the position of the pylorus or the fundus. There are cases with no gastroptosis but a pyloroptosis which is evidenced by the movability of the pylorus. There are cases, as a rule a result of overloading and dilatation, which are recognized by the lengthening of the stomach, the decrease of the angle, and the small size of the stomach, which may be falsely considered to be cases of gastroptosis owing to the low position of the fundus. In atonic ectasia (atonic widening finally combined with lengthening) the lower part of the organ is stretched by chyme, the upper portion by air; between the two there is a narrowing. In megalogastrica (lasting dilatation of the stomach fixed by muscle hypertrophy) the food collects in the lower part of the organ with its horizontal upper border in the lower part of the fundus; the angle is not visible. This is caused by pyloric stenosis.

The Nature and Treatment of Hysteria.—Romberg says that hysteria may be considered to be a congenital pathological lesion of the associations. Close relations are easily broken. For a longer or shorter period the coordination of a greater or smaller number of associations is destroyed. The character and the duration of the defect determine the character of the hysteria. For the explanation of the irritating symptoms of the attack, one must look for a weakness of associated actions of which the inhibitory power is lost. Possibly there may be besides the easy loss of association, an increased activity. By this the irritative symptoms may be explained. Certain definite psychic peculiarities in hysteria suggest such a process. In the treatment of hysteria it is above all things imperative to recognize the discomforts and troubles as real. It is wrong to urge the patient to the exercise of the will. Besides the general treatment, the most necessary thing is the influencing of the individual complaints. The treatment of hysterical diseases by surprises and by neglect is discussed. Hypnosis and psychoanalysis are mentioned. The personal cooperation of the physician is a most favorable plan of action. The physician must keep away from everything suggesting mysticism in treating hysteria.

Comparative Study of the Wassermann Reaction, Lymphocytosis, and the Globulin Reaction in Diseases of the Nervous System.—Arthur Wolff says that these three tests are valuable aids in the differential diagnosis of neurological conditions. Of the three the globulin reaction is of the most practical value, for, though it does not occur with absolute constancy and its presence alone is not definitely diagnostic, it is diagnostically especially useful because in contradistinction to the complement binding and lymphocytosis, it appears always to be negative where there is only a syphilitic history without the presence of para- or meta-syphilitic nervous diseases. If syphilis is ruled out, we may from the behavior of the lymphocytosis and the globulin reaction, taken in connection with the clinical picture, draw definite conclusions for differential diagnosis between organic and peripheral or functional nervous affections in so far as positive findings suggest the former and negative findings the latter. This is especially valuable in the incipient cases of tabes and paresis. The absence of this complement binding reaction in lumbar puncture fluid is of but little value as it is often negative in tabes and paresis. Complement binding, lymphocytosis, and the globulin reaction may occur in cases of the so-called periodic vomiting which gives evidence of the central cause of this disease.

Book Reviews.

Girl and Woman. A book for Mothers and Daughters. By Caroline Wormeley Latimer, M.D., M.A., with an introduction by Howard A. Kelly, M.D. Pages 8 to 381. New York and London: D. Appleton & Co., 1910.

There is need for a book written by a woman for the use of women, which shall describe accurately and fully many things which they should know concerning what may be termed "the physiology of femininity." The essays here presented in book form were published originally in a popular magazine read widely by women, and are on the whole interesting and instructive. Dr. Latimer discusses the physical, mental, and moral disturbances of girlhood, the facts of menstruation and reproduction, the life of the girl at school, her life after leaving school, and the importance of the proper care of the body, exercise, rest, and sleep. Her recommendation as to the use of chloroform in acute ear conditions, however, is scarcely wise, and she does not, as we think, warn sufficiently against the harm which may result from chronic ear discharge, but with these exceptions the book can be highly recommended.

Treves' Operative Surgery. A Manual of Operative Surgery. By Sir Frederick Treves, Bart., and Jonathan Hutchinson, F.R.C.S. In two octave volumes. Volume I, New (Third) Edition. Philadelphia and New York: Lea and Febiger, 1909.

The present edition of Treves' well-known manual has been completely revised by his colleague, Jonathan Hutchinson. Among the changes necessitated by this revision and in accordance with the great advances which have been made in the science, is the grouping of all the abdominal operations in the first volume. A considerable number of illustrations have been added and also a special series of color plates to elucidate the anatomy of various important operations. These were drawn especially for the work from dissections in the Museums of the Royal College of Surgeons and the London Hospital Medical College. The first part of the book deals with the general principles of surgery, including chapters on the patient, the surgeon, technic, the elements of operative surgery and the after treatment of the wound. These introductory chapters contain a great many valuable features which are often omitted from the larger surgical manuals as being too trivial in character and yet are of considerable importance. Thus, an excellent description is given in the chapter on the "condition of the patient," of the various factors which enter into and affect the results of an operation. In describing the preparation of the patient's skin before operation and also at other places, reference to the frequent use of carbolic solution (1:20) will probably attract the attention of the American operator. The second portion of the book is concerned with the surgery of the entire abdominal cavity, including that of the male and female generative organs and also of the rectum—a separate chapter being devoted to an account of the excision of the latter organ. Although operations on the female genitals are claimed by general surgeons as part of their field, their description in surgical manuals is rarely sufficiently satisfying or complete. There is too much to be said about the lesions which occur in the female pelvis to be included in a few chapters of a general textbook or manual of surgery. The work, as a whole, however, remains a valuable contribution to medical literature and will undoubtedly continue to merit the well deserved attention which has been extended to it since its first appearance almost twenty years ago.

Textbook of Diseases of the Ear. By Macleod Yearsley, F.R.C.S., Senior Surgeon to the Royal Ear Hospital, London. Chicago: Chicago Medical Book Co., 1908.

This volume strikes one as exceedingly practical and helpful, not only for the general practitioner, but to refresh the mind of the specialist and increase his interest in the more exhaustive study of otology found in other works. Dr. Yearsley shows the importance of chronic middle-ear discharge, and deprecates the folly of those doctors who tell the patient that "he will outgrow it." Sixty-three pages are devoted to the influence of general diseases upon diseases of the ear, and this chapter, considering the great neglect of this important matter, is one of the most interesting and helpful in the volume. Some of the general diseases which he mentions and fully details are scarlet fever, diphtheria, syphilis, meningitis, epilepsy, heart disease, adenoids, tonsillitis, pneumonia, diabetes, myxedema, and disorders of the teeth, stomach, and liver. The author's recommendation of the use of peroxide of hydrogen in the treatment of chronic discharge may not be concurred in by all otologists, for its use is attended with danger, but his recommendation of pilocarpine in cases of labyrinthine deafness following parotitis seems a good one and is worthy of trial. The last chapter contains some wholesome advice to the otologist brought into court as a witness, and the pages dealing with life and accident insurance contain some useful hints. The author has written a systematic and accurate essay, which, while sufficiently complete, is not unduly exhaustive. He has supplied a large bibliography in his footnotes, and his volume is altogether satisfactory. The type and illustrations are of excellent quality.

Physiology of the Special Senses. By M. Greenwood, Jr., M.R.C.S., L.R.C.P., F.S.S.; Statistician to the Lister Institute of Preventive Medicine; Director of the London Hospital Statistical Department; Late Senior Demonstrator of Physiology in the London Hospital Medical College; and Examiner in Physiology to the University of St Andrews. New York: Longmans, Green & Co.; London: Edwin Arnold.

This is a very readable little volume on the physiology of the special senses. It is intended for two classes of readers: for students of psychology, who may desire more information on this subject than is usually found in psychological textbooks; and for students of physiology as a bridge between the ordinary textbooks and original memoirs. For the first class of readers the book seems to be admirably adapted. The other class will find it useful as a companion to any of the more modern and complete textbooks, and as a guide to collateral reading; but we do not think that it is much in advance of what our best physiologies contain. At the end of each chapter are references to works which are, as a rule, easily accessible. Two-thirds of the book is concerned with vision, and the remainder is about evenly divided between the other senses.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia. Assisted by H. R. M. Landis, M.D., Assistant Physician to the Out-Patient Medical Department of the Jefferson Medical College Hospital. Philadelphia and New York: Lea & Febiger, March 1, 1910.

The present issue of this valuable publication contains chapters on surgery of the head, neck, and thorax, by C. H. Frazier; infectious diseases, including acute rheumatism, croupous pneumonia, and influenza, by J. Ruhräh; diseases of children, by F. M. Crandall; rhinology and laryngology, by D. B. Kyle; and otology, by A. B. Duel. It will be noted that Dr. Ruhräh of Baltimore now contributes the section so ably supplied for many years by Dr. Preble of Chicago.

Anatomy and Physiology for Nurses. By Leroy Lewis, M.D., Surgeon to and Lecturer on Anatomy and Physiology for Nurses at the Lewis Hospital, Bay City, Michigan. Second edition, revised and enlarged. Philadelphia and London: W. B. Saunders Company, 1910.

The first edition of this book was noticed at some length in the Medical Record of January 6, 1906; it is therefore only necessary to say that this new edition contains an extra chapter on the male organs of generation. For the rest, we can only repeat that in many places the statements in the book are indefinite and inaccurate; and that considerable further revision is necessary before the volume can be recommended to nurses.

The Conquest of Disease through Animal Experimentation. By James Peter Warbasse, M.D.; Surgeon to the German Hospital, Brooklyn, N. Y.; Member of the American Medical Association, American Association for the Advancement of Science, etc.; Author of "Medical Sociology." New York and London: D. Appleton & Company, 1910.

This little book gives in concise form the debt of medicine to animal experimentation. After describing the various procedures used in the medical laboratories and showing the care which is taken to reduce suffering to a minimum, the author devotes separate chapters to the advances which have been made in physiology, medicine, hygiene, surgery, and the diseases of the lower animals by the use of animals for experimental purposes. In his concluding chapter he expresses in plain words his opinions of the sentimentalists who are striving to interfere with the advance of the healing art. The book is written for the laity, but should in these troublesome times be read by every physician also. It is full of facts which may at any time be useful as arguments to be used against the antivivisectionists.

Society Reports

ASSOCIATION OF AMERICAN PHYSICIANS.

Twenty-fifth Annual Meeting, Held in Washington, D. C., May 3, 4, and 5, 1910.

PRESIDENT, DR. HENRY HUN OF ALBANY, N. Y.

(Special Report for the MEDICAL RECORD.)

First Day, Tuesday, May 3.

The President's Address.—Dr. HENRY HUN of Albany, N. Y. said that the association had lost one from each of its classes of membership: emeritus, Dr. Andrew H. Smith; active, Dr. Wharton Sinkler; and honorary, Dr. J. Allison Scott. This was a fitting time to look back over a quarter of a century and seek for suggestions to guide the future and to judge how fully they had been able to fulfill that inspiring prophecy of Dr. Delafield's, made at the first meeting when he said: "We want an association composed of members, each one of whom is able to contribute something real to the common stock of knowledge. We want a society in which we can learn something, to which we may come year after year with the well-founded hope that at each meeting we shall find something to learn." Membership to-day still remained a high honor and privilege to be obtained only by scientific achievement. The selection of worthy candidates was a difficult and disagreeable task, but the good had to be selected and the less fit rejected in spite of the promptings of friendship or self interest. Their membership was practically full and there was a long waiting list. They had been no less successful in their scientific work than in their selection of members. Many papers were offered each year and this was an expression of the vigorous life of the association. He was convinced that it was necessary: (1) To limit the contributors to actual members, unless in very exceptional cases; (2) to have the essentials of each paper presented in as brief abstract as was compatible with clearness; (3) to promote full discussion; and (4) to extend the meeting over sufficient days or sessions to permit the presentation of every paper offered. The social side of these meetings was of great influence and value. Washington offered so many attractions that they lost touch with their members and he hoped that the experiment might be tried of holding their meetings occasionally in Atlantic City where they could live together and be in constant communication with one another. Dr. Hun said the association had given him the privilege of serving as its secretary for twenty-one years.

Observations on the Etiology of Subacute Infective Endocarditis.—Dr. E. LIBMAN and Dr. H. L. CELLER of New York presented this paper. They had had unusual opportunities during the past eight years of making studies in 43 cases of subacute infective endocarditis. Blood cultures were made during life in 36 of the 43 cases. Twenty-nine of these cases had been seen since 1906 and this seemed to show that the disease was being recognized more frequently than formerly. The duration of their cases had varied from four months to a year or a year and a half. In nearly all cases the disease began insidiously. Fever was present in all cases; sweats occurred in nearly all cases; malaise and gastric or intestinal disturbances were frequently present. There was a progressive weakness and emaciation in all the cases. The spleen was nearly always enlarged and palpable. Pains were quite a constant feature; in some cases they were localized in the bones, joints or muscles, in others they seemed to be aural in origin. At times the pains were due to the development of embolic aneurysms. The painful erythematous cutaneous nodules seemed to be pathognomonic. One symptom present in nearly all cases to which no attention had been paid was tenderness of the lower part of the sternum. The progressive anemia and the color of the face were noteworthy features. None of the cases recovered and autopsies were performed on nineteen cases. In fifteen of these blood cultures had been made during life. The lesion was vegetative, not ulcerative in type. When the aortic valve was attacked, there was a marked tendency for the process to spread down and to involve the wall of the ventricle, the ventricular surface of the aortic flap of the mitral valve, and the chordæ tendineæ. The latter were often torn. In ten cases the mitral valve alone was involved. Both valves were affected seven times. In six of these auricular endocarditis was present. When the mitral valve was involved, lesion of the auricle practically always occurred. As a rule the vegetations contained innumerable organisms. In all 103 examinations were undertaken; in thirty-five cases typical cocci were found; in one case the influenza bacilli were found. The number of colonies varied from two colonies in twenty-five centimeters of blood to 500 in one cubic centimeter. They had investigated nineteen strains of pneumococci, sixty-nine of streptococci, and twelve of *Streptococcus mucosus*. They had reached the following conclusions: 1. The type of capsule of the pneumococcus and that of the *Streptococcus mucosus*, as described by Buerger, were diagnostic. All organisms presenting such capsules were dissolved by bile. 2. Solution by bile was diagnostic of the pneumococcus and the *Streptococcus mucosus*. This latter organism was easily distinguishable by its type of capsule and certain other features. 3. The absence of precipitation spoke almost absolutely against an organism being a streptococcus. 4. The fermentation of inulin was not of pathognomonic value. This property might be absent and, furthermore, streptococci occasionally gave a positive result. 5. The ring colonies were diagnostic of the pneumococcus. 6. The growth in the blood plates gave the following results: (a) A definite, large, perfectly clear zone about a colony was diagnostic of streptococci if it was found to persist in several generations. Incomplete clearing was of no diagnostic value, nor was a linear clearing. The clearing might occur in concentric rings. (*b*) Pneumococci always grew green. An organism not productive of a green color always proved of further study not to be a pneumococcus. The conclusions they arrived at in the study were based on the following findings: 1. Type capsules were found on all nineteen pneumococci studied, either in the original material obtained from the patient or in cultures. All the organisms were dissolved by bile. Type capsules were found on all the strains of the *Streptococcus mucosus*. Of sixty-nine ordinary streptococci, thirty-two had capsules. 2. All of the streptococci precipitated. Of nineteen pneumococci only two precipitated; these two had been in bile and did not precipitate in the second generation. Of twelve strains of the *Streptococcus mucosus*, one precipitated for four generations and one for two generations. 3. Of nineteen pneumococci, all fermented inulin except two; with these two a slight result was obtained by passage through two mice. The strains of the *Streptococcus mucosus* all fermented rapidly. Of the sixty-nine streptococci, two fermented inulin; one lost the property in the second generation and also after passage through one mouse. The other lost the property after passage through two mice. 4. On blood media, all but eleven of the streptococci grew in fine grey colonies surrounded by an absolutely clear zone. Of the eleven exceptions, seven gave a good white, moist growth without any clear zone, three grew green like the pneumococcus and one gave an almost colorless dry growth with no clearing. The cocci found in cases of subacute and chronic infective endocarditis during the past few years were all Gram-positive; they had never been found

to have a capsule. They were either round, ovoid, lancet-shaped, or bacillary in form, and might be found in diplococcus form, in groups or in chains. The point to be brought out was that whenever they had found the organism which they had usually called the endocarditis coccus *par excellence* there was always present in infection of the endocardium. In no other disease had they found the organisms in the blood current. They, therefore, seemed to have a diagnostic import.

Dr. Francis P. Kinnicutt of New York said that as he undersood Dr. Libman, the results of the blood cultures determined the prognosis; if this were true it was a very useful means at one's disposal.

Dr. James P. Herrick of Chicago asked Dr. Libman in what proportion of the cases was there a history of valvular lesions having preceded the chronic endocarditis; also what relationship the organism he described bore to the so-called organism of rheumatism.

Dr. E. C. Rosenow said that during the first years of his work in making cultures he thought that he was dealing with the *Streptococcus pyogenes;* further studies had convinced him, however, during the last two years that he was dealing with a modified pneumococcus.

Dr. F. Forchheimer of Cincinnati said that an enormous step forward in the recognition of this disease had been made by the researches of the men who had just spoken, and the work that had been done by the German observers must be gone over again if what they had heard was true.

Dr. E. Libman, in answer to Dr. Herrick's question, said that in all the cases the disease had been superimposed upon previous cardiac disease. In some cases it had been superimposed upon an endocarditis of so-called rheumatic origin. The disease could be diagnosed only by cultural tests of the blood.

The Commoner Types of Functional Cardiac Murmurs.—Dr. S. W. Thayer of Baltimore said that for seven years he had been studying cardiac murmurs in individuals who appeared to be perfectly normal and he had concluded: (1) That a cardiac murmur was but one, and sometimes an unimportant one, of the links in the chain of evidence leading to the recognition of disease of the heart. (2) That certain cardiac murmurs were present normally in a large proportion of healthy young people. (3) That the common form of these murmurs were: (a) The basic systolic murmur, heard best in the third left interspace, and often all over the area in the recumbent posture. (c) The cardiac respiratory inspiratory murmurs. (4) That the commoner functional murmurs, those heard in healthy individuals, should be carefully distinguished from those other murmurs which might arise at various orifices without actual valvular disease; but nevertheless, as a result of pathological changes in the heart muscle or in the blood. The anemic murmurs, the murmurs systolic and diastolic, depended upon weakness of the heart muscle. (5) That a familiarity with the cardiac murmurs, common in the normal individual, was at least as important as an acquaintance with those murmurs which were associated with cardiac disease.

Dr. Henry Sewell of Denver felt quite sure that clinically these functional murmurs, if he could call them such, were to be interpreted by changes in the first sound of the heart; it was a double sound and was heard at the end of inspiration when the individual sat up; when he lay down, however, there was almost always a systolic murmur heard at the apex and this he thought was due to contraction of the papillary muscles which snapped down early in systole. That might play a part. He found this reduplication of the heart sound especially in cases of venous congestion.

Congenital Syphilis of the Heart.—Dr. A. S. Warthin of Ann Arbor presented this paper in which he stated that a few good studies of this condition had been made and that the importance of certain syphilitic affections of the heart in young people was not recognized clinically. Special attention was called to the diffuse fibrosis of the myocardium due to congenital syphilis; a study was presented of the pathology of this condition and of the occurrence of spirochetes in the heart wall. The relation of the congenital fibrosis of the heart to cardiac insufficiency in young and early life was emphasized. Cardiac changes occurred in all cases of congenital syphilis in which the liver showed the changes characteristic of congenital syphilis. He called attention to the association of infantilism and delayed puberty in connection with this form of heart lesion.

The Clinical Significance of Transitory Delirium Cordis.—Dr. A. W. Hewlett of Ann Arbor presented this paper which was written by Dr. George Henry Fox. He stated that by transitory delirium cordis was meant a transitory but extreme irregularity of the heart, during which the auricular waves disappeared from the venous tracings. The paroxysms might be excited by exhaustion, vomiting, exertion, or excitement, or they might come from no apparent cause. In two patients the first paroxysms occurred after operations. The heart might be absolutely negative on physical examination between attacks and the diagnosis of a nervous condition might be made. As five out of the six patients ultimately developed the permanent form of irregularity with cardiac insufficiency the prognosis should be guarded.

Dr. Joseph H. Pratt of Boston reported a case that he had under observation of the type described, and said he wished to emphasize the fact that the condtion might readily be mistaken for a cardiac neurosis. His patient was sixty years old, a very nervous individual, and he had had six or seven attacks since last October. He was not short of breath and had no cyanosis. He had a very irregular pulse. The attacks lasted about twelve hours.

Dr. Walter B. James of New York thought that the study of irregular hearts and the classification of them was very unsatisfactory. From his study of about one hundred and fifty cases and cardiograms had left him with the conviction that arythmia formed an important group of cases which had not been at all satisfactorily subdivided. There was no doubt but that a great many of these cases depended upon an irregular auricular fibrillation. The use of the electric cardiograph was the only way to determine whether or not this was the case. Auricular fibrillation was necessarily associated with permanent irregularity of the heart.

Dr. Richard C. Cabot of Boston asked the age of these patients.

Dr. Isaac Adler of New York had seen a large number of cases like the ones described, but he had not had any experience with the electric cardiograph. If the conditions were based upon a purely nervous condition, after exercise the heart not only became regular, but the blood pressure rose. In those cases, on the other hand, which depended upon disease of the heart muscle, the orthodiascope would show that after exercise the blood pressure decreased, and the arythmia did not disappear.

Dr. Hewlett said that in the cases he described one should be very guarded in giving a prognosis. Some cases that he had seen operated upon, apparently insignificant operations, resulted in bringing on a paroxysm. The patients were all over forty years of age.

(*To be continued.*)

An All-Russian Anti-Tuberculosis Association has been formed, with headquarters at Moscow.

Societies for the promotion of public health measures and particularly for the erection of tuberculosis sanatoria have been formed in Bosnia and Herzegovina.

AMERICAN SURGICAL ASSOCIATION.

Annual Meeting Held in Washington, May 3, 4, and 5, 1910.

(Special Report for the MEDICAL RECORD.)

RUDOLPH MATAS, M.D., OF NEW ORLEANS, PRESIDENT, IN THE CHAIR.

(*Concluded from page 900.*)

Abnormal Position of the Duodenum.—Dr. ARMSTRONG of Montreal reported a case where the duodenum lay outside of the colon at its hepatic flexure, had a mesentery and could be lifted out of the abdomen. A case of maldevelopment where the cecum did not rise as usual and pass in front of the duodenum, but the fetal condition persisted. In this case he had operated for pyloric stenosis.

Dr. MAURICE RICHARDSON of Boston, speaking of the anomalous position of the abdominal viscera said that he had not until recently seen a case of transposition of the viscera, but that he had recently operated on a case for appendicitis and not finding the appendix had followed the colon to the left iliac fossa before finding the cecum.

Dr. RIXFORD of San Francisco said that he had found one case of failure of rotation of the primary gut, during an operation for fibroids of the uterus. The case was followed by intestinal obstruction and led to the investigation of the upper abdominal region. He considered this failure of rotation as due probably to a fetal adhesion of the cecum to the parietal peritoneum.

Dr. BLAKE of New York City considered the location of the duodenum outside the colon as one of the fairly common anomalies. He had seen two such cases.

Dr. BLOODGOOD of Baltimore noted a case of absence of the appendix associated with a very high location of the cecum.

Biliary Fistula.—Dr. G. E. BREWER of New York reported a case in which he had operated for acute cholecystitis and the wound had been infected. The patient got up in the eighth week with a persistent biliary discharge. The wound closed of itself only to have further symptoms and to reopen of itself. No bile passed into the intestine. On the second operation he had found that the common duct had sloughed away, and the head of the pancreas was exposed without finding any useful duct. He had, therefore, inserted a rubber tube into the end of the common duct next to the liver and carried the other end of the rubber tube into the duodenum. Attempt to pull the duodenum up to the end of the duct had been futile, so he had wrapped the exposed inch of rubber tube with duodenum omentum and closed the abdominal wound without drainage. Bile passed into the intestine and there was no leakage of bile from the skin wound. Six weeks after the operation the patient was discharged from the hospital in excellent general condition. Ten days later he had returned with fever, jaundice, and no bile in the stools but the condition had cleared up of itself. The rubber tube had not been found in the stools, or in the *x*-ray pictures that had been taken.

Resection of the Pancreas.—Dr. FINNEY of Baltimore reported a case of this nature: There was a primary solid tumor of the pancreas in its middle third and he had resected the pancreas and sutured the head to the tail. The patient was a woman of 43 years who for three years had had a freely movable mass in the upper abdomen the size of her fist. The time of greatest comfort was after eating. On operation the mass was found to be under the gastrohepatic omentum. Two-thirds of the pancreas were involved and after excision the part of the pancreas left was about the size of a walnut. After operation there persisted for a year, a fistula discharging pancreatic juice. The tumor was called an adenocystoma. Partial excision of the pancreas had been shown to be safe though total excision was fatal. The secretion of the pancreas was harmless to the peritoneum though destructive of fat.

Dr. HARRIS of Chicago described a case of bullet wound of the pancreas with associated perforation of liver, stomach, and left kidney. The abdomen was opened and the wounds sewed up as securely as possible and then drainage left in both anterior and posterior. In twelve weeks the wounds closed and the patient had fully recovered.

Dr. ARMSTRONG of Montreal, called attention to the generally unappreciated factor in diagnosis that the pancreatic tumor moved freely with respiration and under manipulation.

Dr. WILLY MEYER of New York City, confirmed the statement that the pancreatic juice did not effect the peritoneum. In two cases he had cut the pancreas in removing a splenic tumor and no bad result had followed.

Dr. MATAS of New Orleans reported a case of thrombosis of the splenic artery with degeneration of the body of the pancreas and multiple tumors in the spleen in which he had removed the spleen and on investigating the pancreas had pinched off the greater part of that organ bloodlessly, as the gland was degenerated to the point where it felt like a mass of soft putty.

Dr. FINNEY in closing said that he had hopes before long of finding that the head of the pancreas also could be resected.

Congestion of the Base of the Right Lung an Early Symptom in Appendicitis.—Dr. J. D. ROBERTS of Philadelphia thought the presence of râles and the decreased breath sounds could be found in many cases of acute appendicitis if searched for.

Vaccine Therapy.—Dr. JOHN B. DEAVER of Philadelphia cited a series of cases of surgical conditions including cellulitis of the extremities and pelvis, suppuration of kidney and sepsis. In many of the cases there was an apparent change in the patient's condition dating from the administration of the vaccine. Of five cases with blood cultures showing streptococci three recovered and two died. In pelvic sinuses closure had followed in some. The vaccine treatment was not meant to supplant other methods of treatment but merely as an important adjunct. The use of the stock bacterins was only a makeshift and not nearly as reliable as the autogenous vaccines. The dosage should be the smallest that would give a reaction and should be smaller the weaker the patient, in contrast to the antitoxin treatment. In the cases where the patient was already overwhelmed with the poison the vaccines did no good. The intervals between treatments should vary. It was better to give too little rather than too much, and the intervals should be too long rather than too short. In the staphylococcus cases the results were usually good. The localized conditions at times gave as good results as the staphylococcus cases.

Dr. DE FORREST WILLARD of Philadelphia agreed with Dr. Deaver as to the usefulness of vaccine treatment especially in the chronic bone cases. The autogenous vaccine should be used and the work followed by a skilled pathologist and bacteriologist, the clinical symptoms remaining as a guide to the treatment.

Therapy by Bacterins and Tuberculins in Mixed Suppurative Bone and Joint Diseases.—Dr. B. A. THOMAS of Philadelphia read this paper: He said that in the treatment of the chronic bone and joint lesions it was necessary to use the several strains of bacteria as found in the mixed cultures from the bone and hence to change repeatedly during the prolonged treatment as the types changed as shown in the repeated cultures. The temperature of the patient was the most significant sign. If two bacteria were culturable from a bone cavity they should be used alternately every five or ten days or the bacterin and the tuberculin were used alternately or one abandoned

and the other used. If fever followed the injection of the tuberculin or vaccine the dose should be cut down. The use of tuberculin should be especially cautious and not used unless the temperature was persistently below 100° F. If the temperature was above 100° only the bacterin should be used. In the mild cases, the use of vaccines was superfluous as the cases got well anyhow. In the acute cases tuberculin alone was not helpful.

Dr. MacDonald of Albany said that while he had never seen any fatality from overdose of a vaccine yet he had seen most distressing sickness. In one case (of a skin infection) he had seen an illness lasting a year follow a small dose of vaccine.

General Sternberg of Washington spoke of the lack of knowledge on the part of the surgeons as to the theory of this treatment. Why when the body was filled with a vast number of bacteria should injecting a few more of the same dead bacteria lead to a cure? The principle seemed certainly that of *similia similibus curantur* and the dose was surely homeopathic.

Dr. McArthur of Chicago mentioned cases of essential hemorrhage of the kidneys without evident cause for the hematuria in the urine or in the kidney on operation, which not infrequently showed a bacteriuria, the colon bacillus being the most common germ. An autogenous vaccine had been curative in his hands in five cases.

Study of the Etiology of Cancer Based on Clinical Statistics.—Dr. Isaac Levin of New York said that statistics showed that, with the exception of cancer of the breast and uterus, cancer occurred in man much more frequently than in woman, organ for organ. Nearly half of the cases of cancer of the extremities occurred in people under thirty-four years of age. In women childbearing had no effect on the frequency of the occurrence of cancer. The primitive races not having the same wear and tear in the stress of life as the more highly civilized were less prone to cancer. Cancer was rare in miners. Arteriosclerosis was a frequently associated condition, especially in the cancers of the head, face, and neck. The same organ had been previously diseased in many of the cases: Such were ulcer of the stomach preceding cancer, chronic mastitis preceding breast cancer, balanitis preceding cancer of the penis. Heredity was a small factor probably negligible. In cancer of the extremities only one per cent. and in cancer of the penis two per cent. of the cases gave other cases of cancer in the patient's family. In general it seemed to show that local trauma and heredity were not as important factors as the increased vulnerability from the increased stress of life.

A Review of the Cancer Cures of America.—Dr. Bevan of Chicago spoke of the treatment by *x*-rays, radium, mixed toxins of erysipelas and *Bacillus prodigiosus*, and of the serum therapy from an immune. One of these methods of treatment should be considered as the choice. Though the *x*-rays or radium might be acceptable in the precancerous stages of the senile skin changes, and in the inoperable cases, the only sure cure was the early radical removal by the knife.

Dr. McLaren of St. Paul, said that he had given the mixed toxins in several cases with disappearance of the masses but recurrence followed, causing death.

Dr. Finney of Baltimore had not seen good results from *x*-ray or radium. He had used the mixed toxins in some forty cases with no permanent results. The immune serum he had used in seven cases. In one breast case with multiple nodules in the skin. Many of the nodules had disappeared and there had been a local reaction about other nodules. But new nodules appeared and the patient died of the recurrences. In every case a certain amount of temporary effect was seen. The limit of technique in operative treatment had, however, almost been reached, and the serum treatment gave the most hope for cure.

Dr. Deaver of Philadelphia had been trying the reinjection treatment suggested by Coca of Philadelphia and believed that a cure was at hand for the recurrent cases, though it was yet too early to report.

Dr. Keen thought that every operable case should be operated on, but that the discussion had been carried on by the wielders of the knife in the absence of the authorities on the *x*-ray treatment, Abbe, Coley, and Hodenpyl, all of whom reported undoubted cures. And he would beg for the next meeting of the association a symposium with the leaders in these lines present.

Dr. Gerster of New York did not believe in the skepticism of the pure knife surgeon. He had seen one cure from a natural erysipelas and one from the use of the mixed toxins.

Dr. Wier of New York said that the treatment of the early cases was by the scalpel; and of the late cases with hope. The work on immune serum and embryonic tissue serum was still in its infancy. Personally he believed more in the *x*-rays and radium. Both had a marked influence on external cancer. The effect might not be permanent but temporarily it was very marked.

Dr. Blake of New York agreed with Dr. Bevan that there was as yet no better cure than the knife, liquid air and carbonic oxide snow gave also skin destruction. In one case he had referred to Dr. Hodenpyl for treatment, the maximum dose had been given intravenouly of 17,000 c.c. This had been followed by a cessation of growth. It was interesting to note, however, that in animals an indifferent serum did the same as Dr. Hodenpyl's serum in man.

Dr. Rodman of Philadelphia had used the mixed toxins in many cases with distinct betterment in many but no cures. He had three cures from the *x*-ray. In the cancers of the mucous membrane the *x*-ray did no good but more harm. He uses the *x*-ray now only in postoperative conditions where he has done an incomplete operation.

Dr. Bevan in closing urged the furtherance of cancer research to find a cure for the inoperable cases.

A Review of One Hundred and Twenty Resections of the Rectum for Cancer.—Dr. William Mayo of Rochester, Minn., presented this paper. Of this series sixty-three had been in men and fifty-seven in women. The youngest was twenty-seven years of age, the oldest eighty-one years, and the average age had been fifty-two years. One hundred and eighteen had been carcinoma and two sarcoma. He had operated by the perineal route in thirty-eight, by the posterior route in fifty-six, and by the abdominal route in twenty-six. The portion of the bowel removed had been: the lower rectum, in five; the middle rectum in five; the entire rectum in seventy-five; the sigmoid and the rectum in thirty-two; a panhysterectomy, the sigmoid and the entire rectum in one; the prostate and the rectum in two. The operative mortality had been twenty per cent. The operation had been done more than five years ago in thirty-two cases. The present condition of only seventeen of those was known and of those seventeen, four were alive and well. Two of those four had been done by the abdominal route, eight and nine years ago respectively; and the other two had been done by the perineal route, nine and five years ago respectively. Sixty of the cases had been done more than three years, of whom the present condition was known in forty-three. Of these thirteen were alive and well, four done by the abdominal route, three by the perineal route, and six by the posterior route. One hundred and two cases had been done over one year and of those the present condition was known in eighty-two. Of those thirty-six were alive and well.

Chorion Epithelioma.—Dr. A. Primrose of Toronto discussed the types of these growths noting the more or

less benign chorion adenoma with the structure of the chorionic villi, predominant in the milder cases and the chorion carcinoma with the villus structure less evident and the mitosis cells predominant in the malignant cases. The secondary nodules in the tissues at times seemed to disappear with the removal of the uterine growth. The metastases in the liver seemed to show the spread through the blood vessels. He described a case of the most malignant type.

The Changes in the Central Nervous System in Infections, in Hyperthyroidism, in Anemia, and in Surgical Shock.—Dr. CRILE of Cleveland said that the neuropathological cytology had been instigated by the belief that when the function of any organ was disturbed that some pathological changes could be found, and as no gross lesions were found in the central nervous system in the conditions mentioned although their functions were disordered, the cytology had been studied. In uncomplicated surgical shock from trauma, the brain cytology had been studied and showed the size of the pyramidal cells to be increased, the nucleus to be larger than normal in proportion to the size of the cell, the limiting membrane of the nucleus to be ruptured and uneven in contour, the Nisl staining bodies to be larger and the nucleolus to be abnormal. Even in the fatal cases of shock not all of the cells were thus involved, but more of the cells were destroyed the more severe the shock. In anesthesia similar changes were found, but the changes under nitrous oxide and oxygen were only one-fourth as frequent as under ether. Mere changes in the cortex and fewer in the cord were found than in shock. In Graves' disease, anemia, and the infectious diseases similar cell changes were found. In peritonitis, toxemia, streptococcus sepsis, and chorea, the same types of changes were found in the cells. In cases of intestinal gangrene after the blood supply had been cut off for a certain length of time, if the blood circulation through that intestinal loop were restored, the patient died quickly. If the blood supply were not restored the patient died later. The expressed juice from the loop of the gangrenous gut if injected into the lumen of the gut elsewhere or into the subcutaneous tissues, or into a vein, produced destruction of the brain cells. Therefore, in operating on strangulated intestine it, was very deleterious to express the contents of the gut into the healthy gut after releasing the constriction and much wiser to block the circulation to that loop before operation on the intestine. In Graves' disease the cell destruction was most marked in the cortex, less in the cerebellum, and still less in the medulla. The cellular pathology did not afford a diagnosis of the condition but allowed a class diagnosis. The several conditions also augmented each other in their action, so that it was not wise to add anesthesia to a case that already was suffering from infection, hemorrhage, trauma, and fear.

Operative Intervention for Fractures of the Base of the Skull.—Dr. RANSOHOFF of Cincinnati read this paper. Of 190 cases of fracture of the base of the skull somewhat more than half had been operated on. Fifty-six per cent. of the cases seen had died within twelve hours of the injury; seventy-eight per cent. had died within twenty-four hours, and eighty-five per cent had died within forty-eight hours. After the second day eighty per cent. of the cases recovered. Of the other cases a decompression operation might save a few. The most constant symptom of fracture of the base, present in all but eleven cases (95 per cent.), was coma. The depth of the coma was significant; the greater and more persistent the coma, the worse the prognosis. On the other hand, of eleven that were conscious all the time, three died. Of those having but a light stupor, all recovered but one of ninety-eight, with deep stupor, only twenty-six recovered. The possibility of an associated delirium or stupor of alcoholic origin must always be remembered. The temperature was significant to the extent that all those with an early marked rise of temperature all died. Hemorrhage had occurred in one hundred and sixty-three cases, the most common hemorrhages were from the eye or into the ear. Hemorrhage from the nose occurred in but eleven cases of which four died. The cases with paralysis (hemiplegia) almost invariably died. The pupils were of the greatest prognostic value. Of forty-two cases in which the pupils were fixed and failed to react to light forty-one died. Whether the case was operated on or not made no difference. The operative treatment was indicated to relieve intracranial pressure. The cases in which a cranial wound could be enlarged were not included as fractures of the base operated on. In some cases fluid could be evacuated. In the last nineteen cases operated on seven had recovered and twelve died. Of twelve cases not operated on nine recovered, but the cases not operated on naturally were the less severe cases. If there was a hemorrhage supradural that could be removed, most of the cases recovered; but if the hemorrhage was subdural only two recovered. In many of the cases there was an antemortem rise of temperature and a tachycardia after operation, similar to what occurred in the non-operated cases The most of the operations were done within the first twenty-four hours after the injury. Of three cases operated on after the first day two recovered. One of these would have recovered anyhow. Cushing reported the loss of only two of the last fifteen cases of basal fracture operated on and these were lost because only unilateral exploration was made. The late occurrence of neuroses and epilepsy from scars was a possible objection to operation. Lumbar puncture and decompression seemed to be indicated in pressure. If the symptoms did not indicate severe intracranial pressure, but the pressure was increasing, then decompression should be done. Subtemporal decompression should be done for fracture in the anterior of middle fossæ, but in fractures involving the mastoid region and posterior fossa a subtentorial trephine must be done or else a bulbar paralysis would follow. Taking the ordinary cases, if the blood-pressure was increasing and a choked disc appearing the case ought to be decompressed, but routine decompression was not advisable.

Dr. BLOODGOOD of Baltimore reported that no case of epilepsy had been found unless the button of bone had been removed. In children he would do a temporary resection of the skull and close the skull again by a later operation.

Dr. MACDONALD of Albany called attention to the cases where lumbar puncture made the breathing worse from bulbar pressure, while bilateral temporal trephining improved the breathing. In two cases of which he knew, epilepsy had followed loss of a part of the skull.

Dr. CRILE of Cleveland thought that unconsciousness showed fatal destruction of the brain tissue. If the thermogenic center was upset he considered that the injury was usually fatal as the temperature regulation was one of the oldest and most fundamental functions of the brain.

Dr. POWERS of Denver reported a case in which the temperature rose to 105.5° and the patient recovered.

A Method of Overcoming Shortening After Old Fractures Treated by the Open Method.—Dr. EDWARD MARTIN of Philadelphia described this method. He put a strip of canvas over the end of the exposed bone and let the canvas exert a steady uniform pull on the distal fragment. This in three to five minutes with twenty-five or thirty pounds weight gave a satisfactory lengthening in cases where prolonged traction with greater weights without an anesthetic had not given sufficient lengthening.

Dr. HARTE of Philadelphia used a similar method fixing the trunk by two perineal bands formed from sheets, and applied the traction by a roller towel fastened to the leg

by a clove hitch and then pulled by a rope over two pulleys several feet apart. He showed a number of special elevators for dissecting out and manipulating the ends of the bones. He advocated the use of steel (not silver) plates and screws to hold the ends of the bones in place when they had been reduced.

Dr. Ochsner of Chicago advocated the slow stretching of the muscles by traction on two rubber adhesive bands applied high up in the thigh in the case of fractures of the femur. Twenty-four pounds traction would suffice in every case.

Dr. Thompson of Galveston called attention to the frequent interposition of a blood clot between the ends of the bones that prevented reduction of the fragments. Removal of the clot permitted reduction of the fracture.

Dr. Sherman of San Francisco exerted traction and countertraction by hanks of yarn one on either side of the perineum and one on the foot; this traction was continued until the plate fixing the ends of the bone were in place.

Dislocations of the Os Innominatum.—Dr. Sherman of San Francisco reported a series of cases from literature and two of his own, in which there existed a pure fracture dislocation of the bones of the pelvis not associated with any visceral injury and hence the fracture dislocations ran mild courses. In the cases of injury to the urethra or bladder as evidenced on attempt at catherization, the proper treatment was drainage of the prevesical space of Retzius and the fascial planes perforated by the urethra. Intraperitoneal rupture of the bladder was unusual as a consequence of fracture of the pelvis.

Dr. Gerster of New York reported a case of interference with the function of the urethra with no rupture. In this case a hematoma had formed and compressed the urethra.

Momberg's Method of Artificial Anemia by Suprapelvic Constriction.—Dr. Gerster of New York City said Momberg had extended the application of the Esmark construction band to the compression of the aorta, and by its application in over three hundred cases had shown the futility of the fear that any injury to the intestines would be done. No injury had been shown by symptoms in many of the cases nor in the postmortem demonstrations. The great mass of the intestines rolled above the ligature. Personally he had seen it applied in only one case, a case of sarcoma of the pelvis in which removal of one leg and one-half of the pelvis was done. The patient was put in the extreme Trendelenburg position and a three-fourths inch rubber tube placed under the waist. Then the operator and his assistant stretching the band to its limit of elasticity carried one end over the abdomen and around the waist crossing the ends in front of the patient. The tube was carried round and round the patient from two to six times until the femoral pulse disappeared. The ends of the tube were then tied and the tubes relaxed. The number of turns depended on the amount of fat and the relaxation of the muscles. The Trendelenburg position was important to carry the intestines above the constriction band. Addition constriction bands were applied to the thighs and the knees to allow gradual return of circulation to the tissues when the main band was later removed after operation. The band around the waist constricted the aorta and the inferior or at times the superior mesenteric artery. This constrictor gave a bloodless pelvis for operation and was especially suitable for injuries to the pelvis as occurring on the battlefield, railroad, and in the factory. On trial it had been shown to be safe for at least two hours and forty minutes, which would allow time for transportation to a hospital. It seemed also applicable in cancer of the uterus operations. In those cases a transverse incision could be made below the line of application and then if any intestines were found caught in the constriction band, the band could be loosened and the intestines placed above the line of constriction and then the band reapplied. The band was of special utility in obstetrical practice with a postpartum hemorrhage. It had been noted that the lax and bleeding uterus contracted with the anemia produced by the application of the constriction band, and that when the band was released the uterus contracted again firmer than ever expelling the placenta if it happened to be still retained. The question of the safety of the method had been tested on animals; in dogs the only bad sequence had been the paralysis of the back legs. This was not to be expected in man as the blood supply to the spinal cord came off of the aorta above the point at which the band was applied, so that it would have a continuous blood supply. When the superior mesenteric artery root was included in the band there was a greater increase in blood pressure by twenty millimeters in five minutes; and when the band was removed the blood pressure fell forty-five millimeters. If only the inferior mesenteric artery was included, the change in blood pressure was not so great. In youth this change in circulation was not dangerous; in older people and those with sclerotic arteries the vascular strain was much greater. In myocarditis and in valvular lesions the upset at times was alarming. In one case there had been an immediate collapse with the application of the band. This was repeated on an animal and showed suppression of the venous but not of the arterial circulation, thus giving congestion and accumulation of the blood below the band, with anemia of the brain and other tissues above the band. In one case of cancer of the uterus the band had been applied and on removing the hand symptoms of an unsuspected mitral stenosis had developed requiring the use of digitalis for three weeks.

Dr. Matas of New Orleans spoke of the value of the method and noted the cautions advised. He had tried it on his freshman class, not, however, under an anesthetic so that the constriction required was much greater than in the cases under ether or in the relaxed postpartum abdomen. In his cases it was necessary to carry the band four or five times around the abdomen to obliterate the femoral pulse. Then there still was the mental apprehension left to upset the circulatory quiet. At first all of the class had volunteered to be experimented on in this way. With the first four all went well, and then the fifth man fainted and the sixth man and the seventh man did the same, and the others then backed out. Dr. Matas, however, considered the trouble to be the mental impression, and not due to the circulatory disturbance produced by the Momberg band. In all the case the femoral pulse disappeared so that it did not seem probable that the trouble lay in the insufficiently tight ligature. Of the cases with the band applied in one the pulse continued to beat seventy times a minute and the blood pressure was one hundred and nineteen. In another the blood pressure went up to one hundred and sixty-eight but the rate of pulse dropped to sixty. In several of the cases the blood pressure dropped. The main caution seemed to the not to try the method or persons with cardiovascular lesions.

Dr. Gerster in closing said that the reactive hyperemia was present just as in the Esmarch bandage and that was a good reason for using the secondary ligatures. In Dr. Matas's cases the trouble probably was not all mental as in the conscious postpartum cases no pain had been evinced nor mental effect noted.

Splenomegaly and Hydrocephalus.—F. Parkes Weber reports a child aged 13 months with slight internal hydrocephalus, the head measuring 20⅞ inches. The spleen reached nearly to the ilium. The blood count was: Hemoglobin, 20 per cent.; red cells, 2,568,000, and leucocytes, 6,300. The Wassermann reaction was negative.—*Proceedings of the Royal Society of Medicine.*

Pathological Society of Philadelphia.

At a stated meeting, held May 12, Dr. C. C. Norris exhibited two specimens of "Carcinoma of the Vermiform Appendix." In one case the organ had been removed seven years ago and the patient was still living. In the other the appendix had been removed more recently in connection with abdominal section for another cause. Both specimens exhibited the basal or spherical tpye of epithelium, whose evolution is characterized by a relative want of malignancy. Cases of this sort demonstrate the wisdom of removing the appendix whenever the abdomen is opened for whatever cause, provided no contraindication exists. Dr. John Speese also exhibited a specimen of Carcinoma of the Appendix, the growth being present at the extreme tip of the organ. Dr. Brooke M. Anspach exhibited "A Series of Interesting Gynecological Speciments." One was a specimen of multiple fibromata of the uterus, one of the tumors presenting the contour and occupying the situation of an enlarged liver. Another was a specimen of epithelioma of the vulva in which removal was undertaken to free the patient from the offensive discharge. Still another was a twisted ovarian cyst causing symptoms like those of renal calculus. Dr. Alfred Gordon exhibited "A Brain from a Man Who Died Five Hours After a Violent Fright." The patient had been greatly alarmed while riding in a street car against which various missles had been thrown during the time of a strikers' riot. He suffered no physical injury, but he became unconscious and paralyzed, dying after being assisted to his home in a carriage. Post-mortem examination disclosed a large extravastion of blood in the white matter of the left cerebral hemisphere in its posterior aspect, disorganizing the internal capsule and other adjacent structures. Dr. David Riesman exhibited a specimen of "Malignant Endocarditis of the Pulmonary Leaflets." The heart came from a patient who, previously free from evidence of valvular disease of the heart, developed at the close of the febrile period of an attack of unresolved pneumonia a systolic and a diastolic murmur to the left of the sternum, which were attributed to endocarditis of the pulmonary leaflets. Post-mortem examination disclosed a considerable mass of vegetations involving the leaflets of the pulmonary valve exclusively, quite a rare condition. Dr. D. B. Tint exhibited specimens of "Hypertrophy of the Heart with Asymmetrical Cirrhotic Kidneys." The urine had contained a small amount of albumin and a small number of tube-casts, and death had occurred suddenly. The heart was greatly enlarged, the mitral and aortic leaflets being sclerotic and the aorta atheromatous. Dr. E. H. Goodman presented a communication entitled "A New Method of Examining the Sputum for Tubercle-Bacilli." This consists in treating the sputum with solutions of sodium hypochlorite and sodium bicarbonate and precipating the sediment by centrifugation. In this way it was possible to demonstrate larger numbers of bacilli than by the ordinary platinum-loop method. Dr. W. T. Cummins presented a communication entitled "Tuberculosis of the Myocardium," based upon a study of three cases together with those recorded in the literature, some 82 in all. The various forms of the disorder were discussed and the clinical features analyzed. Dr. John Funke presented a communication entitled "Thrombosis and Embolism of the Pulmonary Artery," and he exhibited three illustrative specimens. One of these came from a patient who had been operated on for inguinal hernia, the other from a patient with pulmonary tuberculosis, and the third from a case in which gangrene of the toes had resulted from obliterative endarteritis.

Iceland has a Society for the Prevention of Tuberculosis and is building a $75,000 sanatorium to accommodate fifty or sixty patients.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of May 21, 1910:

	Cases	Death
Tuberculosis Pulmonalis	589	190
Diptheria	484	41
Measles	1,259	18
Scarlet Fever	563	23
Smallpox	2	—
Varicella	127	—
Typhoid Fever	48	3
Whooping Cough	60	8
Cerebrospinal Meningitis	7	4
Malarial Fever	—	—
Totals	3,139	287

Tuberculosis in Ireland.—A bill will be brought before the new British Parliament, calling for steps to be taken to prevent the high mortality from tuberculosis in Ireland. The bill will demand the compulsory notification and registration of tuberculosis cases, the establishment of special institutions for consumptive patients, the instruction of the public about this disease, and improved control over the meat and milk supplies.

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended May 20, 1910.

CHOLERA

		CASES	DEATHS

ACTINOMYCOSIS (STREPTOTHRICOSIS) IN MAN; WITH THE REPORT OF A CASE OF PULMONARY INVOLVEMENT.*

By ALFRED C. WOOD, M.D.,
AND
AUGUSTUS A. ESHNER, M.D.,
PHILADELPHIA.

The number of contributions that have appeared on the subject of actinomycosis is so large that no effort has been made to review all the literature in this article. Actinomycosis of the jaw in cattle was described by Leblanc, in 1826, under the title of "osteosarcoma." In 1845 Langenbeck observed the "yellow granules" characteristic of some forms of actinomycosis in pus from a case of caries of the spine in the human subject. Lebert in 1848 described similar granules in the pus from a thoracic abscess. The exhaustive contribution of Crookshank appeared in 1858. Rivolta in 1868 noted the presence of the yellow granules in the swollen jaw of an ox. Hahn in 1870 observed similar bodies in the hard, indurated tongue of cattle known as "wooden tongue." Bollinger showed in 1876 that the disease affecting the jaw of cattle and formerly called "osteosarcoma" was due to a fungus that Harz, the botanist, named the "ray fungus," or actinomyces, on account of its shape. In 1878 Israel described the affection as observed in man, and in 1879 Ponfick established the identity of the disease in man with that observed in cattle. In 1885 Bostrom expressed the view that the ray fungus was a bacterium belonging to the genus cladothrix. Since this time the classification of the organism has been the subject of numerous contributions, but authorities still differ widely as to its proper grouping.

Two generic names have been applied to the microorganism causing this disease—actinomyces and streptothrix. The committee appointed by the Pathological Society of London in 1899 recommended the adoption of the latter term, which has been accepted, among others, by Warthin and Olney, who believe it best to classify all streptothrix infections under the general heading of streptothricosis, giving in each instance the specific name of the particular organism causing the infection. Other authors hold, with Stokes, that the generic name for this group of germs should be actinomyces, as the other names suggested have been previously applied to other organisms. Until some agreement is reached, the only solution of this question would appear to be the employment of both terms, or to use them synonymously.

*Read before the College of Physicians of Philadelphia March 2, 1910.

Morphology.—It appears to be established that there are a number of varieties of the ray fungus—Wright tells us there are as many as twenty-five—classified at present at seven species, which produce different manifestations. Stokes says the various forms of pathogenic actinomyces can be classified at present as seven species, which produce suppuration or necrotic pseudotubercles in man and various animals. At the present time the different varieties can be recognized only from their cultural and staining peculiarities.

Microscopically the fungus consists of the following parts: clubs, mycelium threads, and numerous small bodies like micrococci. Clubs may be absent, but the other two forms are always present. The threads are the spore form; the clubs are the mature germs. As Butterfield points out, too much importance has been attached to the presence of clubs. These are extremely variable in appearance, and their absence must not be considered as excluding the possibility of actinomycosis. Branched forms even are not always present, as, in old abscesses, the parasite may have undergone complete segmentation, and thus would be difficult of differentiation from bacilli. Careful search, however, will probably reveal short branches and a few long filaments.

Schabad considers as a subgroup the forms that do not show clubbed ends, and calls them "actinomyces atypica." These are acid-fast, and do not appear as "sulphur-like granules" in the pus.

In view of the fact that the ray fungus resembles the tubercle bacillus in certain particulars, especially in that the lesions caused by the two organisms have definite features in common, the view held by Metchnikoff and revived by Wright is significant. In 1888 Metchnikoff called attention to the variations in the morphology of the tubercle bacillus, which, he believed, was not the final stage, but represented a condition in the developing cycle of a thread-like bacterium, and he pointed out that there is a progressive series of organisms from the harmless butter bacillus, through the turtle and fish bacilli, to the bovine and human bacilli. Actinomyces is essentially aerobic, and it has been shown recently that the tubercle bacillus growing on a favorable medium shows more frequently the branched forms when the access of oxygen has been free.

The ray fungus is said to occur on certain grains and grasses, particularly on rye. It does not appear to have been observed growing on plants externally, but if infected grain is planted, the fungus develops with the growth of the plant, so that the latter is infected throughout.

In addition to its occurrence in certain plants and in man, actinomycosis has been found in cattle, horses, pigs, sheep, and the elephant, but no example has been reported in the carnivora, except

one possible case in which a pet dog died from a large swelling of the lower jaw; and subsequently, the owner of the dog, a woman, developed actinomycosis of the lower jaw. While the relation between the two in this instance may be suspected, it was not definitely established.

Mode of Entrance.—In cattle the disease affects the jaws or tongue in a large majority of instances, and in man the primary seat of the disease is in or about the mouth in over 50 per cent. of the cases. It is probable that infection takes place through the mouth in many additional cases in which the portal of entry cannot be established. It may be concluded, therefore, that the organism usually gains access to the body with the food or other articles taken into the mouth. In man, infection probably takes place, frequently, from chewing grain or pieces of straw or grass. It is stated that 75 per cent. of the cases occur in those who have to do with these articles, *e.g.* farm laborers, grooms, etc.

As to other modes of infection, Müller reports the case of a woman who developed a swelling of the hand at the site where a splinter had penetrated two years before. The swelling proved to be a focus of actinomycosis, and in the center of the mass a minute fragment of wood was found. In another case the disease appeared at the site of a blow from a stick of wood. Von Partsch records a case in which the disease developed in the scar left by a surgical operation; and Kopfstein observed a case in which the disease appeared at the site of a cut on the hand of a woman who had been binding corn before the wound healed. Many cases have occurred at harvest time after threshing, as Illich has shown. Israel, however, disputes the view of infection through the skin, and thinks that in most cases infection takes place through the alimentary canal, as happened, for example, in a case of Soltmann's, in which an infected head of barley stuck in the esophagus of a child and caused infection of the lungs secondarily.

As regards the modes of infection of the lung, Hichens believes the fungus may be conveyed by the blood stream, be air borne, or be spread directly from neighboring viscera. In the miliary variety of the disease the mode of infection is, of course, hemic. In the pleuropulmonary variety the invasion may be by direct extension from neighboring viscera, as in a case in which the disease apparently started in the liver and spread through the diaphragm to the base of the right lung.

Etiology.—In reporting three cases in one family, Knox emphasizes the fact that all three patients had been in the habit of spending a good many weeks in the country—a farm in Perthshire had been visited for several years in succession. During their last visit the farmer was seriously ill with a slow form of "consumption" from which he ultimately died. Cattle in the district had died from anthrax or some similar malady. The first patient developed serious symptoms at the farm; she had an attack of pleurisy, with high temperature, though it must be noted that her early symptoms were observed in London, and she was sent to Scotland to recruit and, if possible, to avert a breakdown in health. She had visited the farm the year before and appeared to be in her usual health. The two boys had adenoids for years, and it is quite likely that the girl may have had them also earlier in life. The girl had glandular trouble, with abscesses, early in life; the second boy also had some glandular trouble; and the older boy had a definite glandular abscess. All had suffered from colds in the head and congested throats at different periods.

Wagner speaks of a case occurring in a farmer who was in the habit of chewing corn as he walked through the fields. McArthur relates a most interesting case in a young woman who frequently played golf, and while playing plucked and chewed hay. An obstinate abscess of the alveolar process first developed, and healed only after three or four months' treatment. Nine or ten months later a tumor developed in the right iliac fossa. At operation, the cecum, being infiltrated, was resected. The disease was found to be actinomycosis. The patient recovered and was well for a period of three months. Then cough, fever, chills, and sweats appeared. These were at first thought to be due to pulmonary tuberculosis, but abscesses of the chest-wall developed later and in the contents of these actinomycetes were found. The patient died.

Ingal's case occurred in a man of 22 years, who worked on a farm in Italy, and on the railroad in America, during which time he slept on a straw bed on a construction train. Hichen's case occurred in a farmer, aged 32 years. In Reignier's case, it is stated that the only possible source of infection was the straws used in drinking iced beverages. A number of cases are reported in which it is stated that the teeth were bad. Wright says: "Many cases seem connected directly with carious teeth." Some patients were the subjects of "winter cough."

Localization.—Almost every part of the body has been affected—mouth, cheeks, abdominal viscera, appendix, lungs, pleura, and brain. The disease may be disseminated by the blood-stream, and cases of generalized actinomycosis have been reported in both cattle and man. The *Centralblatt für Bakteriologie* contains reports of 117 cases from 1887 to 1904, in which the lesions were distributed as follows: Neck, jaws, mouth, pharynx, in 72; primary in abdomen or viscera, in 18; thoracic wall, lung, pleura, in 21; brain, in 3; skin, in 3.

In 1905 Hichens collected 79 cases, reported in the British Isles, and he found the disease distributed as follows: Head and neck, 27, or 34.17 per cent. (face and neck, 24; tongue, 2; brain and orbit, 1); thorax and lungs, 12, or 15.18 per cent.; abdomen, 39, or 49.3 per cent. (liver, 20; intestinal tract, peritoneum, and abdonimal wall, 16; bladder and prostate, 2; generative organs, 1); site not stated, 1. Ruhräh in 1899 collected all the cases at that time reported throughout the world, and presented the following table: Total, probably counting several twice, 1,094; head and neck, 604 (56 per cent.); digestive tract, 233 (20 per cent.); pulmonary, 164 (15 per cent.); skin, 26 (20 per cent.); doubtful, 63 (6 per cent.).

Infectiousness.—It is not believed that the disease is communicated from one person to another, or from animals to man, as a rule; but in a discussion before the Chicago Surgical Society, Dr. Carl Wagner related that one of the pupils of Professor Sacchi, Surgeon-in-Chief of the Doges' Hospital, Genoa, Italy, having opened an actinomycotic abscess, touched his nose before he had disinfected his hands. His nose became infected, and he succumbed in a short time to fulminant actinomycosis.

The pus in actinomycoctic abscesses is usually of limited quantity and has some of the characters mentioned as present in the sputum in pulmonary cases. In Knox's case it is described as "thick, tenacious, yellowish-green in color, and very offensive in odor."

Pathology.—The presence of the ray-fungus in the tissues causes proliferation of round cells about the focus, resulting in a nodule. The central cells undergo granular or fatty degeneration, and more or less liquefaction results, while the cells toward the periphery of the nodule partially organize. The process is similar to that observed in tuberculous and tertiary syphilitic lesions, except that in actinomycosis the tendency to the formation of extensive granulation-tissue masses is greater. If the virulence of the infection is extreme, and especially if pyogenic infection is superadded, there will be more liquefaction and pus-formation, and less partly organized tissue. On the other hand, an uncomplicated infection of feeble virulence in tissues having a high degree of resistance will be followed by but little destruction, while a comparatively large amount of granulomatous tissue will result, which may form tumors of considerable size. Thus two types may be recognized—the inflammatory and the neoplastic. The former is most commonly observed in man, the latter in cattle. The neoplastic type is much more amenable to treatment. Actinomycosis spreads by direct continuity irrespective of anatomical structure (and by the blood).

The prominent pathological characteristics of the affection are briefly: 1. A tendency to great cell-proliferation, with little suppuration. 2. A disposition to spread toward the surface and to gain entrance into the blood-current. 3. The presence of yellow granules (Bell).

Bell and others have found the ray fungus on microscopic examination in cases in which no granules were present; and Bevan records a case in which the pus contained small bodies similar to those observed in actinomycosis, although on microscopic study the tumor was found to be epithelioma, and the supposed granules were found to be "pearly bodies."

Treatment.—The therapeutic problem may be stated as follows: A local infection due to the ray fungus is to be combatted. The germ causes a localized granuloma somewhat similar to that due to inoculation with the virus of tuberculosis or syphilis, and like these the affection tends to spread locally as well as to involve distant parts. Under such circumstances the proper course to pursue is clear.

Complete removal of the infected area by the knife or curette would be ideal. Unfortunately, this is impossible in most cases, as important or vital structures would have to be sacrificed. Whenever feasible, however, this radical procedure should be adopted. In all other cases in which the lesions are accessible to surgical attack, the infected area should be freely incised, diseased tissue removed by the curette as far as possible, and free drainage secured.

In 1885, Thomassen reported that potassium iodide had a curative influence on actinomycosis. This observation appears to have been confirmed by the experience of many surgeons. Unquestionably, however, it has entirely failed to exert the slightest effect in a number of cases, so that it cannot, in any sense, be looked upon as a specific. Bell's statement appears to be correct. He says: "The value of the iodide varies. In some cases it seemed to give marvelous results; in others it appeared to have no effect."

Bevan believes that the most effective treatment when the lesion is not accessible to surgical measures is a combination of potassium iodide internally, and the *x*-ray locally. The explanation is offered that the *x*-ray sets free nascent iodine in greater amount than would otherwise occur. Ochsner calls attention to the necessity of administering large doses of potassium iodide, and speaks of giving as much as a dram three times a day before improvement began. He also points to the fact that veterinarians interrupt the administration of the iodide for about a week in order to give the spores an opportunity to develop, as they seem to resist the treatment. He cites an instance in which he ordered 90 grains three times a day for four days, then intermitted for three weeks; then repeated the dose. An obstinate case of actinomycosis of the face was thus cured after 30 grains had been given three times a day for a month without any effect. Ochsner believes that so long as abscesses are not present, patients invariably recover. Baracz states that he brought about recovery in nine consecutive cases by injecting 20 per cent. solution of silver nitrate into the tissues around the lesion. The injections cause the formation of a connective tissue wall around the disease, which is thus circumscribed and held in check, and he believes the silver kills the germs.

Pulmonary Actinomycosis.—In many of the reported cases the infection appears to have taken place through the mouth. The majority of patients suffered from adenoids, decayed teeth, pyorrhea alveolaris, catarrhal lesions, etc. It is quite probable that these conditions favor the lodgment and development of the germ, whereas a healthy mucous membrane might resist its invasion, and the disease thus be averted.

Hichens divides pulmonary actinomycosis into four varieties: (1) Bronchitic, (2) bronchopulmonary, (3) pleuropulmonary; (4) miliary or hemic. Karowski recognizes but two forms: (*a*) Catarrhal, in which the germ becomes established on the surface of the bronchial mucous membrane, resulting in a chronic catarrh of the bronchi, with actinomyces in the sputum; and (*b*) destructive, which passes through three stages: (1) The germs penetrate the deeper layers of the bronchial walls, producing a destructive peribronchitis. The symptoms of this stage are indefinite; the condition may be mistaken for a beginning tuberculosis, but the absence of tubercle bacilli and the presence of actinomyces in the sputum will establish the diagnosis. In addition, the lesion is likely to be below the clavicle, whereas in tuberculosis it is usually apical. (2) The fungus has reached the pleura, causing a hemorrhagic exudation, which is attended with the usual physical signs of fluid in the pleural cavity. If not relieved by operation, the accumulation may discharge spontaneously, either through the skin or the diaphragm. (3) Metastatic deposits form in different parts of the body. In this stage the patient presents symptoms of general septicemia, and rapidly succumbs to the increasing toxemia.

There appear to be no typical symptoms. In many cases there is a history of a period of depressed vitality during which the patient was lethargic and easily fatigued. Anemia and emaciation sometimes follow. The temperature remains normal or is but slightly elevated in most cases, but mild febrile attacks occur in some instances. The pulse is persistently increased in frequency, but less so than in tuberculosis. The febrile attacks were sometimes followed by the development of "congested throat"; and later by bronchial catarrh and expectoration. In some cases the sputum has had no offensive or characteristic odor. The discovery

of the mycelium in the sputum is essential in making a diagnosis.

In many cases the sputum seems to have been somewhat characteristic. In Wynn's case it "was abundant and had a feculent odor." In Hichen's case "it was thick, tenacious, not nummulated, and of a peculiar color, resembling pale anchovy sauce. On being spread on a plate or glass, minute whitish-yellow bodies, about as large as half a pin's head, were observed." Bevan has observed that it "has a distinctive odor, suggesting that of freshly turned earth." As reported in Henry's case, it was "abundant, very thick, viscous, extremely offensive, yellowish-green in color, and contained numerous yellowish granules of about the size of a pin's head." A specimen was sent to Dr. J. F. Hodgson, who reported: "The sputum is characteristic of actinomycosis of the lungs. The granules contain the fungus of actinomycosis. Filamentous forms are present, club-shaped bodies being absent. The filaments stain well with Gram's method. Numerous pus cells and pyogenic cocci are present."

There are no pathognomonic symptoms upon which a diagnosis may be made. In the catarrhal form the symptoms will be those of bronchitis, such as might occur in the early stages of tuberculosis. A careful examination of the expectoration should clear up the case. The same comment applies to the pulmonary and pleural forms. The presence of the ray fungus in the lesion must be demonstrated to justify a diagnosis of actinomycosis.

Actinomycosis often evinces itself as a chronic empyema. A diagnostic point in favor of actinomycosis is that when one opens what appears to be an empyæma necessitatis, expecting to find a large cavity and quantities of pus, one finds no proper cavity at all, and only a small quantity of pus that oozes from a spongy tissue.

As regards the situation of the lesion, it is much more often basal than apical. Israel went so far as to say that it always began at the base, but Hichens shows that this is not the case. Illich found that among fifty-eight cases of pulmonary actinomycosis, the disease had begun in the upper lobe in nine instances. It must also be remembered that pulmonary tuberculosis may begin at the base. Nevertheless, a basal situation is a distinct point in favor of actinomycosis. Excavation and hemoptysis are rare in pulmonary actinomycosis.

Pain, even of a severe character, is common in actinomycosis when the disease has spread to the pleura and neighboring tissues. Pleuritic pains are, of course, not uncommon in tuberculosis, but in the latter they do not exhibit the same persistency and severity.

The temperature in actinomycosis is more irregular and generally less elevated, and does not exhibit in so marked a degree the hectic type so common in tuberculosis.

The tuberculin reaction has been observed by Illich and Friedrich in cases of actinomycosis as well as in those of tuberculosis. As a minor point, it may be observed that the lymph nodes are but rarely involved in actinomycosis. Furthermore, it must be remembered that pulmonary actinomycosis and pulmonary tuberculosis may coexist in the same patient. Two such cases have been recorded by Littledale and Eichhorst (Hichens).

Adami suggests that when actinomycosis is suspected, some of the discharge from the affected tissue should be collected and cleared by weak caustic potash, and smears made from the deposit. In this way it is possible to find the scattered threads.

Pulmonary actinomycosis is usually fatal. Illich was inclined to believe that death occurred in every case. Naussac places the mortality of the pleuropulmonary form at 75 per cent., and of the bronchopulmonary form at 72 per cent. As Bevan has shown, it is not safe to consider a patient cured because the lesion appears to have healed, as relapses are not uncommon after apparent recovery. Karowski states that cases of pulmonary actinomycosis in which operation has been performed successfully are extremely rare, but they would certainly be more frequent if an early diagnosis were possible.

Wynn found the average duration of the disease about ten months. In a few cases cure has been reported, but such a result cannot be expected with any confidence, as the affection appears to be only a little less fatal than streptothricosis of the brain or liver, from which, according to Acland, no case of recovery has been recorded. The case reported by Wynn is especially interesting, as it adds one more to the number of infections that apparently have been successfully treated with a specific vaccine prepared from the infecting organism.

In the pulmonary cases, the lesion is, as a rule, not accessible to surgical intervention until the later stages, when the disease has spread widely in all directions, or has even been carried to distant parts. Therefore, if actinomycosis of the lung is detected early, as it usually can be by careful microscopic examination of the expectoration, the administration of potassium iodide, in addition to appropriate hygienic measures, would appear to be indicated. By the time the pleural deposits have occurred, and abscesses of the chest wall have appeared, the disease has reached an incurable stage.

Knox reports the case of a boy 15 years of age, in whom the mycelium was found in the sputum, and who gained 28 pounds in weight from December 6th to the following April, after the removal of adenoids, and the continued internal administration of potassium iodide. There was a corresponding improvement in the general condition and in spirits. A second case in the same family seemed equally benefited by a similar course of treatment.

Oil of eucalyptus has been employed by some surgeons, and Ruhräh cites a case reported by Butler, in which cure appeared to be effected by eucalyptus oil in spray and in capsules. This treatment has been employed also in conjunction with the internal use of potassium iodide.

As v. Baracz' method of administration of silver nitrate by hypodermic injection is inapplicable to cases involving the lung, he recommends intravenous injections of colloidal silver as advised by Credé in the pulmonary form of the disease.

The most striking recent contribution on the treatment of pulmonary actinomycosis is the report by Wynn of a case involving the lung and the liver, successfully treated by a vaccine prepared as follows: Agar cultures of actinomyces less than forty-eight hours old were taken, the growth scraped off, sterilized, and dried for one hour at 60° C. It was then ground in an agate mortar with normal saline solution containing 10 per cent. of glycerin. The vaccine was standardized by weight, 1 c.c. of the emulsion containing 1 mg. of "actinomycotin." This was diluted a thousand times, and the dose was 0.001 mg. of the solid substance.

The case thus treated was that of a boy, aged 14 years, admitted to the General Hospital, Birmingham, under the care of Professor Saundby, on account of troublesome cough, abundant, offensive expectoration, and pain and swelling of the left side of the chest. The lower half of the left chest, anteriorly and laterally, below the fourth interspace, was absolutely dull on percussion. Breath sounds and vocal resonance and fremitus were absent over this area. Posteriorly, resonance was impaired and moist râles were heard. Just below and outside the left nipple there was a rounded swelling, the most prominent part corresponding with the sixth interspace. The swelling was red, tender, and fluctuating. A diagnosis of empyema pointing through the chest wall was made.

Under chloroform anesthesia, the swelling was incised and about eight ounces of most offensive pus obtained. An inch of the seventh rib was removed. There was thus opened a ragged cavity extending upward toward the axilla, and apparently in the lung. The pus contained large numbers of small granules, which proved to be actinomyces. No other germs were present in the pus. The sputum contained the actinomyces, in addition to cocci and bacilli, but no tubercle bacilli were present. After the operation, on December 19, considerable discharge of pus took place through the drainage tube. This gradually lost its fetid odor. The sputum remained abundant, frothy, and offensive. Coarse râles were heard all over both lungs. The temperature for the first week was irregular, with evening rises to 99° and 99.5°; the pulse rate was between 100 and 120, and the respiration, which was between 32 and 36 on December 20, fell to between 20 and 24 by the end of the week. On December 28 the patient was transferred to the Jaffray Suburban Hospital.

The temperature from December 28 to January 8, the date of the first inoculation, was pyrexial, showing evening rises to 100°, and once to 102.3°. With the rise in temperature the rate of respiration increased to between 28 and 34, the pulse remaining between 100 and 120. The patient now looked and felt extremely ill, the cough was troublesome, and there was an abundant discharge from the drainage tube; the sputum was also considerable in amount. The day following his removal to the Jaffray Hospital he complained of pain in the region of the liver, and this organ was found to extend downward to within 1 inch of the umbilicus, and to be tender on pressure; the spleen also could be felt. It seemed probable that the operation had resulted in autoinoculation, with extension of the infection to the liver. The organisms in the pus and sputum were still active, and grew readily on culture media.

On January 3 the opsonic index was estimated at 0.3, and on January 7 at 0.5. On January 8 the first inoculation of 0.001 mg. of "actinomycotin" was given. Twenty-four hours later the negative phase was apparently over, as the index had risen to 0.7, and by January 16 it was 1.2. The patient had a good night after the inoculation, and in a few days the cough became less troublesome, and the sputum and discharge of pus diminished in a remarkable degree. The temperature dropped to normal the day following the inoculation, and remained normal for three days. On January 12 the discharge had so diminished that the drainage tube was removed; a slight irregularity of temperature occurred for a day or two.

On January 18 a second inoculation of 0.001 mg. was given, and on January 21 the temperature fell to normal, and afterward remained so. The respiration had decreased to between 22 and 24, and the pulse rate to between 96 and 108. The patient was allowed to get up for a short time on January 19. Inoculations of 0.001 mg. were given on February 11 and 25 and March 11 and 27—six inoculations altogether being given.

The opsonic index was estimated at intervals, the highest point reached being 1.7. A negative phase was never observed to last more than twenty-four hours, and the positive phase reached its maximum between the eighth and tenth days. Generally the temperature taken a few hours after an inoculation showed a slight fall, but on one occasion there was a rise to 99.2°.

Wynn was not disposed to attach too much importance to the actual figures given for the opsonic index, as the difficulties in the way of making a satisfactory emulsion were great; but the difference between the films, made from preparations with his own serum, and those made from preparations with the patient's serum, was marked before inoculation was begun. Afterward there was no doubt that the patient's serum had a much higher opsonic power than Wynn's, and with practice the difficulties of technique were largely overcome and a fairly accurate count made. The improvement in the patient's condition after inoculation was most marked. There was no sputum a week after the first inoculation, the cough had disappeared by January 22nd, and the sinus closed rapidly, the discharge by the first week in February being exceedingly little. Attempts were made on several occasions to grow the organism from the pus, but these were unsuccessful after the second inoculation. There was a steady increase in weight from 4 st. 8 lbs. (64 lbs.) on December 29, to 5 st. 8 lbs. (78 lbs.) on February 4, and on leaving the hospital on March 27 the weight was 6 st. (84 lbs.), gain of 1 st. 6 lbs. (20 lbs.) in three months. The moist sounds in the lungs had disappeared and examination on the day before leaving the hospital showed some flattening of the left side of the chest in the lower axillary region, slight dullness on percussion, and a large area below the angle of the left scapula over which cavernous breathing was heard. This cavity was quite dry and no moist sounds were heard over it or elsewhere. The liver had slowly decreased in size until it could not be felt below the ribs. It was evident that the condition had left behind thickened pleura with a large cavity in the lung. There was no sputum, and only occasionally a dry cough. On April 26, 1907, the patient was shown to the members of the Pathological and Clinical Section of the Birmingham Branch of the British Medical Association. He then had not received an inoculation for a month and looked well and robust. No other treatment besides that described was given, except from January 11 to 18, when 10 grains of potassium iodide were administered three times a day.

The patient was seen subsequently at intervals of about a month as an out-patient. He continued well and was free from pain or cough, except for a slight attack of bronchitis during the first fortnight in December, 1907. He was seen for the last time on February 20, 1908. There was then more flattening of the chest at the left base; the cavity was smaller and no moist sounds could be heard; occasionally he had a dry cough, but there was no sputum and the breath was not offensive.

The liver and spleen could not be felt. His weight was then 6 st. 3 lbs. (87 lbs.). No inoculations of "actinomycotin" had been given since March 27, 1907.

It will be important in the future to determine whether a vaccine prepared from one of the easily grown species, or from a stock of laboratory culture, will have any effect upon an infection caused by another species of streptothrix. In this connection it is worth while recalling that temporary benefit was found in Ziegler's case of severe actinomycosis of the head and neck after injections of "bacterial protein" obtained from staphylococcus aureus, and in Billroth's case after tuberculin injections.

As this is the only case treated by this method, so far as reported, it is cited in some detail. Being a single observation, further confirmation is needed before a definite opinion can be given. It is to be hoped that additional proof will be speedily forthcoming.

Case.—J. R., male, 36 years of age, married, a worker in furs for 23 years, applied to the Polyclinic Hospital on July 28, 1906, in the service of Dr. Eshner, complaining of pain in the left side of the chest intermittently for five months, but worse and persistent in the preceding five weeks. There was also pain in the left shoulder. Breathing was painful and difficult and there was dyspnea on exertion. The breath was fetid and the tongue heavily coated. There was no cough or expectoration. The appetite was lost and the bowels were constipated. Sleep was poor. The man was weak, although there had been little or no loss of weight. He was 5 ft. 3 in. in height and weighed 123 lbs. There was no headache, no edema, no derangement of micturition. The urine was free from albumin and sugar.

The patient was born in Russia, but had lived in the United States for 16 years. He related that his parents, as well as a brother, were living and well. Another brother had died insane and a sister had died in confinement. There was no family history of tuberculosis, malignant disease, heart disease, or kidney disease.

The man had had measles, mumps, and chickenpox in early life, but he denied venereal disease, and he had no knowledge of a previous attack of pleurisy or pneumonia. He did not drink tea or coffee, but was in the habit of taking a small glass of whiskey before breakfast; he smoked but little. He had been married for 16 years. Five children were living and well; twin children had died, one from measles and the other from diphtheria. His wife had had no miscarriages.

On physical examination the action of the heart was found to be rhythmic and the sounds were clear. The percussion note was impaired at the base of the left chest, the breath sounds were feeble, and vocal resonance was diminished. It was at first thought that this condition was the remains of a previous pleurisy. The distress in the left side of the chest persisted, and in a short time tenderness developed in the splenic region and was increased by the ingestion of food. Later, tenderness became localized over the seventh and eighth ribs on the left side of the chest in front. The man was steadily losing weight and became lachrymose and easily agitated. By September 18 he had become reduced to 117 lbs. Movable dulness was detected at the base of the left chest, in addition to other signs of the presence of fluid in the pleural cavity. The possibility of malignant disease of the pleura now presented itself, and the patient was admitted to the Polyclinic Hospital, where, on September 20, the chest was aspirated and 27 ounces of turbid, straw-colored fluid were removed. The area of abnormal dullness on percussion diminished, and the breath sounds became audible in the affected area. A trace of albumin and a few granular casts were now found in the urine.

A second aspiration was performed on October 4 and 13½ ounces of thick, stringy, turbid, reddish fluid were removed. This was found to be slightly alkaline, loaded with albumin, free from sugar, containing a few mononuclear leucocytes and pneumococci, but no tubercle bacilli.

The symptoms grew progressively more aggravated, and sweating set in, while the physical signs underwent little change. On December 15, 6 or 8 ounces of fluid were removed from the chest by aspiration, with little or no relief. Chills occurred and the finger nails became curved.

Dr. J. H. Musser saw the patient in consultation on January 11, 1907, and advised resection of a rib or aspiration. Accordingly, the patient was again admitted to the Polyclinic Hospital. Aspiration was attempted, but no fluid was obtained.

On January 29 Dr. L. W. Steinbach resected about 1¼ inches of the seventh rib in the midclavicular line. When the pleura was incised a small amount of pus, perhaps 3 ounces, having an offensive odor, escaped. Exploration with the finger disclosed pleural adhesions, but the source of the pus could not be discovered. A culture was taken, but no report of the result was made. The patient improved somewhat and was discharged from the hospital on February 12.

Subsequently the man grew worse again, and he was admitted to the Hospital of the University of Pennsylvania, February 22, in the service of Professor J. William White. The following notes were taken by Dr. E. L. Eliason, resident surgeon:

"The man complains of pain in the lower part of the chest on the left side, shortness of breath, fever, and loss of weight and strength. Temperature, 99.1°; pulse, 108; respiration, 28. He is emaciated, pale, phthisical-looking, emotional, and nervous. Pulse full and strong; breath offensive; tongue coated; teeth poor; eyes bright and restless; skin dry, pale, and pearly.

"Inspection of the chest shows a marked decrease in the respiratory excursion on the left side, especially below the fourth rib in the anterior axillary line. The interspaces are bulging below this level and there is slight edema of the surface.

"Percussion elicits a flat note over the entire left side of the chest below the lower border of the second rib in front; the fourth rib in the anterior axillary line; the seventh rib in the posterior axillary line, and just below the spine of the scapula posteriorly. The dull area is stationary on change of posture. No egophony or cracked-pot sound can be elicited. On palpation, tactile fremitus over the entire surface is greatly diminished. Whispering pectoriloquy is present posteriorly at the fifth rib. Auscultation reveals absent or distant breath sounds and vocal fremitus over the dull area. Resistance is also markedly increased to the percussing finger. Above this area the percussion note is apparently normal, but many moist râles are heard.

"The right lung at the apex shows impaired resonance, bronchovesicular breathing, increased vocal and tactile fremitus and moist râles. Posteriorly at the base near the spine, Grocco's sign of a triangular dull area seems to be present.

"The heart dullness is pushed up and merges into the other dull or flat area. The heart sounds are clear, but somewhat distant; the apex beat is not palpable. No friction sounds or murmurs are heard. Rotch's sign and Ewart's second rib sign are absent.

"There is a wound of the left chest about the sixth rib in the midclavicular line, the result of a recent operation. There is marked pain in the posterior axillary line at the base of the chest. The patient has a troublesome, paroxysmal cough. There is tenderness over the dull area anteriorly from the scar down to the costal border. The abdomen is apparently normal. The leucocytes number 12,640 in the cu. mm. The urine has a sp. gr. of 1,024, is acid in reaction, and contains no albumin, no sugar, and no casts, but some mucus."

It was supposed that the man's condition would be improved by better drainage; hence the wound in the chest was enlarged and thoroughly explored on the 26th, but no pus was found. The aspirating needle was introduced at five or six different points but without finding any pus.

The opinions of those who examined the patient were divided. The evidence pointed to the presence of empyema or of greatly thickened pleura. On March 2 the leucocyte count was 13,520. The wound was still discharging slightly.

On the 13th, further exploration seemed indicated and a portion of the seventh rib was removed. Careful digital examination was made, but no pus was found. No cavity existed, but the finger could be passed in all directions through a soft, friable tissue that bled freely. The condition suggested a soft round-cell sarcoma or a proliferative pleurisy. The section of rib removed appeared to be diseased.* After this exploration the upper wound discharged pus more freely.

On April 1 increased swelling and edema were noted in the midclavicular line about the eighth rib. This was incised and a small amount of pus escaped.

On the 11th a fullness had appeared in the posterior axillary line between the seventh and tenth ribs. There was no redness or heat in the skin. Beneath this area breath sounds, as well as the vocal and tactile fremitus, were diminished. The three wounds already made were discharging pus, but the physical signs did not improve.

Over the right chest, at the ninth rib posteriorly, and in the postaxillary line, there was a swelling that appeared as though something were pushing the entire chest-wall out. There was dullness over this area and increased tactile and vocal fremitus and distant breath sounds were noted. The liver dullness was pushed down in front to the seventh rib, in the midclavicular line.

On May 1 the granules characteristic of the ray fungus were observed in the pus. Microscopic examination confirmed the presence of this organism.

The patient showed increasing emaciation; respiration was shallow and painful. The upper wound in the anterior axillary line was discharging a large amount of pus and the lower one rather less, but still a large amount. Considerable bleeding from the wounds followed the withdrawal of the packing; there was great tenderness and swelling of the sterum at the level of the second rib. An opening was made in this situation on May 5 and a great deal of thick, gelatinous pus, full of sulphur-like bodies, escaped. No organism was present except the ray fungus (Dr. Gildersleeve). The discharge from all the wounds contained the sulphur bodies in large numbers.

Potassium iodide was now ordered in heavy doses and iodine was used locally in the abscesses.

On the 15th it is noted that the area over the last three ribs extending to the spine on the left side posteriorly, which had been painful and tender for a month, showed fluctuation. On incision, a large quantity of fetid pus, of a brownish color, was discharged. Sulphur bodies were present in great numbers. The cough, which had been persistent, was now accompanied by bloody expectoration.

On the 20th another sinus opened spontaneously at the junction of the sixth costal cartilage with the sternum.

On the 22d it is noted that the sulphur bodies from all the wounds were less numerous. The cough had increased; the suptum was purulent, but did not contain blood; the swelling of the ribs on the right side had disappeared. The patient appeared to be improved for a few days, but became weaker again.

On the 25th the iodide was stopped, as it was not well tolerated by the stomach, and subsequently soluble iodin was administered in sherry wine. It was well borne in doses of twenty minims three times daily. By June 12 the sulphur bodies were seldom observed in the pus from any of the wounds. The leucocytes numbered 13,800 in the cu. mm.

The patient grew progressively worse; weakness was extreme: chills occurred irregularly, followed by profuse sweats; the liver showed marked enlargement downward, extending three fingers' breadth below the ribs in the nipple line, and jaundice became marked. Death occurred June 20.

The foregoing case is a typical example of the pleuropulmonary form of actinomycosis. The points of especial interest are: The slow and insidious onset, signs of pleural effusion with an unusual history and course, peculiar character of the aspirated fluid, especially that obtained at the second aspiration, increasing symptoms in spite of the withdrawal of the fluid, the small amount of pus obtained on resection of a rib in the presence of pronounced dullness and the failure of all further explorations to discover any collection, the presence within the chest of soft tissue through which the finger passed readily, the multiple lesions, appearing one after another, the characteristic discharge containing the so-called sulphur granules, the slight degree of fever, progressive loss of strength—and death.

*Dr. George P. Müller kindly examined the portion of rib removed and reported as follows: Specimen, section of rib. Pathological diagnosis, osteomyelitis. Description of specimen: The specimen is a section of bone, apparently of rib. Upon one side an osteophyte, osteoma, or callous formation has taken place. Microscopic section shows an acute inflammatory process within the bone. The Haversian canals are dilated and many of them are filled with an inflammatory exudation consisting of polymorphonuclear leucocytes and blood. The blood-vessels are universally dilated.

ACTINOMYCOSIS OF THE CHEEK FOLLOWING INJURY BY A DENTAL INSTRUMENT; RECOVERY.

By ALFRED STENGEL, M.D.,

PHILADELPHIA, PA.

Miss L. O., aged 15 years, who had been in good health, consulted her dentist on November 1, 1900. While filling one of the upper molar teeth on the right side, the dentist accidentally let the instrument slip and it penetrated the cheek, causing a slight injury from which there was a little bleeding, not sufficient, however, to prevent the filling of the tooth. A week later the patient felt a slight elevation and hardness at the spot of injury on the inside of the cheek and consulted me. My first impression was that it was a swelling of the papilla at the mouth of Steno's duct, such as occasionally occurs in some persons. The induration, however, remained and seemed to be increasing in size during the next three weeks. On December 3 the patient's mother discovered a slight purplish spot on the outside of the cheek opposite the growth within and on examination I found that the whole thickness of the cheek was occupied by a resilient mass that seemed attached to the skin on the outside and the mucous membrane within. Dr. J. William White, who was consulted, advised incision on the inner side, and we then discussed the possibility of actinomycosis on account of the appearances of the growth on the outer side. At the operation, the mass was found to be of uniform, pinkish color with no sign of softening or breaking down within. Portions of the tissue were sectioned and were found to be made up of round cells which suggested an inflammatory process or sarcoma. No actinomyces were discovered. Though drainage with gauze was maintained on the inside, the growth extended outwardly and soon an abscess-like projection formed beneath the skin at the side of the purplish area of discoloration. The danger of extensive involvement of the skin now led to a second operation, which was an incision at the place where the growth pointed externally. A small amount of broken-down yellowish material was obtained and portions of the growth were removed. In the latter, after a number of sections were studied, actinomyces bodies were detected. The patient had in the meantime been given increasing doses of potassium iodide on account of our suspicions of actinomycosis after the first appearance of the purplish discoloration and external projection. Another abscess-like formation developed on January 15 and was opened on January 18. Increasing doses of potassium idodide, up to sixty grains daily, were given without materially influencing the progress of the growth. So far as could be seen the process was advancing in spite of the free openings inside and out. At this time, on the suggestion of Dr. A. C. Wood, a change of the local treatment was made, diluted tincture of iodine being used in each of the incisions or sinuses. Almost immediately there was a manifest improvement in the condition and within a fortnight the whole area of infiltration had resolved. Subsequently the external and internal incisions healed and complete recovery followed. The patient never suffered any recurrence and is now (1910) in good health.

The case is of some interest on account of the suggested etiological bearing of injury and also because the local effect of iodine seemed to play an important part in the cure. Whether or not some factor additional to the local injury was concerned in the etiology was not determined.

DIABETES MELLITUS—A SYMPATHETIC NEUROSIS RATIONALLY TREATED WITH ELECTRICITY.*

By J. MONROE LIEBERMANN, M.D.,

NEW YORK.

Diabetes mellitus, an affection in which the predominating symptom is an excessive flow of saccharine urine, is *per se* only a symptom of perverted function of one or a group of organs of the "digestive" tract.

The voluminous literature on diabetes mellitus with its amount of theoretical deductions based upon physiological experiments, as well as clinical observations, throws little light on its etiology, pathology, or real character. The still obscure etiology and pathology of diabetes mellitus suggests but little definite statement relative to either and the object of this paper is to indicate in a general way its nervous origin and its rational treatment with electrotherapy.

Notwithstanding the fact that this disease has been known for centuries (Hirsch claims that the Hindoos recognized this disease several centuries ago as "the disease of sweet urine"; and in a Cingalese treatise of the fifteenth century it is called "Madu Mehe" or "Honey Urine") our therapeutic knowledge of diabetes mellitus has not advanced very far, and our diabetic cases are treated to-day in the same manner that they were treated years ago. That is: elimination of carbohydrates from the diet, with opiates, strychnine, and atropine which produce temporary elimination of glycosuria but do not prevent its reappearance with the cessation of diet and drugs.

It is the purpose of this paper to describe a treatment in the light of clinical experience extending through twenty years. This treatment has been followed for the last five or six years with fairly good results in a large number of cases.

Assuming that diabetes mellitus has its beginnings in a disturbance of nerve energy supply to the "digestive system" and a consequent perversion of function of the digestive glands, it is but logical that the treatmtent should be directed primarily to the nervous system.

Men like Pavy, Eckhard, Schiff, Arthaud, and Butte, Klebs, Hansen, Mering, and Minkowski, Lepine, Rosenbach, Foster, Burton, and Thierfel-

*Read at the meeting of the Tri-State Medical Association at Richmond, Va., on February 15, 16, and 17 1910.

der, contributed largely to the physiological experiments on diabetes mellitus. And a multitude of other physiological experiments, such as tying the accessory branch of the portal vein, so as to make the whole of the abdominal blood pass through the liver; compression of the aorta or portal vein; irritation of the liver with a needle or electrode, and also a number of drugs, as strychnine, salicylic acid, phosphoric acid, turpentine, and corrosive sublimate, all prove, that, no matter by what physiological process glycosuria is produced, whether by injury to or irritation of the nervous system, hyperemia of the surrounding vessels of the liver must be induced.

The hypothesis of glycosuria at the present time is based upon vasomotor paralysis of the splanchnic area, the nerves of which, in health, keep the blood-vessels of the liver in a state of tonic contraction; and when injured, these vessels dilate and permit a greater afflux of arterial blood into the portal vein without its becoming deoxygenized.

Tyson sums up the entire matter in the following manner: "Among the experimental irritations in addition to the puncture of the floor of the fourth ventricle which produces glycosuria by reflex action, are injuries of the cerebral lobes of the cerebellum, optic thalamus, cerebral peduncles and even the static nerve and brachial plexus. Finally, there is no reason why an inhibitory reflex action should not originate in the sympathetic nerve itself. When we remember that this nerve is both sensory and motor in function and the inhibitory influence to which the heart's action is subject, is accomplished through the sympathetic as a sensory nerve, and the pneumogastric as a motor, there is no reason why similar results may not be brought about by the sympathetic alone. This being the case, we need not ascribe the glycogenic phenomena to a direct, stimulant action of the irritant upon the vasomotor nerves of the liver, but may suppose a sensory influence to ascend one set of sympathetic filaments, and an inhibitory influence to descend through another.

A word or two about the sympathetic nerves. The sympathetic system comprises two principal parts: The gangliated cords and the plexuses with their associated ganglia. The component elements of the plexuses and, indeed, of the entire sympathetic system, are the ganglia and the nerve fibers. The gangliated cord (truncus sympatheticus), one of a symmetrically placed pair of gangliated trunks situated anterior or lateral to the bodies of the vertebræ begins in the head and extends through the neck, thorax, and abdomen to the lower portion of the pelvis, where it terminates by the cords forming a loop, situated anterior to the coccyx and containing the coccygeal ganglion or ganglion impar. The plexuses (plexus sympathetici) are a series of more or less distinct collections of groups of nerve cells (ganglia) and fibers, the most important of which are the cardiac, the pulmonary, the esophageal, the solar, the pelvic, and the suprarenal.

The solar or the epigastric, the largest of the series, supplies all the viscera in the abdominal cavity and is in communication, due to its great network of nerve fibers, with the most important plexuses in the thoracic and abdominal cavities. It is subdivided into two important portions, (1) the semilunar ganglion, (2) the celiac plexus.

A ganglion may or may not be connected with a spinal nerve, but it is always linked by association cords with other ganglia. Other communicantes are the rami communicantes, which are divided into two groups, the white and the gray rami communicantes. The white rami communicantes are composed almost exclusively of the visceral branches of certain of the spinal nerves which use the sympathetic system as the pathway by which they arrive at their destination. The fibers arising from the anterior root are called the splanchnic efferent fibers and those from the posterior root the splanchnic afferent. The splanchnic afferent fibers furnish motor impulses to the unstriped muscles of the vessels and viscera, and secretory ones to the glands of the splanchnic area; they also convey motor impulses to the heart. The splanchnic afferent fibers are the sensory fibers of the splanchnic area and pass by way of the posterior roots into the spinal cord. The gray rami communicantes are bundles of axones of sympathetic neurones which pass from the gangliated cord to each one of the entire series of spinal nerves. The association cords are the longitudinally disposed bundle of fibers comprising the interganglionic portion of the gangliated cord.

From this short anatomical résumé, we see that, although the supply of the thoracic, abdominal, and pelvic organs constitute an important part of the duty of the sympathetic nerves, it is by no means their entire concern: the innervation of the involuntary muscles of the vessels and of the skin, and of the glands throughout the entire body being likewise their task, they follow the course of blood vessels to meet their obligations to the structure within the body and by way of the rami communicantes join the somatic spinal nerves, which they accompany to all parts of the body, to the vessels, skin, and glands outside of the body cavities.

From all this, it is evident that we have in the sympathetic nervous system, due to the free communication between its ganglia and the cerebrospinal nerves and vagi, a medium by which the remotest as well as the nearest, the deepest as well as the most superficial parts of our body are reached and controlled, stimulated, excited, irritated, anesthetized, and calmed by the same set of nerves originating from the same plexus.

From the aforsaid (a short review of the physiological and chemical deduction and the anatomical résumé of the sympathetic) we know that glycosuria following the hyperemia of the surrounding vessels of the liver is induced either (1) by injury or irritation of some nerve of the cerebrospinal system that stands in direct or indirect communication with the sympathetic system; or (2) by injury or irritation of the filaments or ganglia of the sympathetic system direct. Reasoning from this standpoint it is plain that if we can relieve the hyperemia so induced, we will restore physiological balance and correct the function of that part of the nervous system which induced the hyperemia.

Searching through the literature on diabetes mellitus I fail to find anything, as far as treatment is concerned, that would indicate even a suggestion to relieve the hyperemia around the vessels of the liver. And to accomplish this I know of no better method of treatment than acting through the sympathetic system by application of the proper modalities of electricity. We are all aware of the therapeutic value of electricity in general and of its modalities in detail. Physiologically I can only repeat what I have said in my paper on electro therapy, that both high potential and frequency cur-

rents are Nature's own remedy and are incomparable stimulants, affecting nutrition and metabolism of the tissues, inducing a renewed vasomotor tone, awakening cellular activity of dormant organs, sending stimulus into the deep ganglia and through them exercising a reflex action upon the centers of the cerebrospinal and sympathetic systems. They are strongly indicated where penetrative action is required in order to remove deep-seated infiltration, congestion or stasis.

Hence to treat diabetes mellitus I selected the high potential and high frequency currents. Both currents are best indicated from pathological standpoints in disturbances due to errors of nutrition. The therapeutic value of polarity of electricity, which I explained in my paper on electro therapy* is followed through all modalities of electricity.

In the case of diabetes mellitus I use the indirect positive spark or brush with the negative insolation or the same polarity in high frequency effleuve. The treatment of diabetes mellitus by these two currents appears to me both reasonable and scientific, for if we study carefully the successive phenomena in this disease we would find the pathological changes taking place so rapidly that it is very often astonishing and even marvelous to both patient and physician. Both currents, high frequency and potential, differ very little as far as therapeutic indications or effect are concerned. The high frequency is more pleasant to the patient than the static, due to the absence of pain with high frequency, but requires more seances.

In diabetes mellitus the current is applied over the epigastric region directly over the celiac plexus, semilunar, and splanchnic ganglia, directing the current from left to right. The application should be given from ten to fifteen minutes, in sufficient intervals to prevent the patient becoming exhausted. The patient usually, after the treatment feels the sedative effect and usually experiences a gentle restfulness beginning with a pleasant glow over the entire body, breaks into light and warm perspiration, with a pleasant tired feeling, and usually falls asleep. After a short treatment the predominating symptoms of diabetes mellitus subside little by little. The polyuria, excessive thirst, or hunger are decreasing and the sugar is diminishing in quantity. The general nutrition is improving, good spirits and vitality show through every action and the patient feels the improvement himself with every treatment. The usual time required is from six months to a year or a year and a half to accomplish a cure.

During my early treatment (in the latter part of 1903 and early part of 1904) I met with a great many failures and reverses, but I attributed them, as I will show later, to my adherence to the carbohydrate-free diet theory. As soon as I abolished this theory and with the help of the spinal test which I applied freely, out of 144 cases I have only 62 cases without any results, and this was more due to the negligence and lack of attendance on the part of the patients. And even these 62 cases, almost all of whom were treated for periods of from three weeks to three months, have improved, showing a diminution in percentage of sugar, decided relief in polyuria, excessive thirst, and hunger. Some have even gained in weight. A good many of them failed to follow out the treatment on account of financial or other similar embarrassments. While to my personal knowledge I have had no deaths from diabetic coma, I do not wish to say that such may not have occurred. But if so, then it was after they passed from being under my care.

To locate the seat of nervous irritation I use a test which I call "the spinal test." I use it in a great many nervous diseases as I do in diabetes mellitus. While the test is not up to perfection and needs a great deal of improvement, it has served me in many a case to clear up an obscure diagnosis. In cases where the nerves were irritated the results were best and quickest. The test is very simple. Applying a long and broad wet pad made of linen and cotton, the kind described by me in a recent article,* covering the active thoracic and abdominal part of the body, you place your patient on top of it, face downwards, having previously attached the positive pole of the direct current to it, the negative pole being attached to an electrode covered with a wet sponge or cotton. The small galvanic current of not more than 5 milliamperes suffices for the test. Pass the wet electrode on both sides of the entire length of the spinal column several times and, remarkable to say, a few minutes after removing the electrode, well-defined, red spots appear, which in a short time tend to become more vivid and sometimes assume a bluish hue. These spots will, in diabetic cases usually appear in the dorsal region and preferably on the right side.

Permit me to cite a few cases in support of my statement, and in proof of the test:

Case I.—Mr. M. J. D., contractor, age 58. Had diabetes mellitus for 12 or 14 years, and had been under the treatment of many physicians. Voids normal amount of urine. Specific gravity, 1022: sugar, 4 per cent. Spinal test was applied, and red spots appeared on right side of sacrum. All the spots were within an area of two inches. At the end of one year and three months treatment, no sugar, no albumen, gained about 15 or 20 pounds. Test applied. No indication of red spots anywhere. Within a month of being discharged he went to Cuba. He got an attack of diarrhea lasting three or four days, and was treated by surgeon on boat coming back to New York. The diarrhea continued for a week. He was treated by the family physician. When he became debilitated, he was advised to go to Saratoga, but came back in two weeks, having lost 15 to 20 pounds. He called at my office the day after his arrival from Saratoga. Examination of urine proved no sugar. Examination of feces showed a high amount of undigested milk, casein, and fat. Spinal test applied. Red spots appear on the sacrum and were quite prominent. Lower abdomen was treated daily with static and high frequency and three days afterward the bowels were perfect. Within a month he was again restored to good health. The last time the urine was examined was January 28, 1910. No sugar, no albumin. He had gained in weight possibly ten to twelve pounds and passed a high insurance policy. From this report and the spinal test we conclude that (1) the original irritating cause of glycogenic hyperemia in this case was located or at least reflexed in the sacral region. (2) That were it not for the restored metabolism and also restored function of the nerves in the glycogenic area the neurotic enterocolitis would have proved fatal; the usual consequence in those cases being diabetic coma and death.

Case II.—Mrs. B., superintendent of large establishment, was brought to me in 1896 (at that time

*The American Journal of Dermatology, October, 1908.

*New York Medical Journal, February 18, 1905.

at the age of 26) by her husband for sexual apathy. On examination no special features except that she voids 340 ounces of urine a day and suffers from an extreme thirst, also once in awhile with hunger. The specific gravity of the urine was 1026. Showed 6½ per cent of sugar. She is extremely nervous and up till 1904 was treated by me to the best of my ability according to the advice received from my teachers, text-books and colleagues. While I administered the medicine, she religiously took it, and while she did not improve much, she did not become worse. In 1904 I started to treat her with electricity and previous to this I applied the spinal test. She was one of the first patients that I treated thus in 1904. This showed the extravasation spots around the lumbar region. She was treated with static electricity and within a year or so there was no sugar in the urine, the thirst diminished, and the polyuria disappeared. The woman gained in weight and even the obstacle of which her husband originally complained was overcome.

Case III.—Child, two years seven months old. Infantile paralysis of lower limbs. Rigidity of muscles and joints. No relaxation of knee or ankle joints. No reflexes. No muscular power in hands. Neck from seventh vertebra and up strongly bent so that the chin pressed against the breast and child forced to look up from under eyebrows when desiring to look upwards. Mother complained that the child suffers thirst. "He can drink all the time." With this there was polyuria. Mother complains that she has to change diapers every ten or fifteen minutes. Voids more than 2½ ounces at one micturition, and if mother's statements be correct, rate amounts to ten ounces per hour, if not more, and to 240 ounces in 24 hours. On examination urine shows specific gravity of 1028. Sugar 6 per cent. Upon the spinal test being applied, red spots appeared on both sides of cervical region between the third, fourth, and fifth vertebræ, showing the extravasation points. Was treated daily for one month, special attention being paid to chest, neck, and extremities. Within three weeks rigidity subsided. Child can draw up its legs and extend them. Started to creep. When placed on the floor stands flat on its feet. Coordination improved. When given a chocolate candy puts it in his mouth. Says "Mama." Neck greatly reduced in curvature. Child looks almost straight forward. Thirst and polyuria greatly diminished. Due to statement of mother that the child is too heavy for her to carry such a long distance (she lives in Brooklyn) and thanks to the remark of a kind colleague who said that the child was an idiot, treatment was discontinued. Had no chance to reexamine urine or to reapply test.

The theory of carbohydrate-free diet is based upon the idea that the saccharine and amlaceous foods fail to be consumed in the economy of the body, not being oxidized in the blood as they should be. Hence if these foods be excluded from the diet the symptoms of glycosuria will disappear. Careful observers and clinicians like Osborne, Crofton, Labbe, Eccles, Goodhart, and Falta report unsatisfactory results from carbohydrate-free diet in diabetes mellitus. They cite cases of diabetic coma directly due to the carbohydrate-free diet, claiming that the body "being deprived of carbohydrates continuously must necessarily consume itself or starve in order to supply the missing unit."

Some good observers and clinicians advise the administration of fats, others do not, and look upon it with suspicion. Fats used with carbohydrates can be taken in large quantities without any disturbance in digestion. I usually advise sweet butter and sour cream to be taken with the meals in possible larger quantities than usual. Other fats given alone, and in large quantities, induce very often a marked indigestion.

We listen to the advice of good men advising a diet of starch and sugar. Another group of equally good men advise giving no starch or sugar. Both groups consist of sincere observers. What is to be done? Physiological chemistry is the basic fact and it is our business to find if possible the influences that restore to the normal the physiological chemistry of the cell, or what is inclusively termed cell metabolism.

Diet.—As to the rules of diet they are as follows, providing the idiosyncrasy of the patient demands special instruction: The diet must be a mixed and nutritive one. Eat slowly. Masticate your food thoroughly. Partake of a small meal at a time. Better six or eight small ones than two or three large ones. Abstain from all carbonized liquors, like champagne, beer, ale, ginger ale, and even carbonized water. If liquor must be drunk use whiskey or good brandy, diluted with plain water. I advise a great deal of cooked vegetables and fruit, cooked cabbage, spinach, cooked apples, prunes, and tamarinds.

Case IV.—July, 1906. Paul N., aged 48. No thirst, no polyuria. Voids 70 ounces a day; 3½ per cent. of sugar. Specific gravity 1029. There was no wasting. Loss of sexual desire. Was treated with high frequency and static. No special diet. March, 1908, discharged cured. No sugar. Sexual desire restored.

Case V.—January, 1905. C. S., female, 28 years old. Complained of polyuria, thirst and wasting. Specific gravity of urine 1030, 4½ per cent. sugar. Suffered with pruritus vaginæ and under the arms. High frequency and static electricity. Magnesia sulphate solution baths. December, 1906, discharged cured, gained 18 pounds. No special diet.

Case VI.—March, 1907. Fred W., aged 56 years, retired, noticed that he used to pass urine oftener than usual. Thirst and bulimia. Had urine examined in a laboratory; 64 ounces in 24 hours. Specific gravity 1028. Sugar 2 per cent. Trace of albumin and casts. Treated with high frequency and static electricity. July 15, 1907, voids 48 ounces in 24 hours. Specific gravity 1024. No sugar. Trace of albumen, no casts. I advised trip to Europe. He came back in September, when urine showed no sugar. Was treated for other complications. No special diet.

Case VII.—January, 1908. John L., age 16 years, voids 320 ounces in 24 hours. Specific gravity 1030. Sugar 4½ per cent. Height 5 ft. 8, weight 96 pounds. Six months ago fell in an air-shaft. Excessive thirst, no hunger. Treated as previous case. No special diet. May, 1909, discharged cured. Gained over 30 pounds.

Case VIII.—January, 1908. Katie D., 34 years old, married, with three children. She had had one miscarriage, but mensturated regularly. Was operated in the latter part of 1906 for small ovarian tumor. Lost over 40 pounds in the last 6 months. Voids 240 ounces in 24 hours. Specific gravity of urine 1028. February, 1910, no sugar, no polyuria, no special diet.

Case IX.—September, 1909. Carrie K., 12 years old, tall, very poorly nourished, exceptionally bright in school; weighs 83 pounds; tuberculous history

on both sides of the family, although neither father nor mother are sufferers of phthisis. Suffers with diabetes mellitus for the last two years. Voids between 120 to 140 ounces of urine in 24 hours. Specific gravity 1026. Sugar 4 per cent. No albumen. The treatment consisted of physical exercise in fresh air and expansion of chest and deep breathing ordered. High frequency and static electricity. January 28, 1910, has gained 14 pounds, no sugar in the urine, voids 80 to 85 ounces in 24 hours. Still in treatment. No special diet.

As to drugs I will say that I do not use many. Opium, strychnine, and atropine or its compounds are usually used. But we should not use drugs in diabetes mellitus in a general way. Their only possible justification is to meet symptoms.

Physical exercise is of great importance. Breathing exercises with chest expanded, at an open window, first thing in the morning, or in the open air during the day, is imperative. But the exercise as well as playing at games must be advised and regulated by the attending physician with due regard to the circulation and not carried on to overfatigue.

Warm baths before going to bed and a sponge with a solution of magnesium sulphate three or four times a week. Cold baths only in large plunges or in the sea during the hot part of the day when the patient can exercise by swimming.

In conclusion I wish to say that diabetes mellitus should be placed on the list of curable diseases. The other complications, such as nervous, pulmonary, thoracic, digestive, and genitourinary, should be treated secondary to diabetes mellitus. Never use the knife in diabetes mellitus. Electricity is Nature's own remedy in diabetes mellitus; the sooner applied, the quicker the result. But, and this I must emphasize, the one who applies it must be one who thoroughly understands its potentiality and its modality.

Let me make a summary statement. Back of all that has been written relative to this nutritional disorder, so-called diabetes mellitus, lies the primary and vital fact that we are dealing with disordered cell metabolism which has its origin in a disadjustment of the *ego* to its environment, what the world calls worry.

THE PRINCIPLES AND TECHNIQUE OF THE WASSERMANN REACTION.

By GEORGE GILLMAN, A.B., Ph.G., PhC.,
SAN FRANCISCO, CAL.

As almost all the valuable literature that has appeared in the last few years, dealing with the Wassermann reaction, has dealt principally with the use, value, and scope of this test as a means of diagnosing syphilis, and as the result of an extensive review and study of the subject involved it is thought not to be amiss to write this paper, the purpose of which is to set forth only, in detail, the principles underlying this reaction and the technique employed. Considering the fact that the use of this reaction for the diagnosis of syphilis is increasing daily, and its specificity and great value confirmed by many authorities, it is hoped that this paper will be of aid in making those who are but little familiar with the reaction, more familiar, and as an encouragement to those who may have hesitated to undertake the performance of the test on account of its apparent difficulty.

It has been a long established fact, discovered by Belfanti and Carbone[1] that an animal of one species acquires a specific lytic power when injected with the washed red blood corpuscles obtained from an animal of another species. For convenience, we will call the immunized animal "B" and the animal whose blood was used for immunizing "B," "A." The lytic power acquired may be expressed as the power of "B's" blood serum (hemolytic amboceptor) to hemolyze (lake) or rendering transparent, an opaque suspension of "A's" blood corpuscles. This lytic power may be explained as being due to and dependent upon "complement" which is present in all normal blood serum and capable of being destroyed (inactivated) by heating the serum to 56° C., and the immune body (hemolytic amboceptor) which is present in the blood serum of the immunized animal and not capable of being destroyed (inactivated) at 56° C. Complement is thermolabile (destroyed by heat) and the immune body, thermostabile (not destroyed by heat).

The laking of the blood is due to the immune body (hemolytic amboceptor) combining with its specific red blood corpuscles in the presence of complement. In the reaction the complement is said to be "fixed" and hemolysis (laking of the blood) occurs.

Bordet and Gengou[2] showed that in the same manner as specific immune bodies (hemolytic amboceptors) are produced in animals injected with the blood of an animal of another species, by the injection of bacteria (or albuminoid substances), immune bodies (amboceptors) are produced in the injected animal which will combine with the specific bacteria (or albuminoid substance) and complement which is contained in any normal serum.

This principle was used by the above investigators to determine the nature of an infection. It was done by mixing the inactivated serum (complement destroyed) of the infected animal with the supposed causal bacteria (antigen) and then adding complement (fresh normal blood serum). If the immune body is present in the serum of the animal it will unite with the bacteria (antigen) and complement

(in normal serum), thereby fixing the complement. Now, if to this some blood corpuscles plus its inactivated specific hemolytic serum be added, hemolysis (laking of the blood corpuscles) will not occur on account of the complement being previously fixed. Should the blood serum of the animal not have contained the specific immune body, the complement would not have been fixed in the first place and the blood would have been hemolyzed (laked). The laking of the blood would then indicate a negative reaction (absence of immune body), whereas, if the immune body was present no laking occurs and indicates a positive reaction.

It can be readily seen that the foregoing experiments permitted the demonstration of immune bodies (antibodies) as well as the substances which cause them (bacteria, etc.).

It is the above reaction which Bordet and Gengou called "reaction of fixation" (fixation of complement), that the Wassermann reaction is based upon. The reaction that takes place, in the case of syphilitics is, the fixation of complement is caused by the specific antibody contained in the syphilitic's blood serum, combining with the antigen (emulsion of liver obtained from a syphilitic fetus which contains the causal organism of syphilis, the *Treponema pallidum* in large numbers), and thereby fixing the complement and preventing hemolysis.

Wassermann, Neisser, and Bruck[3] were the first to describe a means of diagnosing syphilis based upon the above principles (fixation of complement). These investigators came to the conclusion that the blood serum of syphilitics contains an antisubstance (immune body) to the cause of syphilis. The experiment that brought them to this conclusion was as follows: They found that a mixture of a watery extract of liver, obtained from a syphilitic fetus and the blood serum of a syphilitic person would fix alexin (complement), whereas a mixture of normal serum or of serum from other diseases and the extract of syphilitic liver did not fix complement. The originators, in their experiments used as antigen the syphilitic liver of a fetus. This was used on account of the abundance of the causal organism, the treponema pallidum, present.

Landsteiner, Müller, and Plötzl,[4] Levaditi and Yamanouchi,[5] and other investigators found that an alcoholic extract of either syphilitic or normal liver would give the same reaction as an emulsion in normal salt solution of syphilitic liver obtained from a fetus such as used by the original investigators. Porges and Meier[6] demonstrated the value of lecithin as antigen, while Landsteiner proved the value of an alcoholic extract of guinea-pig heart as antigen. These investigators have compared the value, as antigen, of a watery extract of syphilitic liver, an alcoholic extract of normal liver and pure lecithin, the results only confirming the fact that they are equally efficacious.

From the above investigations, which have been confirmed by many workers, may be concluded that the Wassermann reaction is due to certain bodies in the blood serum of syphilitic persons that display a marked affinity for lipoids and in particular, lecithin. Many workers now use, as antigen, an emulsion of licithin or guinea-pig heart, in place of the watery emulsion of the liver obtained from a syphilitic fetus as described by the originators of the reaction; the advantages being that lecithin and guinea pig's heart are always on hand and alcoholic extracts are more stable than watery extracts.

The necessary materials and their preparation:

1. Antigen (*a*) (original Wassermann); the liver of a syphilitic fetus is cut up into very small pieces and an emulsion made of it by shaking it up very well with normal salt solution (0.85 per cent.) in the proportion of one (1) part of the liver to five (5) parts of the salt solution. After the shaking is completed, the supernatant liquid is removed and clarified by centrifugalization, after which the clear liquid is pipetted off, one-half of one per cent. of phenol added to it and stored on ice for use.

(*b*) If lecithin is to be used as the antigen, it is prepared as follows: Make up a solution of pure lecithin in alcohol; of this alcoholic solution, a quantity equal to 0.1 gms. of lecithin, is added to 100 c.c. of normal salt solution. This is also stored on ice for use.

(*c*) Guinea-pig heart extract is prepared as follows: The heart is rubbed up very fine in a mortar (containing ground glass) with absolute alcohol in the proportion of one (1) gram of the heart to 25 c.c. of absolute alcohol. It is then heated to 60° C. for an hour, filtered through filter paper and kept in the refrigerator ready for use.

As the strength of the antigen will vary in different preparations, it must be standardized before being used. It should be of such strength that the quantity used will not hemolyze 1.0 c.c. of a 5 per cent. suspension of washed lamb's blood corpuscles in the presence of 0.2 c.c. of a known positive serum, 0.1 c.c. of complement, and 2 minimal units of the hemolytic serum. The unit is determined as follows: A series of test tubes are prepared, each containing the same quantities of the reagents mentioned above and varying amounts of the antigen. The usual technique is followed and the unit determined by the quantity of antigen that inhibited hemolyses. After this determination the same antigen must be tested with a known negative serum used in place of the positive serum and using double the unit of antigen. This double unit should not inhibit hemolyses of the blood cells. The unit being determined, the antigen is so diluted that 1.0 c.c. will contain the unit.

2. Antibody: The blood serum or cerebrospinal fluid of the spyhilitic person. A sufficient quantity of the patient's blood is collected from the lobe of the ear or finger tip, in any sterile vial (best in a Wright's capsule), aseptic precautions, of course, being observed. The blood is then centrifugalized and the serum used. The spinal fluid is obtained in the usual manner by lumbar puncture.

3. Complement: The normal blood serum of a guinea-pig. A guinea-pig is bled to death each day, as the serum loses its complementing value if kept over twenty-four (24) hours. The blood is defibrinated, centrifugalized, and the serum used. If stored, it should be frozen.

4. Hemolytic serum: The blood serum of a rabbit that has been injected with washed lamb's blood corpuscles. The rabbit is immunized as follows: The lamb's blood is first obtained, best by cutting its ear and allowing 10 c.c. of blood to run into 30 c.c. of a 1 per cent. sodium citrate solution in normal salt solution. (This will prevent the blood from clotting). It is then centrifugalized, the supernatant fluid pipetted off, and the blood corpuscles washed with normal salt solution by repeated centrifugalization and dejection of the supernatant fluid. Five c.c. of the washed blood corpuscles are injected into the rabbit five (5) or six (6) times

at repeated intervals of five (5) days. On about the tenth day after the last injection, blood is taken from the rabbit, centrifugalized, and the serum used. Before using this serum, it is necessary to test its power after being inactivated (heated for three-quarters of an hour at 56° C. to destroy complement). The test is made to determine the minimum quantity of the serum that will hemolyze 1 c.c. of the 5 per cent. suspension of lamb's blood corpuscles, with 0.1 c.c. of complement (normal guinea-pig serum). Various quantities of the serum to be tested are put in a series of test tubes with 1 c.c. of the suspension of lamb's blood corpuscles and 0.1 c.c. of the complement in each tube. The tubes are put in the incubator at 37° C., for an hour and then examined to determine the smallest quantity of serum that produced hemolysis. (The proper quantity is usually 1 c.c. of a 1 in 2000 dilution, in normal salt solution. The quantity necessary for the reaction is two minimal units, so 1 c.c. of a 1000 dilution is used for the reaction.) The dilution used should never be lower than 1:1000. If it happens to be lower it will be necessary to give the rabbit a few more injections of blood corpuscles, before using its serum.

5. Lamb's blood corpuscles: 5 c.c. of defibrinated lamb's blood is collected and washed with normal salt solution in the same way as the blood for the injection was washed, then a 5 per cent. suspension made in normal salt solution.

The antigen, the patient's serum, and the hemolytic serum must be inactivated (to destroy complement) before using, by heating them for three-quarters of an hour at 56° C. The serums should be inactivated as soon after obtaining them.

The antigen, antibody (patient's serum) complement, and hemolytic serum should each be so diluted with normal salt solution that 1 c.c. of the dilution will contain the necessary quantities needed for the reaction.

Technique for performing the reaction: Into a test tube place 0.2 c.c. of the antigen, 0.2 c.c. of the patient's serum (antibody), and 0.1 c.c. of the complement. Incubate this at 37° C. for three-quarters of an hour and then add to it 1.0 c.c. of the solution of hemolytic serum, containing two minimal doses and then 1.0 c.c. of the 5 per cent. suspension of lamb's blood corpuscles. Now, incubate the whole for two hours, place in the refrigerator over night, and then note if hemolysis has occurred. If the antibody of syphilis is present in the suspected blood serum, hemolysis will not occur because the complement is "fixed" to the immune body by the aid of the antigen and the reaction is positive. Should the suspected blood serum not contain the specific antibody, hemolysis will occur because there is no immune body to "fix" the complement, therefore causing the hemolytic amboceptor (hemolytic serum), by the aid of the red corpuscles, to fix the complement, producing hemolysis and the reaction is then negative.

The substances employed are subject to many external influences, and it is, therefore, necessary to control their action. The controls made are necessary in order to demonstrate that none of the employed substances alone "fix" the complement, and that the occurrence of either a positive or a negative reaction, when testing a suspected serum, is due to and dependent upon, only to the fixation or nonfixation of the complement by means of the immune body, present or not present in the suspected serum, and the specific antigen.

	Test-Tube Number	Antigen 1:5 Dilution	Suspected Serum, 1:5 Dilution	Known Positive Serum, 1:5 Dilution	Known Negative Serum, 1:5 Dilution	Complement, 1:10 Dilution	Standardized Hemolytic Amboceptor, Containing 2 Minimum Hemolytic Doses (Usual Dilution = 1:1000)	Washed Lamb's Blood Corpuscles, 1:20 Dilution	Proper Results After Being Overnight in the Refrigerator	The Purpose of the Controls
						Incubate at 37° C. for forty-five minutes and then add the following:			The fluid in all the tubes are filled up to the same level by the addition of 0.85% sodium chloride solution. Incubate at 37° C. for two hours and then place in the refrigerator over night.	
*The Test and Controls for the Suspected Serum	1	1.0 c.c.	1.0 c.c.	.....	.....	1.0 c.c.	1.0 c.c.	1.0 c.c.	Positive = no hemolysis Negative = hemolysis.	The test proper of the suspected serum.
	2	"	0.5 c.c.	.....	.....	"	"	"	Pos. = trace hemolysis. Neg. = comp.	A quantitative control of the suspected serum's power in the above reaction.
	3	.....	1.0 c.c.	.....	.....	.....	"	"	No hemolysis.....	To prove that the suspected serum is inactivated.
The Test and Controls for the Known Positive Serum	4	1.0 c.c.	.....	1.0 c.c.	.....	1.0 c.c.	1.0 c.c.	1.0 c.c.	No hemolysis.....	The test proper of the known positive serum.
	5	"	.....	0.5 c.c.	.....	"	"	"	Trace hemolysis.....	A quantitative control of the known positive serum's power in the above reaction.
	6	.....	.....	1.0 c.c.	.....	"	"	"	Complete hemolysis.	To prove that the immune body of itself will not "fix" the complement.
	7	.....	.....	0.5 c.c.	.....	"	"	"	" "	A quantitative control of the immune body's power in the above reaction.
	8	.....	.....	1.0 c.c.	.....	.....	"	"	No hemolysis.....	To prove that the known positive serum is inactivated.
The Test and Controls for the Known Negative Serum	9	1.0 c.c.	.....	.....	1.0 c.c.	1.0 c.c.	1.0 c.c.	1.0 c.c.	Complete hemolysis.	The test proper of the known negative serum.
	10	"	.....	.....	0.5 c.c.	"	"	"	" "	A quantitative control of the known negative serum's power in the above reaction.
	11	.....	.....	.....	1.0 c.c.	"	"	"	" "	To prove that the known negative serum of itself will not "fix" complement.
	12	.....	.....	.....	0.5 c.c.	"	"	"	" "	A quantitative control of the known negative serum's power in the above reaction.
	13	.....	.....	.....	1.0 c.c.	.....	"	"	No hemolysis.....	To prove that the known negative serum is inactivated.
Antigen Controls	14	1.0 c.c.	.....	.....	.....	1.0 c.c.	1.0 c.c.	1.0 c.c.	Complete hemolysis.	To prove that the antigen of itself will not "fix" the complement.
	15	"	.....	.....	.....	.....	.....	.....	No hemolysis.....	To prove that the antigen of itself will not hemolyze the red blood corpuscles.
	16	.....	.....	.....	.....	.....	1.0 c.c.	"	" "	To prove that the antigen will not act as complement.
Hemolytic System Controls	17	.....	.....	.....	.....	1.0 c.c.	1.0 c.c.	1.0 c.c.	Complete hemolysis.	To prove that the "hemolytic system" reacts properly.
	18	.....	.....	.....	.....	"	.....	"	No hemolysis.....	To prove that the complement of itself will not hemolyze the red blood corpuscles.
	19	.....	.....	.....	.....	.....	1.0 c.c.	.....	" "	To prove that the hemolytic serum is inactivated.

*These three tests are to be made for each suspected serum.

The following table presents the tests and controls to be made. The technique employed is as already mentioned, and graphically arranged in the table on page 960.

The quantity of antigen used for the reaction may have to be either increased or decreased. The controls will indicate when a change is required and the proper quantity necessary is determined by the method given under the preparation of the antigen.

GRAPHIC EXPLANATION OF THE DIFFERENT REACTIONS THAT HAVE BEEN MENTIONED.

1. Complement (normal serum) + hemolytic amboceptor (serum of immunized animal) + suspension of red blood corpuscles = hemolysis (the complement is fixed and the blood is laked).

2. Hemolytic amboceptor + suspension of red blood corpuscles = no hemolysis as there was no complement to be fixed which is necessary to produce hemolysis.

3. Antibody (immune serum) + antigen (specific for the antibody) + complement = fixation of complement.

4. Antibody + antigen + complement, incubated three-quarters of an hour (complement is fixed) + hemolytic amboceptor + suspension of the specific red blood corpuscles = no hemolysis. The antibody, by the aid of the antigen, "fixed" the complement and so prevented the hemolytic amboceptors from combining with it (complement) and thereby preventing hemolysis. This is the reaction that takes place in positive cases of syphilis, due to the presence of the antibody (immune body).

5. a. [Antigen + suspected serum, containing no antibody (any normal serum) + complement incubated three-quarters of an hour] + b [suspension of specific red blood corpuscles + hemolytic amboceptor] = hemolysis. There was no antibody present in the suspected serum to "fix" the complement ("a" reaction) so that the hemolytic amboceptor fixed it and thereby produced hemolysis ("b" reaction). This reaction takes place in suspected negative cases, due to the absence of the antibody.

THE TREATMENT OF PROGRESSIVE SCOLIOSIS.

By MAX STRUNSKY, M.D.,

NEW YORK.

ASSISTANT SURGEON IN THE HOSPITAL FOR DEFORMITIES AND JOINT DISEASES; FORMERLY ADJUNCT TO THE CHAIR OF ORTHOPEDICS IN THE COLLEGE OF PHYSICIANS AND SURGEONS SAN FRANCISCO, CALIFORNIA.

Scoliosis comes on insidiously and is painless. Often the parents are not even aware that their child is in this condition. When the deformity is discovered, it has usually progressed so far as to make it beyond remedy. I have had cases in which the curvatures were so advanced that some of the vertebræ were ankylosed, yet the parents were ignorant all this while that their child had anything wrong with its spine. I hope to interest the Boards of Health on behalf of a routine examination of school children's backs. The physicians of the Boards of Health examine children for diseases or defects, but the back, which is the seat of scoliosis, a deformity which is widespread and serious and comes on at school age, is left to take care of itself. The result is that scoliosis is permitted to progress and is recognized here in the United States only when one shoulder becomes depressed enough or the angle of the scapula becomes sufficiently prominent to be noticeable through the child's clothes. We still leave the early diagnosis of scoliosis in the hands of the mother, teacher, and dressmaker.

In Switzerland and Germany routine examinations of the school children's backs are made by competent orthopedists and prophylactic measures are promptly instituted in suspicious cases. They are so enthusiastic in those countries over the result of prophylaxis in scoliosis that, as they say in one of their official statements, "It is a question whether in the entire domain of medicine and surgery prophylaxis has ever done as much good as prophylaxis in scoliosis."

Fig. 1.—The "creeping" exercise. The patient by making alternate wide semicircular sweep with his arm and bringing his knee forward to his chest forces the vertebra to bend to its extreme capacity and to twist and rotate to its fullest extent.

But as far as static scoliosis is concerned, the patient can still be benefited by treatment. The suspending and correcting machines break up vertebral adhesions, while gymnastics increase the tone of the system, build up muscles, and develop the elasticity of the spine. What is important in these cases, especially from a cosmetic standpoint, is that we can teach the patient to stand straight and carry himself correctly.

I have seen Professor Schantz get good results in chronic cases from his method of forcible correction. Nevertheless, in the static variety the main deformity remains during life. A glance at the pathological picture will convince us that this result is inevitable in chronic scoliosis. In these specimens we see that some of the vertebral ligaments are ossified while many of the intervertebral cartilages have disappeared altogether. The vertebræ are distorted, their bodies are atrophied on one side, hypertrophied on the other side, ankylosed into one twisted column, and a number of the spinal muscles which are stretched and compressed by the convexity become attenuated, and replaced by fibrous or fatty tissue. It is, therefore, obvious that no treatment can restore to the normal a spinal column which has undergone such radical organic changes. The hope, therefore, of good results depends upon prophylaxis, and failing in prophylaxis, the good

results depend upon the measures which stop the progress of the deformity. The structural changes of scoliosis which occur in the spinal column and the thorax are the result of the pressure of the superincumbent weight upon displaced vertebræ. Whenever bones become displaced from their normal position, structural changes always occur. Another example of structural changes is the ankylosis with altered shape of the tarsal bones that follows the displacement of the tarsal bones in flat feet.

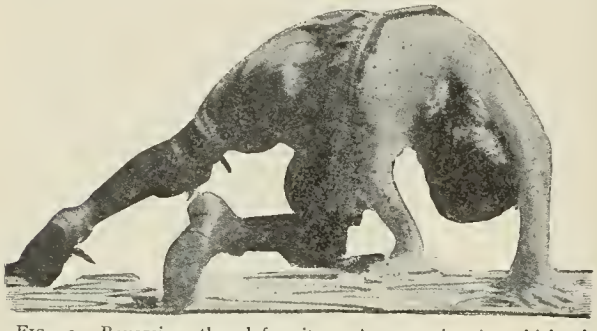

Fig. 2.—Reversing the deformity. An exercise in which the patient forces the fallen-in ribs to bulge out and widen the rib spaces while he presses the convexity inward and forward.

Structural changes follow rapidly when young bones are displaced. I can recall cases of incipient scoliosis where the vertebræ in the curvatures were free and not adherent and the spines straightened completely when the patients lay down. In an astonishingly short time, in two weeks or a month, I would find that some of the vertebræ in the curvatures had already become ankylosed and the spines did not straighten completely when the patients lay down. We have learned the same truth of the rapidity with which structural changes form in the young from displaced vertebræ through our experiments on animals. This was done by curving the spines of puppies and holding them in plaster-of-Paris casts. In three weeks permanent scoliosis was produced in some of these puppies.

In every case of scoliosis there is a period which is characterized by the formation of curvatures. This period may be short, as in the case of the mild types, or protracted as in the severe types. The tendency towards the formation of curvatures during the progressive period is apt to be obstinate and often goes on in spite of the treatment with gymnastics and corsets. To stop this tendency is the most difficult problem with which we have to contend, and at the same time the most important part in the entire question. When the progressive tendency of scoliosis is stopped successfully and promptly, the patient will remain straight or relatively straight, while failure dooms the spine and thorax to deformity.

Fig. 3.—The same as Fig. 2, when the move is to the opposite side.

The fact that thousands of new recruits are added to the army of scoliosis every year in spite of the treatment of even competent men with gymnastics or corsets, or the combination of gymnastics and corsets, and the further fact the treatment of progressive scoliosis has undergone a change in the methods of some orthopedists since Professor Klapp gave us his excellent system of gymnastics, are my only excuses for writing upon this subject.

The old theories of scoliosis, the "ligamentous", the "osseous", and the "muscular", or any other theory that pointed to the weakness of a single structure of the spinal column, have been exploded by recent investigation. Unbalanced chest muscles, one side pulling stronger on the vertebræ than their opponents, empyema, a short limb, all may be causes of scoliosis. Still these factors are only predisposing causes, for often these conditions exist in children a long time without ever producing scoliosis. Clinically, we know that patients with scoliosis often have anemia and diminished vitality. Of the few cases of early scoliosis that have come to autopsy, we have learned that the cancellous tissue of the vertebræ is less tough than in the normal vertebræ; also that the intervertebral discs are more gelatinous, the vertebral ligaments less elastic, and the spinal muscles more atonic than in normal children of corresponding age. Scoliosis occurs in animals, fishes, and fowls, which has led some observers to conclude that scoliosis was not due to the erect position. Nevertheless, scoliosis in the lower vertebrata is rare while in men it is widespread, and this points to the erect position as being the main factor in the cause of the deformity. The latest report of Lou-

Fig. 4.—Correcting the deformity. The patient corrects the deformity by pressing the convexity inward and forward.

sanne shows that of the three thousand school children examined, scoliosis was present to some degree in 24.6 per cent., or about one-fourth of the total number.

In men the spinal column has the additional function of weight-bearing. A spinal column made up of soft vertebræ, inelastic ligaments, and atonic muscles naturally is weak and has little supporting power. It cannot efficiently support the head, the arms, the chest, and its contents, with the result that the spine bends and twists. All movable and flexible columns upon which there are weights heavier than they can support, bend, and twist. This is the law of mechanics. The weight forces the column into a stronger position, and it is a fact that bent and twisted columns are stronger and have more supporting power than the straight columns.

In examining a patient with scoliosis I frequently elicit a history that he had in his early life some form of disturbed nutrition, either due to lack of food or improper food. This must have diminished the nutrition of the vertebræ. In a careful examination of patients with scoliosis, I have found evidences of delayed bone ossification in other parts of the body beside the vertebræ, such as slight bowlegs, knock-knee, flat feet, or nodes.

Our methods of education are also at fault. For years the child is deprived of fresh air, sunshine,

and exercise at the very age when they are necessary in nutrition. The spine is strained and fatigued by hours of sitting. All this and the additional fact that with approaching puberty the head, the arms, the chest, and its contents increase in size, is sufficient cause for the rotary deviation of the spine.

Fig. 5.—Unwinding the deformity. One of the many valuable table exercises is where the patient is strapped down by the pelvis and his trunk poised in the air. He then concentrates his mind on certain groups of muscles and forces them to unwind the deformity.

In the treatment of progressive scoliosis no corsets, casts, or braces should be worn. No vertebræ can grow if they are prevented from bending. The function of the vertebræ is to bend and slightly rotate, and the exercise of this function is the stimulus to the growth of the vertebræ and to the hardening process of their cancellous tissue. The artificial supports immobilize the spine and interfere with the function of the vertebræ. We all know how quickly the muscles atrophy if the cast is worn even for a short time. This atrophy, however, is not limited to the muscles, but extends also to the vertebræ, intervertebral cartilages, ligaments, and fasciæ. The harm that results to the spine and chest from the confinement of supporting apparatuses is only compensated by the calisthenics which these patients usually practise. The corset, to actually hold the spine, must be laced tight, and the suffering produced by the wearing of a tight corset is often unbearable. In order to ease this suffering, parents usually compromise with the patients by lacing the corset a "little loosely," with the result that the corset loses its supporting power and becomes only an additional weight that the spine is forced to carry. The danger of the corset is that it lulls the parents into a sense of false security and creates the belief in them that their child is wearing something that is actually curing her. This tends to make them neglect the gymnastics, etc., which are the essential elements in the treatment. In Klapp's experiences the patients who are treated with supporting apparatuses are apt to suffer from excoriations, and the discomfort produced by the wearing of apparatuses often robs them of their appetite. They also suffer from "air hunger," for all apparatuses limit chest expansion and partly shut off the patients' breathing. These various tortures soon aggravate the usual existing anemia, and the sallow complexion of the scoliotic who is being treated with apparatus is familiar to every orthopedist. The counterpressure of the apparatus upon the ribs of the curvature causes the ribs, which are usually soft in this condition, to bend at an angle, with the result that patients who have worn apparatus for a long time often have a hideous angle which is situated at the junction of the lateral and posterior walls of the convexity.

The corset may prevent deviation of the spine, but it does not prevent the deforming process going on within the spinal column, nor does it always prevent the rotating and twisting of the spine. "It is a noticeable fact," says Klapp, "that the worst cases of scoliosis that I have seen had a history of long treatment with supporting apparatuses."

My experience has taught me that rest to the spine from the pressure of the superincumbent weight is essential in the treatment of progressive scoliosis. Clinically we know that the scoliotic spine is a weak spine and is not able to support the superincumbent weight. Take for example a case of incipient scoliosis. With the patient in the erect position, the spine curves. Let the patient lie down, the pressure of the superincumbent weight is removed and immediately the spine straightens by itself. These patients always complain of feeling tired and have frequently an irresistible desire to lie down. I have always interpreted this symptom as a protest on the part of nature from continuing to carry the burden of the superincumbent weight upon the weak spine.

In treating progressive scoliosis the sunniest and the best ventilated room in the house should be selected and the floor be kept dust-clean by frequent washing. Protectors made of thick felt and leather should cover the patient's knees, for the patient spends a great deal of time in crawling around the room. If the patient is not embarrassed, crawling should be practised in the city on the roofs and in the country on the lawns. The patient should study his lessons in a recumbent position and sleep on a scoliosis bed. An effort should be made to build up his strength by fresh air, sunshine, nourishing diet, stimulating baths, massage, etc., in order to hasten the toughening process of the cancellous tissue of the vertebræ. Experience has shown that Professor Klapp's system of horizontal exercises is best. In my practice, however, I supplement Klapp's exercises by some that I have taken from the clinics of Professors Hoffa and Lorenz. The clumsy child with flabby muscles can be converted into an athlete, capable of executing the necessary acrobatic trunk movements. The time allowed the patient to assume the erect position is from two to eight hours, diminished or increased, according to the progress of the lesion. Professor Klapp has tried this system of treatment in its various modifications for some time in a large number of patients, with surprisingly gratifying results. Several orthopedists have told me that this system of treatment may be good enough for the Continent, where time is no factor, but that it would not do in America. Here the parents are loath to interfere with the child's education. They prefer to have a corset made and send the child to the gymnasium after school hours. My experience, however, has been that at least the intelligent parent is willing

Fig. 6.—Trunk exercise. The patient is strapped by the shoulders. He then contracts the trunk muscles, bulging out the concavity and forcing in the convexity.

to give up a great deal provided the treatment actually benefits the child. The prolonged recumbency prevents the pressure of the superincumbent weight on the soft vertebræ and the gelatinous discs and prevents it from straining the soft parts of the spinal column. As soon as the vertebræ have hard-

ened and the cartilaginification of the discs has been promoted, the muscles built up, and the tendency of scoliosis arrested, the patient is gradually allowed to return to his former mode of living.

The advantages of the horizontal exercise as compared with the erect are as follows: 1. It gives a wider range to the excursions of the vertebræ. A person walking keeps his spine fairly stiff, while animals, on the contrary, move their vertebræ freely. A cat by turning abruptly can bend its spinal column into a bow. The movements of the vertebræ increase its growth and stimulate the toughening process of its cancellous tissue. They convert the gelatinous cartilage into normal cartilage and increase the size and elasticity of the vertebral ligaments. It is, therefore, important that the range of the excursions of the vertebræ be increased to its full limit. This is best accomplished by the horizontal position when the pressure of the superincumbent weight is off the vertebræ and the trunk muscles relaxed.

2. It gives a wider amplitude of muscular contraction. The acrobatic horizontal exercises force the muscles to contract and to relax to their fullest physiological limit. Children who have practised the Klapp system for some time have their spinal muscles developed to a thick mass which is as hard as steel.

3. It tends to restore the muscles to their normal length. The muscles of a convexity are stretched, that of a concavity contracted. Abnormally contracted or stretched muscles do not increase in size or strength with exercise. The horizontal position straightens the spine in the incipient stage, and thus the muscles are restored to their normal length.

4. It gives the vertebræ relief from the pressure of the superincumbent weight.

In following this line of treatment which Professor Klapp has suggested, I know I am taking over to myself the prejudices and criticisms which were leveled against him; but to my mind no prejudice is too bitter, no criticism too severe, no régime that the patient has to endure too irksome, no amount of interference with the patient's education for a limited time too much, for the price of a straight spine.

95 West One Hundred and Nineteenth Street.

THREE YEARS OF RABIES IN INDIANA.

By J. P. SIMONDS, M.D.,

INDIANAPOLIS.

SUPERINTENDENT OF BACTERIOLOGICAL LABORATORY, INDIANA STATE BOARD OF HEALTH.

For the past three years an epidemic of rabies of no small proportions has existed in Indiana. Beginning with a few sporadic cases in 1906, the disease has spread to almost every section of the State. The epidemic seems to have reached its height in the summer of 1908 and now appears to be abating somewhat, although the danger is still far from being past.

The records of the State Bacteriological Laboratory contain data concerning this epidemic, which while necessarily incomplete will give some idea of the extent of the disease and the financial losses it has caused. It is doubtful if the laboratory records really show half the damage actually done by rabid dogs.

From December, 1906, to December, 1909, the brains of 260 animals were examined, of which 157, or 60 per cent., were found to contain Negri bodies.* The number and kinds of animals affected were as follows: 135 dogs, 8 cats, 9 hogs, 4 cows, 1 sheep. The number of heads received and especially the relative number of positive results varied largely with the amount of excitement among the people in a given community. Between May 1 and August 31, 1909, 63 brains were examined, of which only 21, or 33⅓ per cent., were positive. The small per cent. of positive results during this period—only a little more than one-half the average per cent. for the entire three years—is due largely to the fact that in May, 1909, a woman died in Indianapolis with what was said to be hydrophobia. The case was given wide newspaper notoriety, particularly in the central part of the State. Persons who had been scratched by the teeth of an overplayful dog, or licked by an unduly friendly pet, became panic-stricken, killed the animal at once and sent its head to the laboratory for examination, although it had not shown the slightest symptom of any disease.

During the entire year 1909 we examined the brains of 151 animals. Of these 63 contained Negri bodies. The number received during each month is shown in the following table:

	POSITIVE.	NEGATIVE.	TOTAL.
January	7	8	15
February	2	11	13
March	7	4	11
April	6	5	11
May	6	16	22
June	8	11	19
July	5	8	13
August	2	7	9
September	4	6	10
October	4	4	8
November	6	6	12
December	6	2	8
Totals	63	88	151

From the entire State only two positive brains were received at the State laboratory in 1906; 11 in 1907; 81 in 1908; and 63 in 1909. During the summer of last year—the hot season in which many of the laity still believe dogs may develop rabies spontaneously—we received only 11 positive brains. It is this decline in the number of positive cases during the summer months that seemed to warrant the statement made in the beginning, that the epidemic seems to be abating. And yet, even this apparent improvement can hardly be taken at its face value. It is discounted by the fact that many cases are never examined microscopically at all and therefore never get into the records. For instance, between March 11 and August 2, 1909, we received four positive dog's heads from Mishawaka, while a local newspaper (*South Bend Times*) reported at least five other cases in Mishawaka diagnosed rabies clinically that were not sent to the laboratory at all. Several of these had been bitten by dogs which had been proved to have rabies by microscopic examination.

For purposes of convenience the Indiana State Board of Health has divided the State into three sanitary sections, the northern, central, and southern sections including the respective thirds of the State. From the northern sanitary section 26 positive brains have been received; from the central, 107; and from the southern, 24. Positive brains have been received from 40 of the 92 counties of the State—from 9 of the 31 counties of the northern

*All examinations made before December 1, 1908, were done by Drs. T. V. Keen and J. B. Rucker, former superintendents, and Dr. Helene Knabe, formerly acting superintendent of the laboratory.

section; from 18 of the 33 counties in the central section; and from 13 of the 28 counties of the southern section. Up to the beginning of 1909 the northern section had suffered much less than the southern. During last year this condition was reversed.

Local epidemics have been a prominent feature of the general one. On November 1, 1908, we received from Bedford, Lawrence County, the head of a dog which was proved to have rabies. Following this there came positive heads from Bedford on December 15, 1908, January 20, 1909, February 13, 1909, and two on February 25, 1909. March 11, 1909, we received a dog's head from Mishawaka and found Negri bodies in the brain. A series of cases (five of which were collected from the *South Bend Times*) then occurred in Mishawaka as follows: March 26, March 31, May 4, May 17, June 9, June 23, and August 2.

The records of the laboratory show that at least 128 humans have been bitten by rabid animals. This probably does not include one-half of the persons actually injured. But even this number taking Pasteur treatment, at an average cost of one hundred dollars each, furnishes no small item of expense to the citizens of the State. In addition to this, the mortuary statistics of the Indiana State Board of Health show that in the three years 1906 to 1908 inclusive there were 13 deaths in the State said to have been due to hydrophobia. The diagnosis in none of these cases was verified by microscopic examination of the brain after death.

It has not been possible to collect accurate data in regard to the number of live stock that have died of rabies. A number of farmers have lost heavily, hogs furnishing the largest number of victims. A township trustee in the northern part of the State in the early autumn stated that if the demand for reimbursement for stock killed by rabid dogs kept up, the fund for that purpose—the so-called dog tax—would soon be exhausted.

The method used at this laboratory for the diagnosis of rabies in animals is that described by Dr. D. L. Harris.[1] The technique is as follows: Thin, uniform smears are made by pressing a small piece of the hippocampus major between two slides. Place the smear without drying in methyl alcohol for one minute. Wash off the alcohol in water. Stain for three minutes in a saturated alcoholic solution of eosin which must be at least two months old. Wash in water. Stain for eight seconds in a fresh solution of Unna's methylene blue. Wash in water. Differentiate in ordinary alcohol until, when examined under the low power of the microscope, the large brain cells appear a translucent blue, the nuclei a deep blue, and the red blood cells a coppery red. For uniform decolorization the smear should be kept in constant motion while in the alcohol, and should not be allowed to dry while being examined with the microscope.

In using this stain it should be remembered that the smear is affected by two colors, both of which dissolve out in the process of differentiation. The secret of success is to have both elements of the stain present in the smear in such proportion that when the differentiation is complete, each will have the proper degree of intensity. The length of time given above for each solution works satisfactorily but can be varied from in accord with the principle just stated. The Negri bodies stained by this method are quite distinct, and the examinations are much more satisfactory than with either of the other two methods tried at this laboratory.

In cases in which the dog has bitten some human and we are unable to find Negri bodies, a guinea-pig is injected subdurally with an emulsion of the suspected brain. In only two cases has the biological test been positive when the microscopic examination was negative. One of these was in the case of a dog suffering from what was diagnosed clinically dumb rabies. On September 4, we received from Dr. Whitestine, a veterinarian of Huntington, Ind., the head of a dog thought to have had the dumb form of the disease. In this we found a few tiny intracellular bodies that had the characteristics of Negri bodies. They were sharply defined and contained, as a rule, a single central brownish granule surrounded by a narrow pink zone of cytoplasm. These bodies were too numerous and too uniform in appearance to be artifacts and the case was pronounced positive. No guinea-pig was injected with this brain. On October 10, we received from Dr. Whitestine the heads of two dogs affected in the same manner as the one received a month previous. After a careful examination no Negri bodies could be found. A guinea-pig was injected subdurally on October 13 with an emulsion of one of these brains, and died on October 25 with the typical symptoms of rabies in a guinea-pig. Dr. Whitestine informs me that a number of other dogs in Huntington have been similarly affected but their heads were not sent to the laboratory. An epidemic of dumb rabies is so rare that this instance is worth recording.

No systematic, State-wide effort has been made to stamp out the epidemic of rabies. In several instances, when conditions have become extremely bad, as in Mishawaka in the summer of 1909, the local authorities have taken the matter in hand and have enforced a muzzling ordinance more or less thoroughly. This sporadic method has not proved effective in dealing with the general epidemic, and has not often worked satisfactorily in the purely localized ones. This has been due chiefly to the difficulty of enforcing the ordinance. Many dogs went unmuzzled in spite of the law and the muzzled animals were thus placed at the mercy of the unmuzzled ones who frequently took a savage delight in attacking their helpless fellows.

At the last session of the State Legislature an act was passed giving the State veterinarian "the power to order and enforce the restraint or muzzling of all dogs in a locality where a case of rabies has occurred, the extent of the locality and the duration of the restraint or muzzling to be determined by him." Even this has not proved effective largely because many cases do not come to the knowledge of the State veterinarian,[2] and the law contains no clear penalty for disobeying his orders.

It is to be hoped that the next Legislature will make possible a general and thorough enforcement of a muzzling ordinance for at least two years. If this is done the history of rabies in Great Britain where, by rigid enforcement of a muzzling law throughout the kingdom, the number of cases of rabies was reduced from 672 in 1895 to none in 1900, may be repeated in Indiana. This disease has been so thoroughly stamped out of Great Britain that professors in English medical colleges are said to have been compelled to import material from America last year to demonstrate the Negri bodies.

ROBERT KOCH.

IN the death of Robert Koch scientific medicine has lost its greatest figure since Pasteur. In saying this we do not forget Lister and the countless thousands who owe their lives to-day to his work and teachings; but Lister's work was practical, not pure science, although his discoveries, made before Koch's time, were those of a genius and could not have been made at that time by any but a genius. Koch's labors, however, have made it possible for such work to be done by any man of ordinary ability and industry. Koch's fame rests largely upon his discovery of the tubercle bacillus and in a lesser degree upon the discovery of the bacillus of cholera. But these discoveries need not have been made by him; they could and would soon have been made by others after he had shown the way. His real title to fame rests upon the development of the science of bacteriology which, as we have said, made possible all the other discoveries, his own and others', in the domain of this science.

We often hear the complaint made, though not so often now as formerly, that this country is handicapped in scientific work by the niggardliness of the government in not building and equipping laboratories and providing salaries and pensions to enable men of ability to give their whole time to scientific labors, and writers often point to Germany as a model which we might follow with benefit. But Koch suffered all his life from being a servant of the Government. The premature announcement of his discovery of tuberculin was forced from him by his government superior who thought it would give éclat to the Berlin International Congress; and time and again he was sent hither and yon, to the interruption of some work of possibly far-reaching importance, at the suggestion of the Emperor or of the Health Ministry, because it was thought the new work would reflect credit on the Fatherland. Had Koch been at the head of some privately endowed institute in America, free to pursue his investigations in his own way and along his own lines, he would undoubtedly have accomplished far more than he did, and might possibly have made other discoveries of incalculable benefit to the world.

Great as Koch was and lasting as his fame will be, he really accomplished less of immediate practical value than some other less gifted men. The discovery of the tubercle bacillus has had but little influence over the therapy of the disease, for the sanatorium treatment was begun thirty years before the cause was discovered by Koch; the discovery of the comma bacillus had no practical results until it was learned how the bacillus gained entrance into the organism; and while the diagnostic value of tuberculin, in bovine tuberculosis, is incalculable, its practical therapeutic value in human tuberculosis is still questioned. His work in Africa on the tsetse fly and sleeping sickness added little to what the English investigators had already discovered. But this detracts in no way from the fame that is a great man's due. He was the founder of the scientific method of bacteriological research, the work of a veritable genius, and fell short of what he might otherwise have accomplished only because his work was hampered by his lay superiors in the Gesundheitsamt. Those of our profession who are urging the creation of a Health Department in our central government, without the proviso that its head shall always be a medically trained sanitarian, should ponder a while on the case of Robert Koch.

THE SENSE OF RESISTANCE IN DIAGNOSIS.

WHILE to the student taking his first tentative steps in the paths of physical diagnosis, the auditory sense is an indispensable agent in interpreting the results of percussion, to the man of long experience the actual hearing of the sounds produced by the impact of the finger becomes of less and less importance, and many skilled diagnosticians are capable of drawing accurate inferences from percussion in surroundings so noisy that hearing is impossible. This change is due to the gradual development of the tactus eruditus, to the appreciation of the sense of resistance felt by the finger lying on the chest or the abdomen. The value of the tactile sense in percussion has in recent years become more and more widely recognized by clinicians, and during the past decade certain clinical teachers have been laying greater and greater stress upon the sense of resistance, and many have largely discarded percussion, placing more reliance upon the elicitation of the sense of resistance by palpation, both for outlining thoracic and abdominal organs and for recognizing consolidations and effusions in the lungs and pleural cavities.

Perhaps the most enthusiastic of the advocates of palpation in thoracic disease, and the man who has given the method the greatest publicity is Pottenger of California, who has recently collected the results of his observations, reported during the past year in the MEDICAL RECORD and other American medical journals, and has given a clear and concise exposition of the subject in the *Deutsche medizinische Wochenschrift* for April 21, 1910, his article being immediately followed by another, by Wolff-Eisner of Berlin, enthusiastically confirming his findings. Besides laying stress upon the case with which the outlines of solid organs and consolidation can be made out by noting the sense of resistance offered to light palpation in the intercostal spaces, a method

the accuracy of which has been thoroughly established by various clinicians for a number of years, Pottenger lays emphasis upon a second and even more important feature of palpation of the thorax. From the study of a large number of cases, chiefly of tuberculosis, he has found a characteristic of the intrinsic and extrinsic muscles of the thorax, somewhat similar to that of the abdominal wall in acute abdominal infections, namely, that an acute inflammation in an organ causes spasm in the overlying muscles. This manifests itself not only in the density of the intercostal muscles over the diseased area, in the restriction of motion on the affected side, but also in cases of acute apical diseases in an easily palpable spastic condition of the scaleni, the sternocleidomastoids, and the other muscles of the neck. Furthermore, while this spasm is marked in association with an acute process, it does not appear with a latent or healed one, in such cases there being at times some muscular induration, but no actual spasm.

These various points in thoracic palpation will probably add somewhat to the difficulties of the student, to whom the sense of resistance, for some time at least, appears to be a myth evolved in the mind of his teacher. To the man, however, who has educated his fingers, the ability to feel through the chest wall is a thoroughly useful art, especially valuable when dealing with children with whom percussion is too often a signal for vociferation. If the second feature of the work, the spasm of the muscles of the chest and neck, proves to be as accurate in the differentiation of acute and latent diseases in the apices of the lungs as Pottenger and Wolff-Eisner believed it to be, Pottenger's discovery must be accepted as a valuable addition to the means of diagnosis of early tuberculosis.

THE PHILOSOPHY OF A PHYSICIAN.

The retranslation of Ernst Baron von Feuchtersleben's "Zur Diätetik der Seele" by an American* calls to mind a character of singular beauty, serenity, and gentleness. Feuchtersleben was born in Vienna in 1806, took his M.D. at the University in 1833, and in an incredibly short time became Professor of Medicine there. His success as a practitioner and teacher and his love of philosophy led him to deliver what are said to be the first lectures in any language on the subject of medical psychology. These lectures were immensely popular, so popular indeed that those professors who were unfortunate enough to have classes of their own at the hour when Feuchtersleben held forth found their benches empty of listeners. It is said that jealousy thus engendered was in part responsible for the severe criticism and contumely to which the sensitive author was subsequently subjected which finally brought about his resignation from the Faculty and his retirement to private life. However this may be, the Diätetik is the typical German classic on mental healing, and something more than forty editions attest its excellence in its field. Hufeland in his "Makrobiotik" had concentrated the various currents of thought of the preceding centuries relative to the value of suggestive therapy, and Kant, the illustrious philosopher, following up this pioneer work, had written a brief essay on "that faculty of man's soul through which, by a mere act of willing, a mastery over our marked sensations may be gained." But it remained for Feuchtersleben to clarify the atmosphere and reduce the chaotic mass of data to something like a working system. We see therefore that the so-called "movement" in America is little more than an echo of the essentials which had existed for many years throughout the Prussian empire. Several passages in the Diätetik are strongly reminiscent of Emerson's essay on "Compensation;" for example, "In the entire realm of nature there exists no advantage without a defect, no profit without a loss, no ascent without a fall, no discord without harmony." There is also now and then a glimpse of that rare combination of wit and wisdom which so endeared Oliver Wendell Holmes to all his readers: ". . . Everybody thinks himself entitled to ridicule the doctors. Old women (and young ones, too) dabble in our art, and pass judgment on us. . . . Their ranks are reinforced by the hypochondriacs, who feed on the poison which they suck out of medical books, and which they get rid of only to wish that it might kill the doctors. . . . Hypochondria consists not only in conjuring up imaginary ailments, but in dwelling too much on those that are real. . . . We may learn through the writings of careful medical observers that anger acts on the bile-ducts very much like an emetic by increasing or altering the secretions." Feuchtersleben's love of truth seems to have rivaled that of the physician-poet Keats—"There is," he says, "but one morality, truth, and but one depravity, falsehood. . . . And genius is in the last analysis the power to be true. . . . There is no strength without truth; and without truth there is no charm."

Feuchtersleben was a devoted lover of medicine, both as a science and as an art, and what he thought as a philosopher he practised as a physician. He demanded the highest ethical and scientific standards, and drew constant inspiration to this end from the works of Marcus Aurelius and Epictetus. His qualities both of mind and heart are well worthy of study and emulation by the physician of to-day, and no one who reads what he has written understandingly can fail to derive therefrom much mental and spiritual satisfaction.

*Health and Suggestion, by Ernst Baron von Feuchtersleben. Translated and edited by Ludwig Lewisohn, M.A. New York: B. W. Huebsch, 1910.

Diaphragmatic Respiration for Heart Disease.

It is a fairly well recognized fact that to obtain the best results in the treatment of chronic heart disease, one must pay especial attention to the functional activity of the organs more or less remote from the primary seat of the disease and proportionally less attention to the heart itself. Muscular activity is carefully regulated; the greatest pains are taken to maintain bowel regularity; a diet is prescribed which will not produce flatulence, and a proper activity of the kidneys is striven for. In the *Deutsche medizinische Wochenschrift* for April

7, 1910, Rumpf of Bonn calls attention to still another bodily function and its relation to cardiac competency. For several years this author has been observing the two types of respiration, and the effect of each upon the size and action of the heart. According to his observations every respiration produced by elevation of the chest wall tends, by the increased negative pressure generated, to dilate the cardiac cavities, especially the auricles. Diaphragmatic respiration, on the other hand, with the thorax held immobile, acts in a different manner. The lung, following the diaphragm downwards, presses upon the heart from above and the side, the organ assumes a more erect posture and tends to be contracted rather than dilated. The contents of the abdomen are pressed upon; the veins and lymphatics therein are compressed, while those of the thorax are dilated and the circulation is materially aided, and the reduced abdominal pressure during expiration further aids by refilling the splanchnic vessels. Such are the physiological premises as propounded by Rumpf, the inferences from which he considers to be obvious. Thoracic respiration, causing further dilatation of the already overdisturbed heart, is a dangerous procedure, while breathing of the abdominal type is an aid to circulation and tends to reduce cardiac dilatation; *ergo* all patients with heart disease should breathe with the diaphragm exclusively. The theory appears at first glance to be plausible. How it would work out in practice is another matter.

Lesions of the Nervous System in Cerebrospinal Meningitis.

The nervous symptoms ascribed to cerebrospinal meningitis and its sequelæ are numerous and varied. Some of the so-called sequelæ are in reality the results of an accompanying encephalitis, which may indeed begin the trouble, to be followed by the meningeal inflammation and its characteristic symptoms. To cortical inflammation are generally due blindness, deafness, and many of the mental troubles that follow the disease, and the sclerotic process which results from the encephalitis may go on progressing for life. H. Claude and P. Lejonne, in the *Gazette des Hôpitaux*, for March 21 and 24, 1910, state that the symptoms due to the affections of the nervous centers are mistaken for complications or sequelæ. The inflammation is propagated along the vessels so as to attack separate areas reached by certain vessels, and thus the symptoms are spread about in the cortical centers. Disturbances of the reflexes and the Babinski sign are manifestations of the cortical irritation. But these signs are often masked by the meningeal symptoms. The authors give interesting observations in which these facts are shown to be true, autopsy demonstrating the existence of the cerebral lesions in one case. The authors have caused an inflammation in dogs by injections of chloride of zinc under the meninges, and got as result a hemorrhagic meningitis and vascular lesions in the gray matter near by, some of which was not directly adjacent to the meninges. Only those conditions should be denominated sequelæ of the meningitis which are caused by the organization of the soft meningeal exudate and its transformation into fibrous tissue. The cortical lesions resulting from this process cause mental troubles, motor troubles, sensory troubles, flaccid or spastic paralysis, ataxia, and troubles of the organs of sense.

News of the Week.

The International Association of Medical Museums held its third stated meeting at Washington, D. C., May 3 and 4, 1910. The following officers were elected: *President,* Prof. A. S. Warthin, University of Michigan, Ann Arbor, Mich.; *Vice-Presidents,* Prof. G. Sims Woodhead of Cambridge, England, Prof. Souchon of Tulane University, New Orleans, La., and Prof. J. Ludwig Aschoff of Freiburg, Germany; *Councillors,* Prof. W. G. MacCallum, College of Physicians and Surgeons, New York, Dr. D. S. Lamb, Army Medical Museum of Washington, D. C., Prof. Le Count, University of Chicago, Ill., Prof. F. F. Wesbrook, University of Minnesota, Minneapolis, Minn., Prof. P. G. Woolley, University of Cincinnati, Prof. W. Ophuls, San Francisco, Cal., and Dr. George Whipple, Baltimore, Md.; *Secretary-Treasurer,* Dr. Maude Abbott, McGill University, Montreal, Canada; *Assistant Secretary,* Dr. W. W. Francis, McGill University, Montreal, Canada; *Editorial Board,* Prof. J. Ludwig Aschoff, Prof. J. G. Adami, McGill University, Montreal, Canada, Major F. F. Russell, Army Medical Museum, Washington, D. C., and Prof. W. G. MacCallum. The establishment of a European section was decided upon, and the secretary was empowered to write to Dr. J. Ludwig Aschoff of Freiburg, Germany, asking him to take charge of its organization. The next meeting will be held in Chicago, in 1911, on the day preceding the meeting of the Association of Pathologists and Bacteriologists.

International Dairy Federation Prize.—A prize of 500 francs has been created by the International Dairy Federation for the best work presented in response to a question of scientific or technological character proposed by the permanent Bureau of the International Dairy Federation. A prize will be awarded at each succeeding International Dairy Congress. Papers in competition should be printed or typewritten and may be written in French, German, or English. They should be forwarded in fivefold copy. The papers should reach the Secretary-General of the International Dairy Federation at least three months before the date fixed for the session of the International Dairy Congress. In case no paper should be deemed worthy of the prize, the corresponding amount may be carried over to the next meeting as a second prize if expedient. The question submitted for the next congress is: "To determine by latest experiments, made at least in part on the human subject, the comparative nutritive value of raw milk and cooked milk (pasteurized, sterilized, or desiccated). In case of an advantage in favor of raw milk, to determine the rôle that the enzymes of the milk play in nutrition." Papers should be forwarded to the Secretary-General of the International Dairy Federation, 23 Rue David Desvachez, Brussels-Uccle, Belgium, not later than April 1, 1911.

Student Riots in Paris.—Much trouble has been experienced recently by the members of the Faculty of Medicine of the University of Paris as the results of riots among the students. The cause of this is the determination on the part of the undergraduates that the method of examining for appointments to the hospitals be changed. When Professor Landouzy addressed the students a few days ago and stated that the authorities were resolved to observe traditions, he was egged by the audience. In order to maintain order police and soldiers have been sta-

tioned at the building of the Faculty of Medicine.

The American College for Girls in Constantinople has undertaken a series of public lectures upon hygienic subjects to which Turkish men and women are invited, this being possible for the first time since the régime of the New Turk party began. The lectures were given by Turkish physicians educated in Germany and France, and covered such subjects as the prevention of typhoid fever and tuberculosis, the hygiene, food, and contagious diseases of children, the education of girls from the standpoint of physiology and hygiene, and the sanitary care of the house. The expected opposition to the health crusade was not met, and the lectures were received with gratitude and enthusiasm.

The Ex-Shah of Persia, according to a dispatch from Odessa, has taken up the study of medicine. He expects after some preliminary work to enter the University of Odessa.

Wood Alcohol in Liquor.—A number of arrests have been made in New York recently of liquor dealers who have been discovered selling liquor containing wood alcohol. Two prisoners were fined recently and the cases of several others were put over under the expectation that the United States Government will take steps against the wholesalers who sold the liquor to the saloonkeepers.

Smallpox in Harlem.—Four cases of variola were discovered recently in the Harlem district of New York City. The first case was in a colored porter on a private car who had just returned ill from Mexico. The cases were close together, and all those exposed were vaccinated by the Board of Health.

The Board of Inebriety Bill has been signed by Mayor Gaynor.

The Rockefeller Institute for Medical Research announces the appointment of Mr. Jerome D. Greene, Secretary of the Harvard College Corporation, as superintendent of the Institute and its new hospital.

The Cancer Commission of Harvard University has published a report of a meeting held on April 13, in which it calls attention to the need of a special hospital for inoperable cases of cancer to be directly under the control of the commission, and unassociated with any other hospital. The purpose of the proposed hospital would be to bring the laboratory workers into close touch with human patients, and to give to incurable cases of cancer the benefits of any new discoveries which hold out hopes of effecting a cure. The plan proposes the building of a hospital of twenty-four beds on the grounds of the Harvard Medical School.

The Jefferson Medical College has purchased the building formerly occupied by the Pennsylvania College of Dental Surgery at Eleventh and Clinton streets, Philadelphia, and will utilize it for laboratory purposes.

Bequest to Hospital.—By the will of the late Estelle P. Melville of Philadelphia, wife of Rear Admiral Melville, the sum of $15,000 is bequeathed to the Episcopal Hospital for the endowment of free beds to be known as the Anna Virginia Polis Bed, the Melina S. Polis Bed, and the Estella S. Polis Bed.

Philadelphia Tuberculosis Hospital.—The following physicians have been appointed to the visiting staff of the tuberculosis hospital recently opened by the city at Ryberry: Dr. Ward Brinton, Dr. Samuel Rhoads, Dr. A. C. Morgan, Dr. Daniel M. Hoyt, Dr. E. J. G. Beardsley, Dr. J. V. C. Roberts, Dr. J. Clinton Foltz, and Dr. J. Willoughby Irwin.

The Yale Medical School.—Dr. Herbert E. Smith, for twenty-five years dean of the school, has resigned. Dr. George Blumer, professor of theory and practice of medicine, will succeed him as dean.

"The American Journal of Physiologic Therapeutics" is a new journal which has made its first appearance with the May number, under the editorship of Dr. Henry R. Harrower of Chicago. The scope of the journal includes hydrotherapy, dietetics, spondylotherapy, massage and manual movements, electrotherapy, radiotherapy, phototherapy, and vaccine and serum treatment. The editorial offices are at 72 Madison street, Chicago, Ill.

The Medical Library Association will hold its thirteenth annual meeting at the Southern Hotel, St. Louis, June 6 and 7, 1910. The *President* of the association is Dr. John H. Musser of Philadelphia, and the *Secretary* is Miss M. R. Charlton of Montreal, Canada.

New York Academy of Medicine.—Professor E. Grawitz, Professor of Pathology at the University of Berlin, will deliver an address before the New York Academy of Medicine on the evening of Thursday, October 6, 1910, on "The Definition of Pernicious Anemia and Its Treatment." Prof. Grawitz will speak in English.

The Iowa State Medical Society held its annual meeting in Des Moines, May 20, 1910, and elected the following officers: *President,* Dr. M. N. Voldeng of Cherokee; *Vice-Presidents,* Dr. W. G. Egloff of Mason City, and Dr. H. A. Minassian of Des Moines; *Secretary,* Dr. V. L. Treynor of Council Bluffs; *Treasurer,* Dr. W. B. Small of Waterloo; *Councilors,* Dr. C. A. Boice of Washington, Dr. G. E. Crawford of Cedar Rapids, Dr. G. C. Moorehead of Ida Grove.

The State Medical Association of Texas, meeting at Dallas, May 12, 1910, elected the following officers: *President,* Dr. John T. Moore of Houston; *Vice-Presidents,* Dr. A. B. McReynolds and W. A. Harper of Austin; *Secretary,* Dr. Holman Taylor of Fort Worth; *Councilors,* Dr. D. R. Fly of Amarillo, Dr. W. A. King of San Antonio, Dr. H. J. Hamilton of Laredo, Dr. James A. Hill of Houston, Dr. A. C. Scott of Temple, and Dr. L. Y. Turner of Daingerfield; *Delegates to the American Medical Association,* Drs. W. B. Russ of San Antonio and J. S. Turner of Dallas.

Obituary Notes.—Dr. George Frederic Barker, Emeritus Professor of Physics in the University of Pennsylvania, died at Philadelphia, on May 24, at the age of 75 years. He was graduated from the Albany Medical College in the class of 1860. In 1863 he was elected professor of chemistry in Wheaton College, later professor of chemistry in the Western University of Pennsylvania, and still later assistant professor and then professor of physiological chemistry and toxicology in Yale University. He was elected to the chair of physics in the University of Pennsylvania, in 1872, serving until 1900. He was a member of many learned societies.

Dr. Edwin Forrest Preston of Amityville, L. I., died at his home, May 26, 1910, aged 70 years. He was a graduate of the New York University Medical College in 1870.

Dr. Anneillio Preziosi of Stamford, Conn., died May 23, 1910. He was a graduate of the College of Physicians and Surgeons of Baltimore in 1909.

ROBERT KOCH.

IN MEMORIAM.*

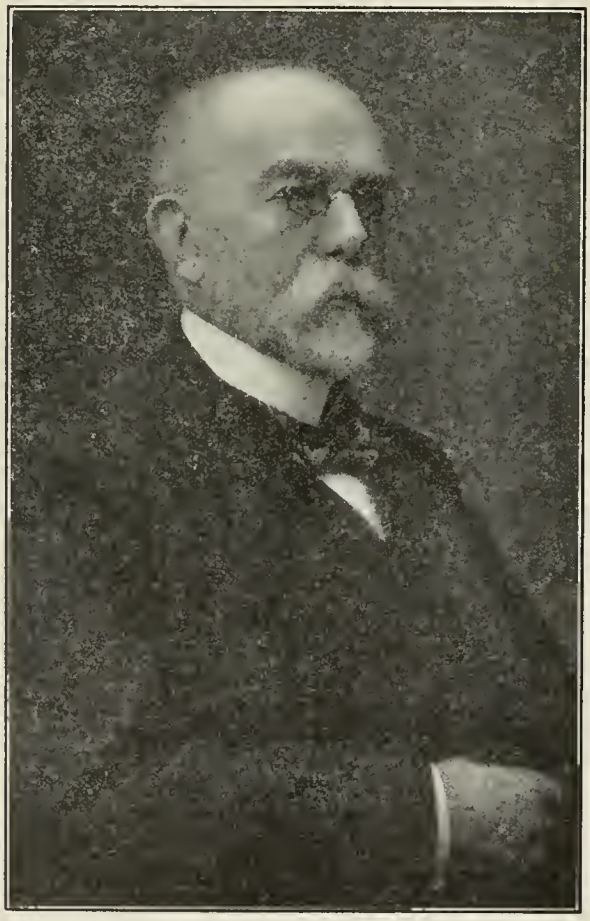
By S. ADOLPHUS KNOPF, M.D.,

NEW YORK,

PROFESSOR OF PHTHISIOTHERAPY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

I DO not believe that I can begin my task to-day in the capacity of a teacher of phthisiotherapy without first paying a tribute to the greatest of all teachers in tuberculosis science. Robert Koch, the discoverer of the bacillus of tuberculosis, died yesterday afternoon (May 27) from a cardiac affliction at Baden Baden, whither he had gone in search of health. I know that you will gladly pause with me in our usual work for a few moments to listen to a brief account of the life of this man whom we all acknowledge to have been the greatest figure in modern medical science.

Robert Koch was born of well-to-do parents in Klausthal, Germany, December 11, 1843. After



finishing his preliminary education, he studied at various universities in Germany. Prior to his graduation at Goettingen, in 1866, he distinguished himself as the winner of a prize essay on an anatomical subject ("The Nerve Ganglions of the Uterus"). His first epoch-making discovery was that of the spores of the anthrax bacillus in 1876. His monograph on "Researches in the Etiology of Surgical Infections" in 1878 is still considered a standard work. Then came that great immortal discovery of the bacillus of tuberculosis in 1882, the discovery of the comma bacillus of Asiatic cholera in 1883, and the discovery of tuberculin in 1890. His more recent works on tropical malaria, sleeping-sickness, typhoid fever, and on the differentiation of bovine and human tuberculosis, are most valuable contributions to our knowledge of these diseases.

Few men have traveled as much and as far as Koch in order to be helpful in the combat of endemic and epidemic diseases. In 1883, at the time when a fearful epidemic of cholera decimated the population of Egypt, he went thither to study the causes and prevention of the disease. In civilized countries we are now in a position, by early and accurate diagnosis, quarantine, proper hygiene, and sanitation, to reduce the mortality from cholera to a minimum, and we owe the victory over this once so prevalent and fatal plague to Koch. Because of his extraordinary thoroughness as a bacteriological diagnostician, hygienist, and sanitarian, the German Government availed itself of his services every time there was a local epidemic of a serious infectious disease anywhere in the Empire.

*An address delivered May 28, 1910, prior to the commencement of the usual Saturday clinic on pulmonary diseases at the New York Post-Graduate Medical School and Hospital.

In the year 1906 Koch extended his researches far beyond his native land, going to South Africa, East India, and later on to German East Africa. In Africa he was able to discover a vaccination method as protection against the rinderpest. He studied the bubonic plague and other tropical diseases where they were endemic, and wherever he went he instituted such prophylactic and sanitary measures as to bestow lasting benefit on regions which were formerly devastated by seemingly unconquerable diseases and plagues.

Without minimizing any of the great master's discoveries or scientific labors, I do not believe I commit any error in saying that the communication which he made, on the evening of March 24, 1882, before the Physiological Society of Berlin, entitled, "The Etiology of Tuberculosis," was his most important contribution to medical science. When we bear in mind the sociological aspect of the disease whose etiological factor and primary cause were revealed to the world in this communication, well may we say that the 24th of March of 1882 was a "red-letter-day," to be forever remembered in the annals of medical history and human progress. Thanks to Koch, tuberculosis can be considered today a preventable disease. It was he who showed us where to find the cause of this scourge of mankind, and how to combat it. Because Koch taught us that the infectious agent—the tubercle bacillus—was alone responsible for the disease, and could be found in the pulmonary secretions of the consumptive, and that, if carelessly deposited, the dried and pulverized sputum containing the germ could be inhaled and ingested by others, producing the disease anew, we have virtually become masters of what was once considered not only the most prevalent, but the most fatal affliction of man and beast. Through the discovery of the tubercle bacillus alone Koch has made mankind his everlasting debtor. When today, as is the case in some localities in America, in England, and in Germany, the mortality from tuberculosis has been reduced to well-nigh half of what it was prior to Koch's discovery and isolation of the tubercle bacillus, the saving of life, the lessening of physical suffering, this diminution of the social misery which accompanies all diseases of the masses, is all due to Robert Koch. The financial

gain which has accrued to countries and communities which have followed Koch's teachings regarding the prophylaxis of tuberculosis in man, by preventing costly invalidism, saving countless valuable lives, and retaining them as bread-winners and useful citizens, is beyond human calculation. By his discovery of tuberculin he has added an invaluable agent to our methods of early diagnosis of tuberculosis in man and beast, and given to our armamentarium in tuberculotherapy a very important remedy. Through the tuberculin test in cattle the weeding out of tuberculous animals has been made practical and an incalculable benefit bestowed upon animal industry and the dairy business; and possible sources of tuberculous transmission from beast to man have been reduced to a minimum. The same may be said of Koch's discoveries regarding anthrax and rinderpest. The vast and inestimable good this one man has been able to bestow upon mankind by his scientific labors will forever remain unique in the history of human possibilities.

The life of Robert Koch should serve as an inspiration, not only to us who are his humble disciples, but to all mankind. The motto of his first scientific communication was "nunquam otiosus" (never idle), and he had adhered to it up to his altogether too early death. In scientific research, in constant work to combat disease and make mankind healthier and happier this great man found his reward.

Honors and distinctions of all kinds have been bestowed upon Robert Koch. The German emperor made him recently a privy councillor with the title of Excellency. He was honorary professor of the University of Berlin and had honorary titles from many German and foreign universities. He was an honorary member of nearly all the great scientific societies of the world, including the New York Academy of Medicine and the German Medical Society of New York. He had been decorated by nearly all the monarchs of Europe and also by the Emperor of Japan. He was awarded the Noble Prize for physiology in 1905.

Those of us who have had the privilege of having been his pupils or having met him, will recall his dignified appearance and the thoroughness with which he discussed any subject, and the firmness with which he defended any theory or fact which he thought right. On many occasions he has paid tribute to the thorough antituberculosis work done in America and particularly in New York, and has held up New York City as a model to other countries in this respect. In a recent letter to me he paid a tribute to our nation at large by saying: "The American people seem to me particularly susceptible to popular antituberculosis education."

You will pardon me if I express here in conclusion my personal feeling on the loss of this great man, for on more than one occasion have I received kind and encouraging words from him for my modest labors. Let us then remember him with gratitude, look upon him as the great master and leader, and strive to emulate him by doing our best as physicians and men, and when the time comes—and it must come some day—when through your labors and through our children's labors and through better social conditions, tuberculosis as a disease of the masses and as an endemic affliction will no longer be with us, the name of Robert Koch will stand out as the one man who had shown us the way to victory.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

KING EDWARD'S DEATH—PLACENTA PRÆVIA AND CESAREAN SECTION—CEREBRAL TUMOR REMOVED—WEBER-PARKES PRIZE ANNOUNCED FOR 1912—HEALTH EXHIBITION—COST OF LUNATIC ASYLUMS—OBITUARY.

LONDON, May 13, 1910.

THE news of our national bereavement reached you as soon as it did a large number of people on this side. We know this from the messages of condolence, sympathy, and mourning which so promptly arrived. To the general public here King Edward's death seemed more startlingly sudden than it really was on account of his activity up to the last. Moreover, he had quite recently recovered from a bronchial catarrh, and the rumor that he had taken a fresh cold, started by his not meeting the Queen on her arrival on Thursday, did not attract as much attention as it otherwise might have done. Accordingly an immense number of people only learned that the King was really ill on opening their morning papers on that fatal Friday morning. The bulletin was, of course, understood by medical men, though the public were less able to grasp its significance. The second one clearly indicated danger, but so rapid a fatality was not thought of. In my own room doctors expressed grave apprehensions; one spoke of the emphysema which it was known to many existed; so, too, pneumonia was held to be probable. Glycosuria was the suggestion of another, and all knew of the strenuous life led by the King and his past illness. Nevertheless, the shock was great to read the next morning that the end had come that very night.

The official authorized report of the last illness was published yesterday, signed by Sir F. Laking, Sir J. Reid, and Sir D. Powell. It shows that on Tuesday they were anxious that the King should rest; but he kept up and gave audiences, though in the evening he admitted that he felt ill, and during that night he had severe attacks of dyspnea. On Wednesday morning his temperature was 99° and the pulse 90, but he again gave audiences. At the evening consultation there was fine crepitation, "imperfect entry of air at both bases and the right side of the heart was embarrassed." On Thursday there was no improvement; dyspneic attacks and increased cyanosis threatened cardiac failure. That evening the first bulletin appeared after it had been submitted to and modified by His Majesty. The Friday morning's bulletin spoke of "grave anxiety," and the third issued in the afternoon said the "condition is now critical." In fact, consciousness had then begun to fail and "never completely returned." The end came after "a prolonged period of perfect calm."

The place of cesarean section in the treatment of placenta prævia was freely discussed in the Obstetrical Section *apropos* of a paper by Dr. Henry Jellett. He thought the usual idea of the mortality of the condition was rather exaggerated, for out of 138 cases at the Rotunda only five died, and of these four were either moribund from hemorrhage or in a state of advanced sepsis on admission. They were treated by polar version. Only three conditions make this impossible; (*a*) rigid undilated cervix; (*b*) where after rupture of membranes the uterus has contracted upon the fetus; (*c*) where the presenting part is fixed in the pelvic brim. Having dealt with each of these, he concluded there was no place for cesarean section in non-complicated placenta prævia. What was really required was an advance in our methods of treating the collapse of hemorrhage and of the shock and of combating infection.

Dr. Macnaughton Jones, president, had taught his students that the two most important methods were bipolar version and plugging. He compared recent statistics by Moncalvi, Pinard, and Krönig, and they all seemed to show that cesarean section could very seldom, if ever, be called for. The accessory conditions must be carefully considered in judging of statistics.

Dr. Herbert Spencer had only seen one case in which he thought it justifiable; but it would be in very rare cases of central placenta prævia at or near full term with undilated rigid cervix. He refers to Krönig and Selheim's twenty-six cases of cesarean section without a death.

Dr. Champneys held that in these cases the child must take its chance. The best obstetrical weapons were nature's—in these cases bipolar version.

Dr. C. E. Purslow said efficient plugging gave good results. Post-partum hemorrhage was a danger against which cesarean section would not guard, unless the uterus was removed at the same time.

Dr. Armand Routh agreed with Dr. Jellett that in ordinary cases there was no place for cesarean section, although it might be justifiable in rare instances with rigid cervix undilatable.

Dr. Gow had performed the operation in one case, both mother and child surviving. When post-partum hemorrhage occurred it might be from lacerations produced in extracting the child.

Dr. W. S. A. Griffith had done cesarean section once, mother and child both living. It was only when there was great danger to both, as well as difficulty, that the operation could be justified.

Mr. Litler Jones, at the Liverpool Institution on the 28th, showed a patient from whom he had removed a cerebral tumor weighing over four ounces. Paralysis of left arm and leg, with twitching of toes, had been present seven months before the operation. Also double optic neuritis and slow cerebration. Mr. Jones operated in two stages and much relief followed the first. He was able to differentiate the tumor from the cerebral substance by palpation. There was profuse hemorrhage from the longitudinal sinus, but this was controlled by plugs of gauze gradually replaced by smaller ones. A fracture of the neck of the femur from a fall has since been sustained, but the patient has gained strength again, the optic neuritis has disappeared, and the normal mental condition returned. Dr. Glynn called the growth hemendothelioma. Mr. Parker approved operating in two stages and thought the plan had contributed to the good result.

The Royal College of Physicians announces that the next award of the Weber-Parkes prize of 150 guineas and a silver medal will be in 1912, and the adjudicators have selected as the subject of the essay "The Influence of Mixed and Secondary Infections Upon Pulmonary Tuberculosis in Man, and the Measures, Preventive and Curative, for Dealing with Them."

The second Municipal and Public Health Exhibition has been open all this week, closing to-morrow. It is thought to be an advance on the first, though that was very successful. Numerous exhibits of daily utility and object lessons of what is being done by municipalities for promoting health and sanitation have been the features of the undertaking. Conferences of and addresses to delegates from local authorities have been held in the afternoons and popular lectures given in the evenings.

The annual report of the Asylums Board, issued this week, shows diminished expenditure, though the daily average of inmates in its establishments was in excess of the previous year. The saving amounts to over £44,000—a most satisfactory statement for the ratepayers. During 1909 the admissions to the fever hospitals were 22,646, the deaths 1,035. In the imbecile asylums 7,724 had been under care. The removals by the board's ambulances numbered 47,613, of which 5,952 were found to be non-contagious.

In reference to the cost of asylums, those of the County Councils do not compare well with those of the Metropolitan Board. A protest was raised on Tuesday at the Surrey Council. Sir John Brunner declared that the extravagant cost of lunatic asylums was a growing scandal. Palatial buildings had no curative effect on the inmates—rather were an oppression on their minds. It was mockery to take people from narrow and confined quarters and keep them in cold-looking, stately buildings. People accustomed to living at an expense of £30 per head were being provided for at a cost of £300. As to those above the pauper class, they ought not to be maintained at the cost of the ratepayers. Their friends would not let them if their names were made public.

The death of Major K. M. Cameron, R.A.M.C., from tetanus, after a cycle accident in which he received a slight cut on his knee, necessitated an inquest, held at the Cambridge Hospital, Aldershot, in which he died, and to which he was surgeon. He was previously staff surgeon at the Indian headquarters. He served in the Northwest frontier operations in 1897, being attached to the Tirah expedition, receiving for his services in the campaign the medal and two clasps. He was sent to South Africa in 1899 and took part in the operations in Natal and in the defense of Ladysmith. Later he was in the Transvaal and was mentioned in dispatches, received the Queen's medal with four clasps and the King's medal with two clasps. Major Cameron was only 41 years of age. He was buried on Wednesday with military honors at Aberdeen, of which he was a native.

The death of Dr. Gordon-Stables occurred on the 10th inst., within a few days of reaching his seventieth year. He was better known as a writer of tales for boys than as a doctor. He had published above 150 and was commonly called the "boys' novelist." He graduated M.D. and C.M. at Aberdeen in 1862. He joined the Naval Medical Service, from which he was invalided after nine years. He then traveled in Africa, India, and America, and took part in two Arctic expeditions. For the last twenty-five years he has been utilizing the material of his travels for the amusement and instruction of succeeding generations of boys.

Lieutenant-Colonel J. A. Anderson, M.D., has died in France at the age of 65. He took the L.R.C.S.I. and the M.D.R.U.I. in 1866 and entered the Army Medical Service the following year. He served in the Zulu campaign, 1879-1880, and was at the battle of Ulundi, was mentioned in dispatches, and recived the medal and clasp. He retired in 1887.

Dr. James Morris, Medical Officer of Health of Dunfermline, died on the 2d inst., aged 84. He qualified at the Glasgow faculty in 1849 and celebrated his jubilee in practice in 1899, when he gave interesting statistics of his career to the many friends who offered him their congratulations. Among other figures he told them he had been at 5,000 births, and among these he had 1,000 consecutively without a death. He had given chloroform to 10,000 persons without any accident. He was then attending the fifth generation of some of his patients. He continued to attend some until a few months ago, when his wonderful health began to fail.

OUR PARIS LETTER.

(From Our Regular Correspondent.)

THIRD INTERNATIONAL CONGRESS OF PHYSIOTHERAPY—NECROLOGY—HENNEQUIN, GREHANT.

PARIS, April 3, 1910.

PHYSIOTHERAPY is the study of treatment of disease by means of physical agents. Two congresses have been held, one six years ago at Liège and one three years ago at Rome. The third congress was opened on March 29 under the active presidency of the President of the Republic of France. Received by Professor Landouzy, Dean of the Faculty of Medicine of Paris and by the secretaries of the congress, Vasquez and Zimmern, and surrounded by the official delegates of the various foreign Governments which participated in the congress (England, United States, Brazil, Denmark, Chili, Bulgaria, Belgium, Germany, Hungary, Italy, and Greece), the President of the Republic opened the congress by an eloquent address. After having thanked the participants for their presence and welcomed all the strangers, President Fallières noted the importance of the rôle of physician and hygienist when they aid in preserving the entire country against epidemics which menace it, and which are arrested by wise measures initiated by them. Landouzy pronounced a discourse of high philosophical value, demonstrating the great importance of physiotherapeutic studies. The conception of the forces of nature made to serve as aids in therapeutics for an effective combat with sickness and old age should be the glory of the congress.

The President of the Republic then opened the important physiotherapeutic exposition which had been installed in the halls of the Faculty of Medicine. This exposition comprised at once a retrospect in which was shown all the resources of the art of healing in the form of natural agents which have been made use of since the earliest civilized times. The Greeks and Romans knew quite well and put into practice the usefulness of exercises, frequent baths, and life in the open air. Besides this, the modern physiotherapeutic exposition was divided into four classes: First, thermal stations; second, instrumentation of physiotherapeutics, electricity, massage, radiotherapy, thermotherapy, etc.; third, alimentary régime, dietetic products, hygienic institutes; fourth, all the works that have been written on physiotherapy.

Among the most important communications we notice that of Marcel Labbé on the "Dietetic and Physiotherapeutic Treatment of Obesity." The production of obesity always results from an excess of the ingesta

over the outgo of the organism; its treatment necessarily implies the increase of the outgo beyond the ingesta. This result is obtained by lessening the foods taken and increasing the energetic and calorific outgo. It is not necessary to grow thin suddenly; the reduction to be sought should be 200 to 300 grams per day, and the foods chosen should be such that they satisfy the appetite while they nourish as little as possible. The physical treatment of obesity includes gymnastics or moderate exercise, both regular and progressive. The life should be active, in the open air, and in a cold climate.

Talliens of Lausanne advocated fruit cures, in which grapes, lemons, and strawberries are utilized. Linossier, Vichy, also advocated the grape cure, which modifies the urinary secretion, increasing it in amount and in elimination of the mineral elements. The grape cure increases the appetite, favors intestinal exchanges, and has a tonic stimulant action upon the heart. The lemon cure gives good results in articular and muscular rheumatism. Dechlorurization has been used with the best effects by Widal of Paris, who was the creator of the dechlorurization method. In the practice of this method the daily use of the scales is of great service. Alimentary dechlorurization causes no damage to the organism, even if it is prolonged for months.

The treatment of deep cancers by radium has been studied by Dominici and Chéron of Paris. Thanks to the new perfection of the technique in the employment of a closed metallic tube with thick walls as a container for the radium salt, we may make use of the ultra-penetrating rays. This new apparatus is valuable for the treatment of deep tumors, being placed in the pathological spaces by introducing the tube into the thickness of the growth by a surgical procedure, which may be done by puncture, transmission, or rotation. Considerable amelioration can be obtained in cancers of the uterus, vagina, or rectum. From the discussion that took place it appeared that to-day we recognize radium as having a curative activity that is very important; it may act well in cases in which the *x*-rays have failed.

The comparative climatic influence of the sea and the mountains was presented by William Huggard of London. Mountain climates are stimulating and exciting. They are characterized by lowering of the temperature and lessened humidity of the air. Marine climates have the reputation of being sedative and calming, but there is nothing absolute in this matter, the factors being variable. The climate at the seaside has sometimes the characters of the land around, and sometimes of the sea. Hirtz of Paris demonstrated the sedative action of moderate altitude and lakes.

The alimentary régime for the tuberculous was studied by Rénon of Paris. Systematic, blind, obstinate superalimentation often gives lamentable results. The alimentary ration of each patient should be established according to the balance of his nutritive needs. Labbé and Vitry of Paris have vigorously demonstrated the uselessness of a régime too highly nitrogenous for the tuberculous. Leven drew the attention of his colleagues to the dyspeptic coughs which may be mistaken for tuberculosis.

Electrical treatment of infantile paralysis has been studied by Zimmern and Bordet of Paris. In infantile paralysis electrization is necessary, but it is necessary to adopt the technique of progressive electrophysiology.

The Congress of Physiotherapy ended on Saturday, April 2. In the closing session Landouzy thanked the strangers who had given their aid and announced that, as a result of the deliberation of the committee from each nation, the next Congress of Physiotherapy would be held at Berlin in two years, under the presidency of Professor His, with the aid of the German Government. His then took up the thread and in an address as delicate as it was perfectly given in French, invited the attendants of the congress to come to Berlin in two years, that is in 1912. The shorter interval between the congresses is necessitated by the occurrence of the International Medical Congress at London in 1913.

Surgery in France has just lost her most authoritative representative on the treatment of fractures by traction apparatus. Alone, without family, seeking neither place nor honor nor money, Jules Hennequin had never an ambition except to learn, to investigate for others, and to do good. He was a member of the Surgical Society for fifteen years, and was very sensible of the high moral recompense which was given him by the masters of surgery in Paris in making him their colleague, simple practitioner as he was, yet learned, patient investigator, and able inventor. The work of Hennequin is known to all the present generation, and his apparatus for fractures is described in every surgical treatise. His name has years ago traveled beyond our frontiers, and his death will awaken regret beyond the borders of the oceans. Member of the Surgical Society, Laureate of the Institute of the Academy of Medicine of the Faculty of Paris, he leaves numerous works, excellent apparatus, and the remembrance of a noble heart and a soul whose elevation was only measured by his modesty.

Grehant, professor of histology of the Museum of Natural History, director of the Laboratory of Research of the "Ecole de Hautes Etudes," member of the Academy of Medicine, died at the age of 72 years of a long and painful malady. His studies on the poisons of the air, the gas of the blood, oxide of carbon, finally the collection of his physiological researches, have given important results which have modified in many points the scientific theories, admitted, and have had important results, such as the experiments with reference to firedamp.

Progress of Medical Science.

Boston Medical and Surgical Journal, May 19, 1910.

Frequency and Dangers of Fibroid Tumors of the Uterus.—From the records of the Boston City Hospital E. B. Young analyzes the cases recorded at the institution up to January 1, 1910. His conclusions are as follows: (1) Fibroids of the uterus occur in from 7 to 16 per cent. of all adult females and in from 7 to 22 per cent. of all over thirty-five years of age. (2) The age at which fibroids giving rise to symptoms which demand their removal are most commonly encountered is shown by American statistics to lie between thirty-five and forty-five and by German figures between forty and fifty. (3) Fibroids may in the main be divided into three groups: (a) Fibroids of considerable size, nearly all of which produce symptoms; (b) fibroid polyps and submucous fibroids, which project markedly into the uterine cavity; (c) small and painless fibroids. (4) In fibroids of considerable or of large size complications and degenerations dangerous to life occur in at least 10.5 per cent., and for this reason alone the routine removal of all such tumors is indicated. (5) In submucous tumors and polyps, necrosis occurs in over 43 per cent. and the excision of all such growths is therefore indicated. (6) Small and symptomless fibroids are absolutely innocuous and of such frequent occurrence that they may be safely let alone. Such tumors, however, when met with in the course of operations for other conditions should be removed when feasible because there is always the possibility that they may increase in size.

Treatment of Constipation.—The views of M. V. Tyrode are expressed in this paper. He reviews the physiology of the gastrointestinal tract and traces the various foodstuffs out to their ultimate disposal. He then discusses treatment under the headings of diet, exercise, and baths, mental therapeutics and medicines, general and local. He says that the old division of these cases into atonic and spastic appears to him meaningless. The real question is, "Is there any inflammation in the gastrointestinal tract?" and ninety-nine times out of one hundred there is. In such cases the rational treatment is not to further irritate an inflamed mucosa by harsh cathartics nor by any rough diet, which will scratch the inflamed mucosa by vegetable residues, but rather to soothe the inflamed tissues and to allow healing by sparing them further irritation. His general idea of diet is to exclude all fibrous vegetables, salads, and fruits, graham bread and rough cereals, smoked and salted meats, also excess of salt, spices, acids, tea, and coffee. Most cases should take considerable outdoor exercise. Systemic abnormalities should be corrected with the proper remedies. We should try to add to the diet non-irritant substances which are with difficulty absorbed and have such a consistency as to keep the feces from hardening and losing their proper amount of water. Valuable for this purpose are fats with a low boiling point, as olive oil and cream, and also liquid petroleum. Another ingredient which is absorbed with difficulty and makes a soft jelly in the intestines by withholding water is agar-agar. In his own experience liquid petroleum has proved the more successful. If some additional laxa-

tive is necessary he prefers the heavy oxide of magnesia given either in capsules or stirred in milk after meals.

The Statistics of Cancer in Massachusetts for the Year 1905.—This study has been made by W. F. Whitney, who finds that in the State in question the deaths from cancer for each million persons living over thirty years are increasing at an average rate of 120 every five years; that this rate of increase is not uniform and that an abnormally low rate is immediately followed by a very high one. His findings are presented in tabulated form. There seems to be little doubt now, he says, of a steady increase, which cannot be explained by improved registration and more careful diagnosis. Furthermore, the possibility that we were at the crest of a "cancer wave" in 1895 has not been realized.

New York Medical Journal, May 21, 1910.

Possibly a Way for Cure of Seminal Vesicle Infection, with Case Reports.—Three cases are reported by C. E. Barnett, in which treatment with autogenous vaccines was employed. They indicate that the bacterins are beneficial and, comparing the stock with the homologous ones, the writer thinks that the autogenous are the ones of choice, for the degree of virulence will be equalized in each individual subject. The mixed infection will also be counteracted. While it takes many cases definitely to prove a given point, he is convinced of the value of this point of the treatment showing at least a possibility of removing the infection in the vesicle, even of removing pathologically changed tissue left behind. He believes that it would be wise for urologists to add autogenous bacterins to their armamentarium in their fight against vesicular infection.

Sensitization in Cancer.—J. W. Vaughan lays down the following rule: Any foreign protein injected into the tissues of a living animal sensitizes that animal to that protein so that a second injection of a sufficient quantity of the same protein after a similar lapse of time is fatal to that animal. When we attempt to apply this subject of specific sensitization to cancer we are confronted by a problem slightly different than is the case in foreign proteins. If we believe that the cancer cell is the active parasite itself, then we are dealing not with a foreign protein but with an altered autogenous protein, and the fact that the body cannot be sensitized to its own body cells must be taken into consideration. While the amount of work that I have been able to do upon this subject during the past three years has not been of sufficient volume to arrive at any definite conclusion concerning this fact, yet one case has progressed remarkably well under the use of the residue from a large round-celled sarcoma obtained from a different patient, who herself has been but little benefited by the use of the autogenous residue. In contradistinction to this is the undoubted fact that a few cases of malignant disease have retrogressed and entirely disappeared. This can best be accounted for by stating that the body, in splitting up the cancer cell, has formed a sufficient percentage of specific ferment to take care of the entire number of cancer cells present. Again, cancer cells are altered normal cells, and hence might be classed as foreign proteins.

Three Years' Experience in General Practice with Bacterial Vaccines.—G. H. Sherman considers this subject in connection with appendicitis, diseases of the respiratory system, acute articular rheumatism, subacute and chronic rheumatism, arthritis deformans, vertigo, staphylococcus infections, and eczema. Illustrative cases are given under each of these headings. He says that in all his experience he has had cases in which no results were obtained, but none in which any bad result could be attributed to the vaccines. An important point in the use of these vaccines is that the earlier they are used in the course of an infection the better the results. They should be used as primary, not as last-resort remedies. As long as physicians try everything else first and use bacterial vaccines as a last resort, disappointments will be met with. As a whole, the author's experience with bacterial vaccines has been eminently satisfactory. The achievements of regular medicine and aseptic surgery in preventing disease and relieving human suffering cannot be questioned. Isolation and disinfection have suppressed and even eradicated contagious disease. Sanitary regulations of water and food supplies have been of inestimable value in preventing cholera, typhoid fever, and other diseases. The discovery that the mosquito conveys the organism causing yellow fever and malaria has brought these diseases under control where they were once most prevalent. Bubonic plague has been traced from the flea of the rat to man, and is being prevented by destroying the rat. Diphtheria, one of our most fatal diseases, by the early and liberal use of diphtheria antitoxin has become one of the most easily cured, but the diseases caused by the pathogenic bacteria most about us, the diseases caused by the pus group of cocci, has been least amenable to our treatment. Here is where bacterial vaccines come in as a new hope.

Bacterial Treatment of Malignant Disease.—H. A. Duncan gives the summaries of the histories of ten cases. The results were as follows: Cancer of the rectum, inoperable, cured, normal condition after ten months; cancer of uterine body, cured, no trace after seven months. These cases did not occur in the author's practice. The following did: Inoperable cancer of the cervix uteri, no improvement; cancer of breast with metastases to femur and clavicles, no improvement; pimple on the cheek, epithelioma, cured; cancer of liver, no improvement; cancer of rectum, no improvement; sarcoma of rectum, no improvement; cancer of rectum, indefinite; cancer of breast, no improvement; inoperable cancer of cervix uteri, another similar case, no improvement; still another, no improvement. Given a patient in which the general health has not been interfered with, where all the resisting powers approximate the normal, there is no reason why the index to some particular organism such as the *Micrococcus neoformans* should not be raised by correct therapy. In three cases of advanced carcinoma the index was markedly improved after the sloughing mass had been removed. A study of the index to other organisms than the *Micrococcus neoformans* in such cases would help to determine whether this resistance is general, due to improved systematic conditions or specific in the case of the *Micrococcus neoformans* alone. If it proves specific there is but one conclusion to be drawn, viz., that the *Micrococcus neoformans* is a causative factor in malignancy. Again, given a case in which the patient is rapidly succumbing to the disease, we would expect her body resistance to weaken to any one or all microorganisms. So it cannot be argued that because a cancer patient has a low index to *Micrococcus neoformans* the *Micrococcus neoformans* has any direct connection as a causative factor.

Journal of the American Medical Association, May 22, 1910.

Preparetic States.—C. L. Dana holds that certain cases of paresis may yield to specific treatment if thoroughly used in the earliest stages. He is led to repeat his statements because they have been misunderstood, some having jumped to the conclusion that he had held that fully developed paresis could be cured, and also because his view as to the essential unity of nervous syphilis and parasyphilis had been confirmed by the discovery of the spirochete and the evidence of its activity by the Wassermann and other tests. He points out the unreliability of the distinctions which have been attempted to be made between paresis and cerebral syphilis. It follows that if there is an essential underlying unity between true paresis and "leutic neurasthenia," "pseudoparesis," "nervous syphilis," and what he calls the "preparetic state" there is no reason to suppose that if we can cure one we cannot also forestall or even cure the others. It has been his experience to see a number of cases which confirm this view, and he puts on record the final history of the five cases he reported five years ago, and adds a number of others. These show that what he is apparently justified in calling incipient paresis may be sometimes arrested or even cured. If the history, he says, of cases of paresis could be traced back in all instances to the first beginnings, he believes that in a good many instances proper medical treatment might have kept them in check. The onset of a parasyphilis, Dana says, occurring in persons who have had infection, takes place in the following different ways: "1. Acute symptoms of syphilitic exudates in the brain, ending promptly or later in paresis, or ending in cure, with or without mental symptoms, or ending in some deterioration with final serious cerebral vascular changes. 2. Acute mental symptoms, maniac or melancholic, ending in cure or paresis. 3. Tabetic and paretic symptoms, ending in taboparesis or in tabes with arrest of paresis. 4. Insidious mental and physical deterioration ending in paresis." The above conditions may or may not end in paresis, depending on treatment, the constitution of the patient and the intensity of the infection. Often

they go on till nearly every symptom of paresis appears and even then may be arrested. This is what he means by the cure of early paresis.

Hypertension.—J. L. Miller reports results of his studies of high blood pressure, his observations having been confined to the direct effects on systolic blood pressure of sweating and venesection, and the various vasodilators. In most of his patients the urinary findings pointed to interstitial nephritis, but this was not always the case, and, as that condition may sometimes exist without urinary symptoms, no attempt was made to classify the nature of the hypertension etiologically. The Stanton sphygmomanometer with a wide armband was used throughout and several trial readings were made before putting the patient to the test to avoid emotional disturbance. Care was also taken to select patients who could have gained no tolerance of the drugs employed and these latter were also first tested by animal experiment. The conclusions are given as follows: "1. In moderate doses active preparations of nitroglycerin and sodium nitrite temporarily reduce the blood pressure in the majority of cases of hypertension. 2. Erythrol tetranitrate causes a more prolonged reduction in blood pressure than nitroglycerin or sodium nitrite, but so frequently causes severe headache that its clinical value is much impaired. 3. Headache after any vasodilator does not mean that we are getting the physiologic effect in the sense that the blood pressure is reduced, as the headache may appear independently of any change in pressure. 4. A patient's blood pressure may be decidedly affected by one of these vasodilators and uninfluenced by another. 5. Occasionally the blood-pressure of patients with marked hypertension may show very marked fluctuations without apparent cause. 6. A sweat reduces hypertension less than a moderate dose of vasodilators. If sweats are given daily, a rather marked reduction of pressure lasting throughout the day is observed not infrequently. When the sweats are discontinued the blood pressure soon returns to its previous level."

The Father of the Pharmacopœia.—J. M. Eager gives an account of Dr. Lyman Spalding, who was the originator of the United States Pharmacopœia. He was born in Cornish, N. H., in 1775. His father was a soldier in the Colonial and Revolutionary Wars. In 1797 he graduated from Harvard Medical School and for three years afterward assisted Dr. Nathan Smith in his lectures on chemistry and materia medica in the then newly established Dartmouth Medical School. In 1799 he settled for practice at Walpole, N. H., but removed in a few months to Portsmouth, where he remained until 1812, taking a post-graduate course of four and a half months, however, in Philadelphia, and one month in the College for Physicians and Surgeons in New York, in the year 1809. He was also post surgeon at Fort Constitution, Portsmouth, for ten years, from 1802 to 1812. Later he was professor of anatomy and president of the Fairfield, N. Y., Medical School, later incorporated as the College of Physicians and Surgeons of the Western Division of New York State. His connection with the Fairfield school continued until 1817, but in the later years he settled in New York. He broached the plan of a national pharmacopœia in 1817 and surrounded himself with a sufficient corps of collaborators, he himself being chairman of the committee on publication. In this work he journeyed between New York, Boston, Philadelphia, and Washington. The Pharmacopœia appeared August 15, 1820, having been printed, both in English and in Latin, under the title of the Pharmacopœia of the United States of America, and was announced as issued by the authority of the medical societies and colleges. Immediately on the completion of the Pharmacopœia he proposed before the New York Medical Society a revision of the code of ethics, but before he could accomplish this, in the spring of 1821, he suffered an accidental injury which ultimately caused his death on October 30 of that year. His demise occurred at Portsmouth, where his relatives lived. Before his time the London and Edinburgh Pharmacopœias were in use in this country, together with special works valid in certain States of the Union.

Nonspecific Urethritis.—Joseph Hume says that there are two types at least of nonspecific urethritis: 1, acute in character, following sexual congress after a regular incubation period, running a well-marked clinical course, and favorably influenced and easily cured by proper treatment; the other chronic from the beginning, sometimes following exposure like the other, but with an irregular incubation period, with urethral lesions which from their pathologic picture must have taken months or years to develop, and showing no tendency toward self-limitation, being resistant to treatment and sometimes incurable. The former class he calls cohabitative, sexual, or infective urethritis; the latter autoinfective or autogenous, both forms being nonspecific. The former class is comparatively infrequent, and has a tendency to a slightly longer incubation period than true gonorrhea, the infection being milder in character. A case is reported. In 11 cases the infecting organism was studied. In 5 cases Gram-positive cocci alone were noted; in 5 cases bacilli alone were found, 4 Gram-positive, 1 Gram-negative, the latter being the colon bacillus. The other has not been recognized by name. In one case the staphylococcus was also present. The other form is probably not often observed until some suspicion arises, and then it is found to be not new at all. It is frequent in medical students, as has been observed by Waelsch. Hume seems to consider a long foreskin as an etiological factor in these conditions, as rendering the urethra less resistant to infective organisms. The prognosis of this autoinfective type is not so favorable. There is often a well-developed localized fibrosis in the urethra and the prostate is often infected. It is best treated by circumcision, prostatic massage followed by intravesical irrigation and hot rectal douches if the prostate is involved. In many of the cases the patients are made neurasthenic without recognizing the cause. The preexistence of such conditions naturally influences the course of true gonorrheal infections and may account for the perniciosity of some first cases. Cases of this kind are also reported, and tabulated statements showing the contrasted clinical pictures of the two forms are given. Many of them are not of a sexual origin and will explain the origin of many cases of obscure prostatic or vesicular infection. The practice of circumcision should be encouraged as a means of preventing autogenous urethral nonspecific infection.

Tonsils and Adenoids.—J. W. Jervey argues for the normal function of the tonsils, the swelling of which he considers to be often purely a compensatory hypertrophy. The majority of cases of recurrence of quinsy he has observed have been with the so-called submerged and ragged tonsils. These call for operation, which, however, he thinks, is too frequently done in case of the swollen or protruding tonsils which often cause no trouble. In the case of adenoids also he says a small growth in Rosenmüller's fossa is more potent for mischief than a much larger one in the vault or posterior pharyngeal wall not causing obstruction or irritation. In the absence of the latter he never removes a growth in the vault or posterior wall, but he always sees that the fossæ are clear. If the tonsils were always as bad as some seem to think, they ought to have disappeared in the course of evolution by this time.

The Wassermann Reaction.—W. J. Heimann proposes a method of reporting the Wassermann reaction similar to the blotting-paper hemoglobin test. We have determined what intensity of color in hemoglobin represents 100 per cent., and have reconstructed our conceptions of weaker concentrations by numbers accordingly. He describes the Wassermann test and says that the gradations between the two extremes of total binding of the complement and total hemolysis are infinite; every man has his own system of recording them. He uses graduated centrifuge tubes and, counting total hemolysis as zero and 1/20 c.c. of erythrocytes in bulk, or the maximum amount as 100, by comparing the volume of surviving erythrocytes according to the scale and recording the result in per cent., one immediately has a quantitative idea of the reaction. Thus if 1/40 c.c. of erythrocytes are left the reaction is 50 per cent.; if 1/30 c.c., 66.6 per cent. He gives a table showing the advantages of this method in actual practice and describes the appearances in a test tube in which the reaction has been made after from sixteen to twenty-four hours have elapsed. With a negative reaction we have a clear wine red fluid; in a strongly positive test the red cells lie heaped at the bottom and above them the fluid is pure white. If the test be positive but weaker, the cells are below and the supernatant fluid containing dissolved hemoglobin is pink, salmon-colored, deep red, etc., according to the amount of hemoglobin in the solution. The weaker the reaction the deeper the intensity of the fluid and the smaller the number of corpuscles. These differences, expressed mathematically, become definite and objective instead of subjective and vague, as they have been heretofore. To procure the results in the table, he obtained the re-

action by introducing 1 c.c. of washed sheep erythrocytes in a 5 per cent. suspension and 1 c.c. of a solution of rabbit serum of known hemolytic titer, the rabbit having been immunized to the aforesaid red corpuscles. After sixteen hours he shook up the contents of the tube, centrifuged for two or three minutes by electricity, and noted what part of 1/20 c.c. of corpuscles remained and calculated the percentage.

The Lancet, May 14, 1910.

A Case of Blackwater Fever.—The history of this case under the care of D. G. Marshall was that of a man who had lived in Africa, returning later to Edinburgh. He had had several attacks of malaria, all slight, while in Africa, and a few months after his return a severe attack, lasting six days, after which he began to improve. He presented the usual features of this disease, which offered the not unusual feature of occurring some time after the man had returned from a malarial environment. During the slight attacks in Africa he had taken but little quinine. The author says that, concerning the influence of this drug in setting up his severe attack, it is to be noted that, having felt out of sorts for a few days, during which time he was probably suffering from the disease, he took a large dose of quinine and developed in a few hours a high temperature with hemoglobinuria. On previous occasions the drug had cut short the febrile attacks and it is impossible to avoid thinking that repeated chills and the large dose of quinine were the active agents in setting up the severe attack. There is much difference among the profession in regard to giving more quinine in such patients. Some regard it as curative, others as dangerous. The author finds the safest course to follow is a middle course, according to the following rules: (1) If malarial organisms are found in the blood, the remedy should be given. (2) If the parasite is not found in the blood or if there is any doubt, as, for example, where the microscopic examination is impracticable, the drug should not be given. Following these rules in his own case, as examination for the parasite in the blood was negative, the remedy was not given. When it is used the hydrobromate or dihydrochloride should be preferred, as the ordinary sulphate often produces hemoglobinuria. The remedy should be employed in fractional doses.

Modern Methods of Delivery in Contracted Pelves.—E. H. Tweedy says: (1) Induction of premature delivery is never advisable. (2) Perforation is not permissible unless the child is dead. (3) Turning should never be employed as a treatment for contracted pelves, but may still be performed for complications of labor, such as prolapse of the cord when associated with contractions of the first and second degree. (4) In the greater degrees of contraction time should not be wasted in an attempt to obtain natural delivery. (5) On the other hand, in lesser degrees ample time should be given the woman to enable her to deliver herself if possible. Eight or ten hours may be necessary for the moulding of the head and intervention should not be considered until there are evidences of maternal or fetal distress. Once fetal signs of distress are evident, there should be no delay in delivery. (6) High forceps should never be applied until all arrangements are perfected for an operation to enlarge the pelvis. It is, in the author's opinion, a pity to proceed to the latter expedient until forceps have been tried tentatively. It must be confessed that they occasionally accomplish their purpose under the most unfavorable circumstances. Finally in these, as in all other obstetric operations, the best results cannot possibly be obtained if rubber gloves are not worn.

The Occurrence of Acetonuria in Cases of Infectious Disease.—A. Harris says that there is no satisfactory explanation to account for the formation of acetone in the body. It occurs much more constantly in diphtheria and scarlet fever than in typhoid—occurring in most of the two former and in only about one-third of the latter. According to recent authorities the acetonuria of fevers is to be attributed to the acidosis accompanying partial or complete deprivation of food. If this explanation is correct, it seems strange that in a disease like typhoid, in which there is a diminished absorption of food, as shown by the condition of the tongue, diarrhea, and pyrexia, acetonuria should only occasionally be met with and then only at the beginning of the disease. On the other hand in diphtheria and scarlet fever acetone is almost invariably present even in the mild cases in which, as there is little disturbance of digestive functions, a fair amount of carbohydrate food can be given. That pyrexia has little to do with acetonuria is shown by the fact of its occurrence in many cases of diphtheria in which no rise of temperature has been noted. In an institution under the direction of the author it has been found that in the two diseases mentioned the more severe the type, the larger the amount of acetone in the urine and the longer the period it remains therein. In a mild case of diphtheria it usually disappears about the seventh day; in a severe case it may persist until the thirteenth. In the so-called "vomiting" diphtheria, which is always fatal, the reaction is not more marked than usually happens in a severe case. There is no increase in the amount at the time of vomiting. The presence of acetonuria may be of diagnostic value in differentiating between the two diseases and ordinary sore throat, being much less common in the latter.

British Medical Journal, May 7 and 14, 1910.

Some Practical Points in the Treatment and Clinical History of Early Syphilis.—W. Coates relates an interesting series of cases, the particulars of which must be studied by those interested. He speaks especially of the curability of the disease, the relapsing chancre, late relapses, early diagnosis, the imprudence of starting treatment before a positive diagnosis of syphilis is made, etc. The author says that the inability to find the spirochetæ in a primary lesion is not conclusive evidence of the absence of the disease, and that the serum test—Wassermann's—is not at the present time to be relied upon, if negative, to determine the nature of a sore or to guide the practitioner in its treatment. The author has seen several cases of syphilis occur without a sore. He advocates the use in suitable cases of mercury atoxylate, of which he was, he admits, at first afraid, but finds that it has a wonderfully immediate influence on intractable symptoms, and so far as he has noted no ill effects. In his experience the intramuscular injection of the soluble mercurial salts appear to cause more pain and depression than do other remedies. Inunctions and the iodides have served him well, especially in "melting away" those large abdominal masses called tuberculous, which he regards as oftener due to hereditary syphilis so frequently seen in children. Injections of gray oil have also been used by him with remarkable benefit. All cases may not do well on the mercurial ataxylate, and it remains for the future to show in just what class of cases its employment is especially indicated.

The Principles of Treatment in Gastroptosis.—In reviewing the various plans of treatment of this condition, R. Hutchison calls attention to the use of local moist heat for hyperesthesia of the stomach, in the form of poultices or fomentations and whenever there is general epigastric tenderness. Such means may be employed during the first week of the rest cure. Gastric sedatives are also of service here. The matter of artificial support is of secondary importance. Gastric supporters probably do not push up displaced organs, but such support gives relief from these feelings of sinking, emptiness, and exhaustion, which are among the most bitter complaints of patients, but these complaints are probably due to lessened intraabdominal tension and a tendency to a pooling of the blood in the splanchnic area when the erect position is assumed. The best belt is a firm abdominal wall and our efforts should be directed toward restoring its tone and to thickening it by the deposition of a substantial layer of subcutaneous and extraperitoneal fat. As regards the development of the abdominal muscles reliance must be placed upon massage and the practice of abdominal exercises. In regard to abdominal belts, the ideal one is yet to be invented. It must cause pressure from the lower part of the abdomen upwards and somewhat backwards. In the pendulous belly of stout subjects this is quite easy, but most patients with gastroptosis are thin with prominent iliac bones, which tend to carry off the pressure from the hypogastric region, where we most wish to apply it. The problem is a purely mechanical one, and the use of a suitable pad helps to overcome it, but the results leave much to be desired. Three things should not be done, patients with gastroptosis should not be over dieted, their stomachs should not be washed out, and they should not be operated on.

Diagnostic Value of the Leucocytosis Occurring in Whooping Cough.—H. T. Ashby says that in a fair number of cases the number of leucocytes was estimated and in every case in which this was done there was a leucocytosis of between 15,000 and 30,000 white cells per c.mm. The number of white cells in children suffering

from bronchitis and other non-febrile diseases was also estimated, but only in rare cases did the numbers reach such a height as in the cases of pertussis. The results confirm those made by Froelich along the same lines. The leucocytosis is itself a valuable aid in the diagnosis of the disease. In examining the blood of a child with pertussis the preponderance of lymphocytes over the polymorphonuclear cells is at once marked, and in nearly every-case which had a well-marked whoop the lymphocytes formed about 60 per cent. of the total white cells, the rest of the white cells being made up of polymorphonuclear cells with an occasional eosinophile cell. The excessive lymphocytes were nearly all of the small variety, but there was at the same time a greater proportion of large lymphocytes than is found per c.mm. in normal blood and in some cases these cells amounted to 10 per cent of the lymphocytes present. This excess of lymphocytes was the case in patients who had not yet reached the spasmodic or whooping stage of the disease and also in mild cases when it was difficult to make a diagnosis from the history as given by the parent.

The Knife and Its Point.—A. C. Cressy commends the use of knives with a blunt point. The blunt point prevents undermining of the tissues and there is no punctured vessel in the course of the incision because the ends of the incision slant to the wound instead of away from it. In dissecting the surgeon cannot scratch, but must cut. In the removal of glands he cuts with the edge and blunt dissects with the back and has no fear of puncturing vessels close by because there is no point to travel further than he can see. In a splitting operation for appendicitis the skin incision with a blunt-ended scalpel has no undertermined end; in splitting the external oblique, the cross-fibers of the internal oblique are not frayed, as so often happens when the point of a knife passes over them. Having retracted the external oblique, the edge of the knife divides the thin fascia over the internal oblique, and reversing the knife the back of it now splits this muscle and the transversalis. Now the peritoneum is picked up and the edge of the knife laid on it; having made a small opening the knife is inserted, edge upward, and a cut made to the right and to the left without any fear of touching the bowel because there is no point to the knife. In removing a varicose vein there is no point to puncture the vessel as it is dissected out from the surrounding tissues and much time is saved. The back of the scalpel makes on occasion a good dissector. The author considers the point of a scalpel an obstacle to quick operating and a dangerous companion.

Hemophilia in a Female.—E. W. Squire reports this rare condition as the disease is generally transmitted through mother to son and not to daughter. He could obtain no family history of hemorrhages except from the lungs in two members of the parents' families known to be phthisical on going back two generations beyond the parents: When born in 1907 there was a brown patch over one eye, which cleared up in a few days, showing disease probably congenital. The mother often noticed that the child bruised easily on falling. At one year of age a sharp attack of bronchitis with melena occurred, much blood being lost; a few months later severe hemorrhage, lasting for three to four days, followed a mere scratch on the finger; one year later there was bleeding from mouth, on both occasions stopping spontaneously; ten days later there was a further attack of bleeding from two points in the mouth, death ensuing. The child was well nourished and had a varied and liberal diet. There was no history of swollen joints as suggesting purpura or scurvy. One brother showed no disposition to hemorrhages.

Plumbism Treated by the Internal Administration of Permanganate.—Five cases are reported by G. A. Stephens. The drug should be given in all cases of the nature indicated, in capsular or palatinoid form, as it has a tendency to nauseate the patient. The author has already pointed out the fact in plumbism that the origin of the red line on the gums is due to the deposit of lead in the form of the sulphide on a preexisting red line caused by irritating particles in the atmosphere in which the men work. This red line is undoubtedly inflammatory in origin, as shown by the enlarged and engorged papillæ on the edge of the gum, and it is an inflammatory line that occurs on the anterior or upper end of the alimentary tract. Calcium permanganate, being of value in gastritis, acts therefore in the nature of a preventive, and it may be well to order its systematic use in all lead workers.

Some Points Relating to Therapeutic Immunization.—The paper of J. C. McWatters is a plea for the extension of the principles of vaccine therapy. He enumerates the various diseased conditions in which he has followed this line of therapy with success. He says that to-day we must regard the process of inflammation as ministering to immunization on the one hand by the transference of the phagocytes and on the other by the transference of antibacterial fluids from the blood to the invaded tissues. In other words, nature attempts cure in a local bacterial invasion by producing a local migration of leucocytes in the affected tissues accompanied by a leveling up of the amount of opsonin in the invading tissues to that in the circulating blood, and it therefore follows that if the opsonic content of the blood is deficient we shall fail to obtain a destruction of the invading bacteria. Herein, says the author, lies an explanation of the failure of Metchnikoff's original theory in those cases of inflammation in which phagocytic migration is unattended by cure.

Traumatic Tuberculosis, Traumatic Pneumonia, and Traumatic Pleurisy.—This paper is by F. Parkes Weber. He discusses first traumatic tuberculosis from direct infection and then alleged traumatic tuberculosis due to injuries by which tubercle bacilli could not have been introduced into the body from without. Cases of the latter kind are divided clinically into three groups: (a) cases in which a decided traumatism of some kind is followed by signs of either acute disseminated miliary tuberculosis or acute metastatic localized tuberculosis; (b) cases in which signs of pulmonary tuberculosis follow or are at first noticed after a supposed injury to the lungs; (c) cases in which an injury to bones, joints, or parts of the body other than the lungs is followed by signs of tuberculosis more or less localized to the region of trauma. These three headings are expanded by the author. He then asks what part does the trauma play in particular cases of alleged traumatic tuberculosis? We have to admit that in all cases, excepting those in which inoculation with bacilli occurs from without, tuberculosis of some kind, whether latent or not, must have been present before the trauma was received. In any given case, therefore, we have to ask, could tuberculosis be recognized before the injury, is there any reason to believe that the trauma played any part in the outbreak of the tuberculosis, and is the whole of the illness practically the result directly or indirectly of the trauma? In order to answer the last two questions a decision must be arrived at with regard to the other two. Then the nature, position, extent, and violence of the trauma have to be investigated; the lapse of time between the injury and the onset of the tuberculous symptoms has to be ascertained and one has to consider whether the existing tuberculous lesions and symptoms are of a kind likely to have followed the trauma in question. With reference to traumatic pneumonia and pleurisy experiments are referred to as affecting animals, and the author passes on to consider what he calls contusional traumatic pneumonia and pleurisy, referring to a series of cases in which these lesions followed such accidents as being run over, etc. In regard to the former malady he says that there is less expectoration than in the non-traumatic form of the disease. Early hemoptysis is not universally present. It is due to mechanical injury of the lung. External bruising is, of course, present, but it is by no means a marked feature. A crises may occur as in ordinary pneumonia. Chronic bronchitis, alcoholism, and degenerative conditions of the blood vessels doubtless act as predisposing causes of contusional pneumonia, and favor the severity of the attack. The shortest period between the reception of the trauma and the development of the pneumonia is, according to Latten, ten hours. With regard to contusional pleurisy the author says that a very important point is that signs of this disease after trauma may be due to tuberculosis. Pleurisy, with or without fluid effusion, has certainly sometimes been associated with signs of pulmonary tuberculosis following thoracic trauma. By such an injury latent foci of tuberculosis, such as a bronchial gland, etc., may be squeezed or torn in such a way that tubercle bacilli are mechanically disseminated over the neighboring lung tissue, the vitality of which is so lowered as to render it a favorable nidus for the subsequent germ development. The lesion commonly resulting is more apt to be peumonic, but may be pleuritic.

Berliner klinische Wochenschrift, May 2, 1910.

Unilateral Orthrostatic Albuminuria.—Kurt Vorpahl reports the case of a twelve-year-old girl who came to him complaining of headache, pain in the back and

joints, weariness, and loss of appetite. It was found that she had an orthostatic albuminuria, the urine being normal when the child was lying down, but containing albumin when she was walking about. The child had a fairly marked scoliosis, convex to the left in the lumbar region and to the right in the dorsal. As orthostatic albuminuria is often associated with lordosis, which this patient had not, Vorpahl thought that in this case it might be due to the scoliosis, and if so might be unilateral. Catheterization of the ureters proved this to be the case, the urine from the left kidney being normal and that from the right containing albumin.

Constipation Albuminuria.—Roubitschek reports a series of experiments on rabbits, in which he produced an artificial constipation by feeding with oats and giving opium and tannic acid. Six to nine days later albuminuria occurred and casts appeared in the urine. The albumin gradually increased in amount to 0.25-0.50 per mille. In one case, in which he put a firm bandage around the abdomen, it rose to 0.75 per mille. Autopsy, after 14-22 days, showed the intestines dilated and full of scybalæ, the liver and spleen hyperemic, the kidneys enlarged, dark grey red, of normal consistency, the capsule highly adherent, and punctiform hemorrhages. Hemorrhages occurred into the glomeruli. The cause of the albuminuria from constipation may be a toxic absorption from the bowel or pressure on the renal veins from the overfilled gut. The author inclines to the latter alternative. The urine contained red and white corpuscles, hyaline, granular, and epithelial casts.

Münchener medizinische Wochenschrift, May 3, 1910.

The Prophylaxis of Acute Anterior Poliomyelitis.—Römer and Joseph say that in discussing the prophylaxis of such a disease as poliomyelitis one must consider two forms of prophylaxis, hygenic and medicinal, especially etilogoically specific treatment. The latter may be preventative or curative. In hygienic prophylaxis domestic animals, as dogs and chickens, must be considered as possible carriers. Another point of importance is the probable part played by human beings as disseminators of the disease. In many ways the mode of transmission seems to be similar to that of meningitis. It has been suggested that the virus is present in the nasal and pharyngeal secretions, both of these suffering from the disease in its abortive or complete form and in the clinically healthy. Contact with secretions from such persons may cause infection. Experiments have shown that the virus remains virulent, and apparently actively virulent, after 28 days of drying. It may, therefore, be transmitted through dust. The authors have exposed the virus to fumes of formaldehyde in a room by the usual disinfection methods and have shown that after seven and a half hours the virus when injected into a monkey was inert; that the usual formaldehyde disinfection destroyed the virus. It is urged that disinfection should be carried out in a room which has held a patient. Careful disinfection of the nose and mouth of patients and all exposed to them is advised to prevent the danger of carriers. The discovery that one attack renders an animal immune to a second infection, and that the serum of an immune animal protects a normal one, holds out hope for the production of an immunizing serum.

The Transmission of Typhoid Fever by an Infant.—Rommeler reports the case of a woman, aged twenty-six, who, while nursing her infant, developed typhoid fever. The mother was admitted to a hospital and the baby was sent to be cared for by a friend. The child had a slight attack of diarrhea, but otherwise appeared quite well. Two weeks later the woman who was caring for the child developed typhoid fever and was soon followed by her three children, a three-year-old niece, and a twenty-year-old servant. The child was then examined and was found to give a positive Widal reaction, and on one occasion typhoid bacilli were isolated from the stools. The author draws from this case the lesson that when a nursing mother develops typhoid fever her infant should also be taken into the hospital. The symptoms of a typhoid infection in an infant are so slight that there is a great danger of a child apparently quite well conveying the disease to others.

The Treatment of Chronic Bronchitis and Bronchial Asthma by the X-Rays.—Theodor Schilling has treated a series of cases of chronic bronchitis and bronchial asthma with the *x*-ray. For the treatment he claims that chronic cases, which have persisted for years, may be improved and even completely cured. The results are especially hopeful in children. Bronchiectasis also may be cured clinically. The prompt improvement in many of the cases gives room for the belief that many forms of these diseases are caused by the presence of enlarged bronchial or hilus glands. Many cases of acute nonfebrile bronchitis also appeared to be improved rapidly by *x*-ray treatment. A knowledge of the technique completely prevents accidents.

Rectal Gonorrhea in Childhood.—Kaumheimer calls attention to the not infrequent occurrence of a gonorrheal infection of the rectum associated with a specific vulvovaginitis of childhood. He believes the contagion is by direct infection from the vaginal discharge. The subjective symptoms are usually very slight and in the majority of the cases are absent entirely, the disease being found only by systematic search. The occurrence of these rectal infections without symptoms may be an explanation of the difficulty in curing and the tendency to relapse in many cases of gonorrheal vulvovaginitis in infants. It may also play an important part in the spreading of epidemics in children's hospitals. On the theory that the infection may be spread by the use of the rectal thermometer, the author advises that in cases of gonorrheal vulvovaginitis the taking of rectal temperatures be stopped.

Deutsche medizinische Wochenschrift, April 28, 1910.

A Contribution to Banti's Disease.—Momm reviews the literature on Banti's disease and reports a case. In Banti's original description the disease was divided into three stages. In the first stage the enlargement of the spleen is followed by anemia. In the second or transitional period, which lasts only a few months, there is mild jaundice, the liver is usually somewhat enlarged, the urine is scanty, and contains urobilin and frequently traces of bile pigment, and finally gastrointestinal symptoms set in. In the third or ascitic stage the ascites comes on and develops slowly and painlessly; the symptoms of anemia become more severe, the blood examination shows a steadily decreasing number of red cells and reduction of hemoglobin, there is no increase of leucocytes, and death occurs after six months or a year. From a careful study of the literature and of his case Momm says that the disease cannot always be divided into these three stages, that especially the ascites may come on much earlier in the illness. The ascites is the result of the abnormal condition of the blood, and more especially of the interference with the flow of lymph by the swelling of the retroperitoneal and mesenteric glands. Talma's operation of splenectomy is not to be recommended. Occasionally trauma is a factor in the etiology. A clinical diagnosis between Banti's disease and thrombosis of the splenic vein cannot be made.

A Case of Nonparasitic Chyluria.—J. Hnatek reports the case of a woman of thirty-three years of age, previously in good health, who suddenly noticed a milky color to the urine, with the passage of hair-like clots, associated with pain resembling renal colic. The urine contained 7.73 grams of albumin to the liter. The chyluria had a definite nocturnal character, the urine pased during the day being quite normal. In the daytime, however, when the patient remained in bed the urine was chylous, and on a constant diet contained 123 times as much chyle as when she was up and about. Catherization of the uretus showed that the left kidney secreted four times as much chyle as the right. The observation teaches that in cases of parasitic chyluria one must lay weight rather on local changes in the neighborhood of the kidney than upon an altered function of the kidneys which are secreting the chylous urine. The question of why one kidney secreting the same amount of urine as the other should pass four times as much fat as its mate must be explained by further study.

Rupture of the Spleen, Extirpation, Recovery.—Richard Mühsam reports the case of a boy ten years of age who was admitted to the Moabit Hospital immediately after having been run over by an automobile. He was in collapse with free fluid in the abdomen and a contusion on the left side. Laparotomy showed a deep tear in the spleen, and extirpation was immediately performed. The abdomen was closed in two layers and the boy did well for a week. Then the fever rose from 101° to 102°, and the leucocytes numbered 80,000. The wound broke down, resulting in an extensive prolapse of the gut. After sewing up with through and through stitches the wound held. No subphrenic abscess was found at the second operation. Eight days later a purulent hematoma lying under the ribs was opened by resecting a piece of rib. Recovery after this was uneventful.

Book Reviews.

High Frequency Electric Currents in Medicine and Dentistry. Their Nature and Actions and Simplified Uses in External Treatments. By S. H. Monell, Professor of Static Electricity, International Correspondence School, 1898-1903; Founder and Chief Instructor New York School of Special Electrotherapeutics 1896-1902, etc. New York: William R. Jenkins Company, 1910.

This book is from the pen of a man who has had large experience with electrotherapeutics in general, and with high frequency currents in particular. It is divided into four parts, namely, (1) general consideration of high frequency currents, (2) clinical experience of other workers with the current, (3) apparatus and administration of the current, and (4) diseases which are amenable to the current. The book is fluently written, and suggests great possibilities in the therapeutic use of the high frequency current, as it informs one that the range of its usefulness ranges from infantile diarrhea to arteriosclerosis. It makes very interesting reading. On close inspection, however, by one desirous of making use of its teachings, the book is found to be lacking, in a way only too common in books of this type, in that, while telling enthusiastically the wonderful results of the author, it becomes somewhat hazy when it comes to describing the essential details of his methods.

Congenital Dislocation of the Hip. By J. Jackson Clarke, M.B., London, F.R.C.S.; Senior Surgeon to the Hampstead and North-West London Hospital, and Surgeon to the Royal National Orthopedic Hospital. London: Bailliere, Tindall & Cox, 1910.

This monograph discusses briefly and clearly the anatomy and diagnosis of the congenital dislocation of the hip joint, and then describes in detail the Lorenz manipulative or bloodless method of reduction, including operative measures, postoperative treatment, and care of special complications. Forty cases so treated are reported. The book is well illustrated with daylight and *x*-ray photographs, is well printed and bound, and in the ninety pages gives a very good discussion of the subject at hand.

Transactions of the American Pediatric Society: Twenty-First Session. Edited by Linnaeus Edford La Fétra, M.D. Volume XXI. Reprinted from *Archives of Pediatrics*, 1909-1910. New York: E. B. Treat & Co., 1910.

The volume contains the minutes of the meeting, the papers read at the sessions, and the discussion, all of which have previously appeared in print. A perusal of the pages gives one a good idea of the class of work on which the pediatrists of America were engaged during the year 1908 to 1909.

The Elements of the Science of Nutrition. By Graham Lusk, Ph.D., Sc.D., F.R.S. (Edin.); Professor of Physiology at the Cornell University Medical College, New York City. Second Edition, revised and enlarged. Philadelphia and London: W. B. Saunders Company, 1909.

The second edition of this book has been required by the advances made in metabolic work during the past three years. For many years German literature has been full of reports of experiments in animal and human metabolism, and during the past few years American workers have more and more taken up this wide field of physiological chemistry of the living body. These articles, however, come so fast, and are so minutely specialized that to the uninitiated they are little more intelligible than Egyptian hieroglyphics. To meet the needs of those who want to know what this modern work really means, the author has written the present book, which takes up the history of metabolic experiments from its incipiency and briefly gives the results of the various investigations which have been made. The book does not go into methods, it gives merely the conclusions, and references where one may find from the original articles the minutiæ of the procedures. The book can hardly be called light reading, but to the man with some knowledge of chemistry who wishes to have an understanding of the present-day trend of chemical investigations of the body processes, a careful study of the contents will be well repaid.

An Outline of Individual Study. By G. G. Partridge, Ph.D., Formerly Lecturer in Clark University. New York: Sturgis & Walton Co.

This volume is divided into three parts. Part I treats of the history and theory of individual study; Part II of the practical study of individuals, and Part III the application and results of individual study. It is primarily intended for the use of those interested in the study of children as individuals, and therefore will appeal to students of education, parents, and teachers. Some attention is paid to abnormal traits, both of body and mind, but the volume treats chiefly of the normal child. Part IV contains a report of the study of twin children, a chapter on types of children, and a final chapter on pedagogical aspects of individuality.

Modern Methods of Street Cleaning. By George A. Soper, Ph.D., Member of the American Society of Civil Engineers. Illustrated. New York: The Engineering News Publishing Company.

The absence of any treatises on this subject and the great experience and practical knowledge of the author make this volume well worthy of interest. The data were gathered in part during a three months' tour of Europe in 1907, while Dr. Soper was acting in an advisory capacity to the New York Street Cleaning Department. The author states that it was once his hope to present a deduction of some general principles, especially as to efficiency and cost of street cleaning, but the nature of the work and the character of the information available have not made this possible. The exceedingly diverse conditions of pavement, of traffic, and of weather, together with varying sanitary standards, make it impossible to treat this subject in analytical fashion, but the author has done well in describing the fundamental principles applicable to street cleaning, including the use and abuse of city streets and the disposal of refuse. As a history of contemporary methods used in Europe and America, this volume is entertaining and interesting, especially as a work of reference.

The Optic Nerve and the Accessory Sinuses of the Nose. By Prof. A. Onodi (University, Budapest). Authorized translation by J. Lückhoff, M.D., Edin., Ch.B. Pp. i to 101, with 50 illustrations. New York: William Wood & Company, 1910.

The subtitle of this volume declares it to be a contribution to the study of canalicular neuritis and atrophy of the optic nerve of nasal origin, pathological conditions of the utmost importance which in this country are just beginning to be studied in relation to their true significance. This work of Prof. Onodi's is therefore very timely, coming as it does from one who for ten years has studied his subject at first hand, both in the clinic and mortuary. As a result of such researches we now know that many hitherto obscure cases of optic neuritis and atrophy, as well as of acute total blindness, are associated with disease of the sphenoid and posterior ethmoid cells. The figures and plates here displayed are in general all that could be desired, taken as they are from photographs of actual specimens; and even without the elaborate descriptive text which accompanies them one may gain a very fair idea of the surgical anatomy of the nasal fossæ. The thirty-three pages at the end of the volume dealing with clinical considerations serve well to reinforce the value of the relations described in the preceding pages.

A word of criticism may be offered in passing relative to the frequent references of the author to his previously published "Atlas," including descriptive data, which are only of use when one has this atlas in hand. Moreover, instead of the legend "Natural Size" it would be easier for the reader if the author had shown by means of a plane passed through a diaphanous skull just where the section was taken; for in some of the pictures it is difficult to get one's bearings without puzzling over them for some time. These slight strictures aside, the volume is indispensable to all who are interested in the surgery of the head, and the author is to be thanked for his painstaking and exhaustive dissections.

Die Syphilis der Nase, des Halses und des Ohres, von Dr. P. H. Gerber, professor zu Koenigsberg, mit 4 kolorieten Tafeln und 1 Abbildung im Text. Zweite veraenderte und vermehrte Auflage, Berlin; Verlag von S. Karger, 1910.

In this excellent and comprehensive monograph, the author considers syphilis of the nose and nasal sinuses, nasopharynx, mouth and pharynx, larynx, trachea, and ear. There are also chapters on therapy, and an enumeration of the literature consulted in the preparation of the book. The various topics are treated in an exhaustive manner which is strictly abreast of the times. The author excels in the preparation of monographs of this kind. We unhesitatingly commend the result of his efforts in the present publication.

Society Reports.

ASSOCIATION OF AMERICAN PHYSICIANS.

Twenty-fifth Annual Meeting, Held in Washington, D. C., May 3, 4, and 5, 1910.

PRESIDENT, DR. HENRY HUN OF ALBANY, N. Y.

(Special Report for the MEDICAL RECORD.)

(*Concluded from page 941.*)

Epidemiology of Acute Anterior Poliomyelitis.—Dr. JOSEPH COLLINS of New York stated that the epidemicity of this disease was abundantly proven by the records of upwards of fifty epidemics. The fact that anterior poliomyelitis occurred in epidemics necessitated the admission of its parasitic origin. In order to aid in the recognition of this parasite they must study the influence of meteorological agents and their diffusion, the vehicles by which the parasites were introduced into the body, the personal and social conditions influencing infection, the circumstances that determined the decline and extinction of epidemics, and all the factors that had any bearing upon the epidemic movements. The influence of meteorological agencies was most striking. Practically all the epidemics had occurred during or after protracted heat and, frequently, after a drought. The occurrence of digestive disorders in one-half the cases would suggest that foodstuffs might be the vehicles by which the parasites gained entrance to the body. Personal and social conditions had very little to do with the occurrence of the disease. The circumstances that determined the decline and extinction of the epidemics were not unlike those that governed the laws of anticipation, association, and antagonism in other epidemic movements. The disease had not been recognized sufficiently long to state that there were secular mutations or multi-annular mutations, but they were certain that there were epidemic waves or explosions of it recurring at more or less regular intervals. The variations in the mortality of epidemics occurring in the same section of the country in different years, showed that anterior poliomyelitis conformed to the laws that governed the multi-annular fluctuations or mutations of other epidemic diseases. Poliomyelitis had prevailed epidemically in many parts of the world during the past twenty-five years. Nothing had been found in literature that indicated that the disease had been recognized or that it had existed before 1843. The most remarkable thing in the epidemicity of poliomyelitis was its seasonable occurrence. The inference was to be drawn that cold was inimical to the saprophytic growth of the non-obligatory parasite. The mortality rate varied decidedly in different epidemics. The most careful investigation had failed to reveal that the epidemic prevalent had anything to do with unhygienic surroundings.

The Pathology of Poliomyelitis.—Dr. B. SACHS of New York said that recent epidemics had shifted the chief interest in poliomyelitis from the study of the pathology to the questions of the etiology and bacteriology of this disease. Nevertheless, it would be of some value to consider to what extent the advanced study of the morbid changes bore out the modern conception of the disease. This disease should be rightly described as polioencephalomyelitis, as its chief effect was upon the anterior gray matter of the spinal cord. However, it was not limited to the anterior portion: the central gray matter and the posterior horns were also affected. Studies during recent epidemics showed a general hyperemia of the meninges, both of the brain and cord; therefore it was not surprising that meningeal symptoms had been so frequently noted. The gray matter of the cord appeared brownish red in the acute cases: inflammation of the pia mater was found surrounding an infiltration of the cord. The infiltration about the vessels was most marked in the sacral and lumbar segments and next in the cervical. The blood vessels evidently played an important role. He thought the disease was on the order of an interstitial and not a parenchymatous inflammation, at least not primarily. The ganglion cells were found in various stages of degeneration. They might be seen surrounded by small round cells or polymorphonuclear cells: in some instances these had entered the cells, presenting a true neron-asphasia. The ganglion cells did not disappear group by group; the cells that disappeared were in areas in which there was a marked interstitial change. In two cases reported by Strauss the cells of the column of Clarke were found to be degenerated; in five out of seven cases examined by the same investigator the ganglia showed the same evidences of an inflammatory process and the findings were very similar to those in rabies. In the cord of monkeys to whom the disease had been communicated entirely similar changes were found. The pathological findings were in entire accord with the infective character of the morbid process. Areas of bronchopneumonia had been found; parenchymatous degeneration had been made out in the liver and kidneys; the spleen was found invariably congested and firm and generally enlarged. General enlargement of the glands of the body was observed in one case and petechiæ were noted in two cases.

Animal Pathology of Poliomyelitis.—Dr. SIMON FLEXNER of New York reported on the experimental study of poliomyelitis in monkeys, which had yielded a large number of important facts relating to the spontaneous disease in man. The nature of the virus had been discovered, many of its properties had been ascertained, some of its immunity effects had been established, the clinical and pathological peculiarities of the disease had been elucidated, and a basis had been secured on which to develop measures of prevention.

Dr. MARK W. RICHARDSON of Boston reported on the work done by the State Board of Health of Massachusetts in investigating this disease. In 1907 the number of cases numbered 235; in 1908 it numbered 185; while in 1909 the number of cases was almost 1,000. It was brought out that the disease was not necessarily a city but a rural disease; Boston ranked, for instance, sixty-fifth among the cities and towns of the State in which this disease appeared. Among 3,600 children in institutions of the State only one case of acute anterior poliomyelitis was found in a child under fifteen years of age. This child had not been out of the institution for a number of months and had received no visitors. A circular letter had been sent to the physicians of the State recommending that whenever the disease appeared the patients should be quarantined as one would do in a case of scarlet fever. In every case that came to autopsy there seemed to be a definite relation between the fatal cases and an enlarged thymus gland.

Dr. B. SACHS of New York said that in performing autopsies on these cases of acute anterior poliomyelitis, other organs besides the thymus would show evidences of a general infection.

Dr. SIMON FLEXNER of New York said that the thymus gland had been found to be enlarged in those who were the victims of this disease.

The Electrocardiogram in Clinical Diagnosis.—Drs. L. F. BARKER, A. D. H'RSCHFELDER, and G. M. BOND of Baltimore made this presentation which consisted of lantern slide demonstrations showing the value of electrocardiograms as a supplement to other methods of investigating cardiovascular conditions. The curves were especially helpful in the diagnosis of cardiac arrhythmias, including the extrasystoles and heart block, in hypertrophy of the right or left ventricle, in atrial paralysis and the

pulsus irregularis perpetuus, in tachycardias and bradycardias, and in fibrillation of the atrium. The work had been done with Einthoven's string galvanometer.

Demonstrations of Electrocardiograms.—Dr. Walter B. James of New York gave a lantern slide demonstration illustrating the heart's action current in fibrillation of the human auricle in the terminal stage of cardiac insufficiency in valvular disease and also electrocardiograms of pulsus bigeminus.

The Structure of the Sweat Glands of the Skin in Cases of Chronic Nephritis.—Dr. Herbert U. Williams of Buffalo made this presentation. He said that in view of the very general practice of attempting to relieve the kidneys by inducing free perspiration, it seemed that a study of the sweat glands in cases of chronic disease of the kidneys might be interesting. In about 75 cases, mostly of chronic interstitial nephritis, the histology of the sweat glands in skin from the sole of the foot was studied; skin from the abdomen was studied in about half of these cases. Dr. Williams gave a lantern slide exhibition of the pathological conditions found in the sweat glands.

Second Day—Wednesday, May 4.

A Study of the Development of the Epiphyses of the Hand and Wrist for the Purpose of Classifying the Cadets at Annapolis.—Dr. Thomas Morgan Rotch of Boston, presented this paper. He said that he had been requested by the Secretary of the Navy to make an index for the grading of cadets at Annapolis similar to the one he had made and presented in his paper entitled "A Study of the Development of Bones for Determining the Anatomical Index for the Grading of Children up to Thirteen Years." The fact that some of the young men ready to enter under the tests usually made were later unable to withstand the strain or would go along until near the end of the four years and then break down was the reason that the Government desired some additional means of ascertaining at the beginning whether an individual student would be able to withstand the strain, both mental and physical, through which he would have to pass. The work had been carried on on young men from fifteen to sixteen up to about twenty years of age. It had been found that the development of the hand and wrist represented so well that of the other epiphyses of the skeleton that they furnished the best material for the study. They could, therefore, practically make use of these different stages of epiphyseal development so as to cover two distinct periods, one corresponding to the first thirteen or fourteen years of life, and the other from fourteen or fifteen up. The earlier period was determined by the appearance in succession of the carpal bones and the epiphyses of the radius and ulna. The later period was represented by the different stages of ossification, leading up to complete union, of the epiphyses of the phalanges, metacarpal bones, ulna, and radius. The grading was determined by the different periods at which the union took place in the above mentioned epiphyses. He had before shown that epiphyseal development seemed in some way to be connected with mental development while other factors did not. It was the equilibrium of mental and physical development which should be watched. This was accomplished by having Roentgen pictures taken from time to time as the cadet was advanced in order to determine whether he should be advanced or even retained in the Government service. Dr. Rotch presented charts and pictures showing cadet's hands in various stages of development.

Cardiac Hemisystole as Illustrated in a Case of Heart Block.—Drs. Alfred Stengel and William Pepper of Philadelphia reported this case. The cases did not show the Stokes-Adams syndrome although there was complete auriculoventricular disassociation. After the administration of atropine there was a change from complete block to an incomplete one with 3-1 rhythm, then 2-1 rhythm alternating with normal rhythm. Finally there was a persistence up to date of a 2-1 rhythm. Observations made upon the tracings showing this transition from 2-1 to normal rhythm and *vice versa* while the tracings were being made: (1) The change that took place in the auricular and ventricular rate at such times, variations of the A-C interval, etc.; (2) Tracing showing an example of hemisystole, the left ventricle contracting while the right did not. He spoke of Leyden as the chief advocate of varieties of hemisystole and thought that probably his cases were examples of bigeminus. He raised the question: "Provided that hemisystole could occur, would not its appearance in a case of heart block suggest a lesion is one or other division of the bundle of His and thus aid possibly in localizing the lesion?"

Dr. A. W. Hewlett of Ann Arbor said that whatever of interest might be attached to cardiac hemisystole came from the experimental side. He had cut one branch of the bundle of His but he got no dissociation, and did not pursue the experiments further. The number of cases which showed a lack of association was certainly increasing.

Dr. Walter B. James of New York said that by cutting the bundle of His on one side, there was a delayed impulse. There was a complete systole on one side, and a slowness on the other.

Dr. W. S. Thayer of Baltimore said it was a very interesting question as to whether these cases reported by Dr. Stengel should be called cases of heart block. He had seen several cases during the past two years; one individual without any delay in his A-C time showed a dropping of alternating beats after exercise or emotion.

The Structure of the Sweat Glands of the Skin in Cases of Chronic Nephrits.—Dr. Herbert U. Williams of Buffalo presented this paper and gave a lantern demonstration of photomicrographs. He said that in view of the very general practice of attempting to relieve the kidneys by inducing free perspiration, it seemed that a study of the condition of the sweat glands in cases of chronic kidney disease might be interesting. In about seventy-five cases, mostly of chronic interstitial nephritis, the histology of the sweat glands in the skin from the sole of the foot was studied; skin from the abdomen was also studied in about one-half of these cases. The subjects showing obvious skin lesions were excluded. The various pathological conditions found in the sweat glands he demonstrated by means of lantern slides from photomicrographs.

Dr. A. S. Warthin of Ann Arbor said it was very difficult to draw any relationship between the pathological changes occurring in the kidneys and the great frequency of changes that occurred in the sweat glands.

The Relation of Combined Intoxication and Bacterial Infection to Necrosis of the Liver, Acute Yellow Atrophy and Cirrhosis.—Dr. Eugene L. Opie of New York said that by the administration of poisons which attacked the liver, namely, chloroform or phosphorus, in combination with bacterial infection, it was possible to reproduce the peculiar midzonal necrosis which in man occurred in association with bacterial infection, under conditions which were not fully understood. The same combination of poison and bacteria, apparently acting with maximum intensity, reproduced a lesion resembling acute yellow atrophy in man; necrosis and hemorrhage were followed by the generative changes. When the poison in association with bacterial infection repeatedly produced relatively slight changes, cirrhosis of the liver occurred and advanced much more rapidly than that produced by the poison alone.

Dr. S. J. Meltzer of New York said that he wrote a paper some years ago in which he stated that any bacteria like that which caused typhoid fever, or the streptococci, when introduced into the circulation, disappeared in a very short time. But if there was a small injury inflicted, then these bacteria would start to develop. In Dr. Opie's experiments it might be that the chloroform or the phosphorus caused such an injury.

Dr. William H. Welch of Baltimore said that experimental work upon cirrhosis of the liver had hitherto been very unsatisfactory, particularly with alcohol. He said he had never succeeded in producing cirrhosis of the liver experimentally with alcohol. He believed that Dr. Opie's inferences were correct. You had something which produced a damage to the liver causing death; but with the liver's enormous power to regenerate after hepatic abscess, for instance, cirrhosis of the liver did not occur. In order to get cirrhosis of this organ one must inhibit this regenerative power. A combination of the action of toxins with something which prevented this regenerative power might lead to the production of liver cirrhosis.

Dr. A. S. Warthin of Ann Arbor reported an interesting case. The patient was seven months pregnant, was operated on for gallstones, and died after the operation. Portions of the liver were at once removed and left in a warm room for six hours. A central necrosis developed in this liver tissue after its removal from the body. The examination of the lever tissue removed immediately after death showed no such change.

The Interpretation of the Metabolic Defects in Diabetes Mellitus Upon the Basis of the Theory of Intracellular Ferment Action.—Dr. A. E. Taylor of Berkeley, Cal., read this paper. He considered the four chief reactions of glucose in the animal body: the formation of glucose from levulose and galactose, and the formation of galactose from glucose; the formation of glycogen from glucose, and the reversed reaction; the formation of fat from glucose; and the combustion of glucose. All were reactions of fermentation. From the nature of the chemical reactions involved, all were presumably related to different enzymes. The reaction of intramolecular conversion was retained fully in true diabetes, namely the formation of glucose from levulose and galactose. The power of forming glycogen from gulcose, of forming fat from glucose, and of burning glucose were more or less completely lost. The formation of glycogen from glucose involved two known stages: the stage of disaccharide and the stage of polysaccharide; they did not know where the difficulty lay in diabetes. They could not study the loss of the power of forming fat from glucose until they knew whether normally sugar was formed from fat in the body. As to the loss of the power of burning sugar, it was known that the difficulty lay in the very first stages of the reaction, before the stage of lactic acid. The loss of the power of forming glycogen and fat from glucose could not be dependent upon the loss of the power of burning glucose. Dr. Taylor interpreted the loss of power of burning glucose physicochemically as follows: Glucose in alkaline reaction was slowly burned, this was the autoreaction. The muscles provided a zymase of low activity only. The pancreas provided a zymoexcitor, whose action was to multiply greatly the acceleration accomplished by the muscular zymase. A direct analogy was to be found in alcohol fermentation, where the zymase of the yeast was the enzyme and phosphoric acid the zymoexcitor. Loss of combustion of glucose could be caused by loss in the mass of the muscular enzyme, by loss in the pancreatic zymoexcitor, or by some disturbance in the reaction. The best investigations indicated that in diabetes of the classical type, the cause was to be found in the pancreas, leading to the more or less complete reduction in the mass of the zymoexcitor.

The Distribution of Protein Digesting Enzymes in the Body and Their Part in Some Pathological Processes.—Dr. Eugene L. Opie of New York read this paper in which he stated that numerous observations had shown that a variety of conditions, often associated with degenerative processes in various organs and with cachectic conditions, were accompanied by increased antienzymotic (antitryptic) activity in the blood serum. Poisoning by chloroform or by phosphorus, associated by advanced changes in the liver, illustrated this increased antienzymotic activity. By the study of the enzymes present in the liver and in the blood serum after the administration of these substances, the attempt had been made to explain the change.

A Study of the Internal Secretion of the Pancreas.—Dr. Joseph Pratt and Dr. Lesley H. Spooner of Boston presented this paper. They discussed atrophy of the pancreas produced by ligating the ducts in dogs and cats. The limit of assimilation of carbohydrates decreased 50 per cent. or more in two months after occluding pancreatic ducts. In a dog kept under observation for one year diabetes did not develop. There was no definite evidence of compensation on the part of other organs for diminished pancreatic function. The limit of assimilation for glucose was markedly increased by feeding fresh pancreases. There was complete disappearance of the islands of Langerhans in atrophied pancreases without the occurrence of diabetes.

Dr. Henry Sewell of Denver made a preliminary report upon an interesting case; his clinical observations had been carried on for two months in a case of diabetes. The patient was a child in whom a very strict diet did not seem to relieve his glycosuria. His experiments were not yet completed, and a detailed report would be made later.

Dr. William Geo. MacCallum of New York was convinced that the remnants referred to were the remains of the islands of Langerhans.

The Pancreatic Reaction of Cammidge in Relation to Diseases of the Pancreas and Ductless Glands.—Dr. Balfour related his experiences with the Cammidge reaction two years ago. He had experimented on eighty cases following Cammidge's technique closely. His results were most discouraging and he gave up.

Dr. Pilcher resumed examinations in May, 1909. He made an effort to improve the technique by running parallel tests of hydrolized and unhydrolized specimens. The experiments were made chiefly on patients showing more or less pancreatic involvement. Of 62 patients showing involvement of the pancreas at operation, 50 gave more or less "positive" reactions. Of 50 cases showing at operation no pancreatic involvement, seven gave more or less positive reactions. Of 25 well individuals one gave a positive reaction. This work served to show the possibilities of error, owing to the indefiniteness of what actually constituted a reaction.

Drs. Willis and McGrath took up the work along with Dr. Pilcher about five months ago and sought: (1) to attain a uniform technique; (2) to analyze the types of reaction; and (3) to eliminate the personal equation by having the end reactions classified by one who knew nothing of the patient. Nineteen types of end reactions were found necessary for accurate recording. From Cammidge's description about four of these types would have been considered positive and the remainder negative. Cases were clinically of four classes: 1. Cases shown at autopsy or operation to have involvement of the pancreas. 2. Cases which at operation or autopsy were shown to have no pancreatic involvement. 3. Sick individuals in whom the pancreas was not examined. 4. Apparently well individuals. Group 1 contained 21 cases, 14 of whom were examined before the operation; six gave positive reac-

tions. Of the same 21 cases examined five days after operation six were positive, three of these having been positive before the operation, one was negative, and two were not examined previously. Eighteen of these were examined about the ninth day after operation and three gave positive reactions. These three had been positive before the operation. One had been positive on the second test and the other two negative. The second group, in which the pancreas was not involved, contained 60 cases. Twenty-one were examined before the operation, fourteen were positive. Five days after the operation all sixty were examined again and fifteen were positive. Four of these had been positive before and the remaining eleven had not been previously examined. Nine days after operation 55 of these cases were again examined and 14 were positive. Of these, five had been positive before operation and the remaining nine had not been examined before operation. Of the third group, sick persons whose pancreases were not examined, 207 cases were examined. Seventy-three of these were positive. Of these 73 positives 15 were goiter cases, eight were appendicitis cases, and the remainder were cases of salpingitis, uterine tumors, etc. Of the group of well persons 17 cases were examined from one to five times each. Of these examinations five were positive. From these facts they summarized as follows: 1. That even where the most elaborate care was exercised to follow the technique of Mr. Cammidge's "6" reaction, if knowledge of the clinical histories and other factors of the personal equation were eliminated, the end results must be considered, both as valueless and misleading as a means of diagnosing disease of the pancreas. 2. There was no apparent clinical relationship between disease of the pancreas and any of the various types of end reaction. 3. It did not seem to them that the end reactions were artifacts but rather that they indicated actual metabolic variations. The relationship of these changes to the welfare of the patient was not apparent.

Dr. Francis F. Kinnicutt of New York said that their observations at the Presbyterian Hospital did not permit him to accept Dr. Wilson's conclusions; they had tried the reaction in 127 cases and there were positive reactions in twenty-four of them. He gave a brief report of the positive cases.

Dr. Louis B. Wilson of Rochester, Minn., said that, strange as it might seem, a positive reaction was obtained in absolutely healthy individuals. There was a larger number of individuals without pancreatic lesions that gave the reaction than did the individuals who had pancreatic lesions. In those patients with pancreatic lesions, the reaction varied greatly.

Election of Officers.—*President,* Dr. F. Forchheimer, Cincinnati; *Vice-President,* Dr. J. George Adami, Montreal; *Secretary* Dr. George M. Kober, Washington; *Recorder,* Dr. Solomon Solis Cohen, Philadelphia; *Treasurer,* Dr. J. P. Crozer Griffith, Philadelphia; *Councillor,* Dr. George Dock, New Orleans. *Elected to Active Membership,* Dr. Albion W. Hewlett, Ann Arbor, Mich.; Dr. E. Libman, New York; Dr. Frederick T. Lord, Boston. *Elected to Associate Membership,* Dr. Thomas R. Boggs, Baltimore; Dr. John Howland, New York; Dr. Leo Loeb, Philadelphia; Dr. Wilder Tileston, New Haven; Dr. Augustus B. Wadsworth, New York.

Digestive or Alimentary Hypersecretion of Gastric Juice.—Dr. Julius Friedenwald of Baltimore presented this paper in which he said that alimentary hypersecretion was characterized by the appearance of abnormally large quantities of gastric secretion after the introduction of an ordinary test meal, being distinguished from continuous hypersecretion by the presence of but little or no gastric juice in the fasting stomach. He had based his observations on the study of fourteen cases, varying in age from 18 to 64 years. The symptoms consisted of fullness, pressure, distention, and eructations after meals, with pain in the region of the stomach, accompanied occasionally by nausea and vomiting. Emaciation was present in all instances; there was usually constipation but rarely heart-burn. The gastric contents extracted after an Ewald-Boas test breakfast ranged between 190 c.c. and 410 c.c. This large amount was always a feature of the disease. The amount of fluid in the stomach contents ranged as high as 94 per cent., but was once as low as 68 per cent. Eight of the fourteen cases presented a hyperacidity, five a normal acidity, and one a subacidity. With the dry test meal two of the cases presented hyperacidity, eleven normal acidity, and one a subacidity. Alimentary gastrosuccorrhea was a nervous affection which was apt to extend over a long period of time and with great variability of symptoms. The fact that the patient enjoyed good health for long periods of time and at those times the increased secretion following meals was apt to disappear, indicate that the disorder was purely a form of gastric neurasthenia.

Some Reactions of the Vasomotor Center.—Drs. Torald Sollmann and J. D. Pilcher of Cleveland said that the reactions of the vasomotor center were being studied by a method which permitted the elimination of all complicating factors, such as cardiac or peripheral vasomotor reactions. They reported on response of the center to various conditions such as reflex pressor and depressor stimulation, asphyxia, cerebral anemia, cardiac stoppage, rise of blood-pressure, hemorrhage, saline infusion, and a series of drugs.

Further Experiments on the Production of Active Immunity in Guinea-Pigs by Mixtures of Diphtheria Toxin and Antitoxin.—Drs. Theobold Smith and Herbert R. Brown of Boston presented this communication, which was a report of the continuation of those experiments published in the *Journal of Experimental Medicine,* 1909, XI. To the trials made with mixtures of toxin and antitoxin they had added some made with toxin alone, and others in which the toxin injection followed the dose of antitoxin by from 24 to 72 hours. The immunity produced was measured, as heretofore, by the passive immunity of the offspring. They concluded with a discussion of the theories involved.

The Bacteriology of Acute Respiratory Infections as Determined by Culture from the Bronchial Secretion.—Dr. L. Emmet Holt of New York read this paper. The object of his work was to obtain facts as to the increased frequency of respiratory infections and to ascertain the part played by the *B. influenzæ.* The results of his first season's observations indicated that the influenza organism played a very important part, especially in winter and early spring infections. The *B. influenzæ* was second only to the pneumococcus. During the present season about 1000 cultures had been made upon 400 patients and 32 nurses, also cultures from the lung's and heart's blood in 65 routine autopsies. The patients were all under three years of age. The method of taking bronchial cultures consisted in inducing a hard cough by pharyngeal irritation and catching the secretion upon a swab. The patients were divided into four groups, pneumonia, bronchitis and mild respiratory infections, non-respiratory infections, pneumonia, and tuberculosis. There were several fairly distinct clinical types recognized. In general, the influenza infections were characterized by wide and irregular fluctuations in temperature, by rather mild general symptoms, and very irregular physical signs, prolonged and recurring. Dr. Holt believed that the *Staphylococcus aureus* played a much more important part in the bronchopneumonias of young children than was usually attributed to it. The findings in bronchitis differed very little from those in cases of pneumonia as to the frequency with which the pneumococcus, streptococcus, and staphylococcus were found. The influenza

bacillus was present in a higher percentage of cases than in the pneumonias. In the non-respiratory cases, though all these organisms were frequently found, the proportion of influenza fell to the lowest point. Otitis frequently complicated these respiratory infections, and cultures after fresh paracentesis of 75 ears showed staphylococcus 66 per cent., pneumococcus 20 per cent., streptococcus 20 per cent. and influenza bacillus 8 per cent. In general the post-mortem findings corresponded with the clinical findings as determining the type of infection. After an experience extending over two years Dr. Holt thought that culture examination was of great assistance in diagnosis, especially in influenza infections. Therapeutically these findings might have some bearing. In about half a dozen cases he had used influenza vaccines and he thought they were indicated in very protracted or in recurring cases of influenza infection.

Dr. Frederick T. Lord of Boston said that he had worked along similar lines in Boston from 1903 to 1905, but he dealt with adults and not with children. In his series of 186 cases about two-thirds showed mixed infections, the remaining one-third having but a single organism predominating. It became apparent, however, that even in this small group of cases where there was but one organism found at the first examination, there appeared sooner or later other organisms. There did not appear to be any increased leucocyte count in infections of the upper respiratory tract; whereas, in the deeper parts of this tract there was a high leucocyte count.

Dr. William H. Park of New York said that there had been emphasized two important points, the importance of employing cultural methods, and the bearing this had on the diagnosis and prognosis.

The General Principles Underlying Vaccine Treatment.—Dr. J. G. Adami of Montreal discussed the differences between reactions *in vivo* and *in vitro* together with the possible differences between the natural cure of disease and the cure by means of antibodies, whether these were directly introduced into the organism, or were developed in the organism by the introduction of dead or living bacteria. He also considered the main principles which seemed to determine successful vaccine therapy.

Vaccine Therapeutics in Typhoid Fever.—Dr. Mark W. Richardson of Boston read this paper. He first reviewed the literature on this subject and then summarized the results obtained with typhoid vaccine in the treatment of typhoid fever, both in the original disease and in relapses. The results obtained were not striking as far as the original disease was concerned. There was, however, a better outlook as to the prevention of relapses. The best field for the use of vaccines lay, undoubtedly, in prophylaxis against the disease. Preventative inoculation was becoming more and more common in widely separated parts of the world.

The Effects of Injections of Killed Streptococci in the Living Body.—Dr. George Henry Weaver of Chicago discussed the destruction of streptococci in the body as accomplished through phagocytosis. The opsonin was the only demonstrable antibody of importance in this process. In regard to the immunizing power of killed streptococci in uninfected animals he said that streptococci killed by strong galactose solutions were much more active than those killed by heat. Immunity in rabbits was associated with increase of opsonin. He discussed the use of prophylactic injections in man against scarlet fever and for the purpose of preventing streptococcus complications in this disease and concluded that they were of uncertain usefulness in the first instance and of no apparent value in the prevention of complications. The therapeutic effects of killed streptococci in man were of no benefit in erysipelas except in subacute and chronic cases. In the streptococcus complications of eruptive diseases there was no benefit from these injections in the acute stage; in subacute and chronic stages there was a marked benefit in some cases. Septic cases were often benefited. The difficulties of judging results accurately were very great because of the natural course of the conditions treated. The failure to obtain favorable results might depend upon exhaustion of reactive ability of the body cells, adaptation of bacteria, distortion of interaction of bacteria and the serum and cells of the body.

Report of the Inoculation Department of the German Hospital, Philadelphia.—Dr. John C. DaCosta, Jr., of Philadelphia made this report. He described the methods and technique employed and reported a number of cases in which vaccine therapy had been employed; these embraced cases of streptococcus and staphylococcus bacteriemia, local suppurative lesions such as furunculosis, carbuncle, mastoiditis, otitis, empyema, subdural abscess, pelvic abscess, pyonephrosis, and diffuse pyogenic lesions as cellulitis and disseminated superficial abscess.

Results in Vaccine Therapy.—Dr. William H. Park of New York spoke of the results that were attained by the use of bacterial vaccines and concluded that bacterial vaccines were of value in many localized bacterial infections, but that their value in general infections, such as typhoid fever and pneumonia, was not yet established.

Dr. Francis F. Kinnicutt of New York said that at the last meeting of the association there were reported several cases of streptococcus bacteriemia associated with endocarditis in which recovery took place. During the past three weeks they had received into the wards of the Presbyterian Hospital three severe cases of puerperal sepsis; in all the autogenous vaccines were used and all these patients had made a good recovery.

A Clinical Aspect of Fifty-two Sporadic Cases of Trichinosis.—Dr. W. Gilman Thompson of New York made this report. He said that the fact that he had been able to obtain records of 52 sporadic cases of trichinosis during a period of six years proved that this malady was much more common as a sporadic disease than was usually supposed, at least in the vicinity of New York. There was no difficulty in determining at once a correct diagnosis of trichinosis based upon the following symptoms: 1. Acute onset, usually with vomiting and abdominal cramps. 2. A high grade of eosinophilia, usually above 30 and frequently much higher, even above 80 per cent. 3. A temperature often reaching 104 or more and lasting in lessening degree for from two to six weeks. 4. Puffiness of the eyelids and face with pains in the eye occurring in one-fourth of the cases. 5. Dyspnea and diaphragmatic breathing occurring without cyanosis in about one-fourth of the cases. 6. The generalized muscle pains, cramps, soreness, and prostration. 7. The sudden occurrence of symmetrical circumscribed corneal hemorrhage in a patient whose blood vessels were not degenerate.

Dr. Richard C. Cabot of Boston said that at the Massachusetts General Hospital during the past year they had had one case of general anasarca, with dropsy of all the serous cavities. In one case the patient had no pain at all. In another case they obtained the embryo from the blood by the method described by Dr. Janeway.

The Resistance to Compression of the Arterial Wall.—Drs. Theodore C. Janeway and Edwards A. Park of New York presented this paper, which was a report of experiments carried on by graphic methods, the pressure of the internal circulation and the external compressing medium being registered, while the variations in the flow beyond the artery were recorded by a Hurthle membrane manometer. The points of the first diminution of the flow, of total cessation, and of the return of the flow after lowering the external pressure, were thus determined. The latter proved by far the most constant index and most analogous to the ordinary criterion of the return of the

pulse in clinical work. Four groups of arteries were tested. 1. Adult's arteries obtained postmortem. These gave data concerning the relatively slight effect of arteriosclerosis and even calcification of the wall on the compressibility. No such vessel required more than 20 mm. overpressure. 2. Infant's arteries obtained very soon after death. These required uniformly but a few mm. to compress. 3. Arteries from amputated limbs kept in Ringer's solution and tested within a few hours. The results were somewhat variable and unsatisfactory, but they seemed to substantiate post-mortem results. 4. Surviving carotids from the ox, all alive when tested, as proved by the contraction to adrenalin and barium chloride by Meyer's method. In this group the effect of tonus was studied in various ways and it was demonstrated that it had a surprising influence on the compressibility of the vessel. They pointed out the sources of error in such experiments which invalidated all previous work.

Third Day—Thursday, May 5.

Peculiar Sickle-Shaped Forms of Red Blood Corpuscles in a Case of Anemia.—Dr. James B. Herrick of Chicago reported this case. A young negro, twenty years of age, was suffering from a severe secondary anemia of obscure origin. His blood showed many red blood corpuscles of peculiar sickle-like shape. Some were nucleated. The patient had yaws and had suffered from weaknes, dyspnea, and jaundice for three years. When he first presented himself he had a cough, fever, dizziness, bronchial catarrh, and acute rhinitis. He had an enlargement of the left ventricle and a systolic murmur. The spleen and liver were not enlarged. The urine showed a trace of albumin and a few casts. He had been under treatment for a year and while he had improved the blood presented practically the same picture as at the beginning of treatment.

Pernicious Anemia.—Dr. Alexander McPhedran of Toronto reported a case of pernicious anemia in which there was apparent complete recovery lasting for a period of sixteen years.

Dr. George Dock of New Orleans said that these remissions in pernicious anemia were very interesting features of the disease and, curiously enough, were not often recognized. He knew of one patient that had been presented to three different medical societies by three different medical men as a cured case of pernicious anemia.

Dr. James B. Herrick of Chicago recalled one patient in which there was an interval of seven years between the attacks.

Dr. William S. Thayer of Baltimore had seen but one such case; the interval was about four and a half years.

Dr. Frederick C. Shattuck of Boston saw one case of pernicious anemia which followed confinement; recovery took place. The blood picture was absolutely typical of the disease, the examination being made by Dr. Cabot.

Study of Experimental Cardiorenal Lesions.—Drs. H. A. Christian, R. M. Smith, and I. C. Walker of Boston presented this report of a year's study of cardirenal lesions produced in rabbits by the injection of various drugs such as uranium nitrate, arsenic, sparteine sulphate, and adrenalin chloride. They gave particular attention to the histological changes produced in the heart and kidneys. Of particular interest among these lesions was a proliferative type of pericarditis following hemorrhagic exudation into the pericardial cavity. This lesion was associated with both myocardial and endocardial changes of a proliferative character.

The Frequency and Significance of Albumin in the Urine of Normal Children.—Drs. Samuel McClintock Hamill and H. D. Blackfan of Philadelphia presented this paper which was based upon the systematic analyses of the urine of 500 children. They discussed the frequency of albuminuria in children presumably normal and the relationship of such albuminurias to the conditions upon which they were supposed to be dependent.

Dr. S. J. Meltzer of New York reminded those present that the mucous membrane of the gastrointestinal tract was more permeable in children than in adults, and this might apply to all the mucous membranes of the body, that they were all more permeable at the time of growth; this was as it should be for purposes of absorption and elimination.

A Clinical Method of Estimating the Coagulation Time of the Blood.—Dr. Robert Dawson Rudolf of Toronto presented this paper. He said that no attempt had been made or could be made to measure the time or extent of the coagulation of the blood when this was surrounded by normal tissues and was circulating in a normal manner, because under those conditions it did not coagulate. The chief object of his communication was to advocate a method of measuring the coagulation time of the blood, which was convenient clinically and which seemed to give reliable results. The temperature at which the experiment was carried out made a marked difference in results. This difference was about one minute for each degree Centigrade. At 20 C. the average coagulation time was eight and one-half minutes. Age, after early childhood, and sex seemed to have no influence upon the time. A diurnal variation did not seem to occur; possibly there was a slight increase in coagulability as the day advanced, but this might have been due to an experimental error. There appeared to be a slight tendency to decrease in the coagulability some two hours after a meal but it was too slight to attach any weight to it. Calcium lactate did not appear to have any influence upon coagulation. Citric acid appeared to have a slight retarding influence. Considerable variation occurred in the coagulation time of a healthy individual from time to time, the nature of which was not evident.

A Preliminary Note on Medical Uses of Rectal Infusions.—Dr. Henry Sewall of Denver made this report. He said that from a theoretical point of view the following summary might be made of the distinctive vital relations of proctolysis: 1. Rectal infusions seemed less disturbing to the economy than fluid presented to the body through other channels. Infusions introduced by the "Murphy method" produced a minimum of peristaltic reaction. 2. Warm rectal infusions had a diuretic effect which was frequently immediate and intense. 3. Soluble toxins proceeding from foci of infection impaired the vitality and reduced the resistance power of healthy tissues. This condition was important in medical as well as surgical cases. Dilution of the circulating toxins with imbibed fluid and their removal by diuresis would seem not only to protect the kidneys by lessening the concentration of the poisons excreted but tended to safeguard sound tissues. 4. Clinical observation indicated that microbic metastasis was inclined to seek regions already injured by circulating toxins. In gonorrheal affection joint pains were probably due to transported toxins and were apt to precede the local establishment of the cocci. Proctoclysis appeared to ameliorate such pains, and might possibly limit the extension of the infection. 5. The addition of foreign fluid was an important aid in the maintenance of normal blood pressure. 6. The exhibition of many medicines by way of rectal infusions commended itself as free from disadvantages inherent to the oral channel. The cases upon which the article was based belonged to two groups: 1. Those in which it was desired to raise arterial tension, or to deplete an effusion; 2. Those in which the object was to reduce toxemia. In the second group there was a pertinent field for proctoclysis.

The Effects of Concentrated Saline Solutions on the

Human Body.—Dr. Harlow Brooks of New York made this report. The patient was a young woman for whom, after an operation for appendicitis, a rectal enema composed of one pint of normal saline and one-half ounce of whiskey was ordered to be repeated q. i. h. for three doses. One hour after the first enema the patient became restless, nervous, and thirsty. After the second dose her symptoms became exaggerated and the surgeon was sent for. She had been given the third enema before he arrived and he found her unconscious. The pulse was small, 120 and temperature 101°. The pupils were contracted and failed to react to light. The temperature rapidly rose to 109° per rectum, respirations became rapid, shallow, and difficult, and the patient died about eight hours after leaving the table. About forty minutes before death she had a convulsive seizure lasting ten minutes and a few minutes before death passed about a quart of blood-stained gelatinous material from the gut. The urine had been voided frequently and showed a specific gravity of 1.015, no sugar and no albumin. A few days later it was found that the nurse had given a saturated solution of NaCl used as a stock solution. Thus the patient received nine ounces of sodium chloride and it was believed that this was the cause of death. Administration of concentrated salines produced symptoms precisely like those in this case, presumably by taking fluids from the blood lymph and tissues and drawing them to the gut or stomach. The administration of NaCl to rabbits produced these symptoms and postmortem examination showed the stomach and intestines filled with gelatinous secretion; hemorrhagic eschars were present in the stomach and intestines. With the idea that although acute administration of excessive quantities of salt might not produce renal lesions, persistent administration might, rabbits were submitted to repeated excessive but not fatal doses of NaCl by the stomach. Aside from emaciation and temporary symptoms, produced immediately by the doses, no effects were obtained. The excretion of the excess of salt was rapidly brought about by the urine. No demonstrable renal lesions were produced, and a certain degree of toleration seemed to be established.

Toxemic Jaundice.—Dr. David Riesman of Philadelphia discussed those forms of jaundice which were not due to obstruction of the ducts, and he distinguished four principal groups: (1) That in which the jaundice was associated with acute infectious diseases; (2) that characterized by extensive anatomic changes in the liver; (3) obscure infections or intoxications without marked changes in the liver; (4) a familial or hereditary type characterized by chronicity, enlargement of the spleen, and hemolysis. The jaundice in these four groups, as well as that experimentally produced by icterogenic poisons such as toluylendiamin, was not hematogenous but was always of hepatic origin. Reference was made to the histological changes in the liver in the jaundice of pneumonia and other infectious diseases, especially to a peculiar loosening up of the cellular texture of the organ. He did not share the view of William Hunter that the jaundice was due to a catarrhal swelling of the finest bile channels and increased viscidity of the bile, but was of the opinion that it was chiefly functional in origin and was due to changes in the pressure relations within the liver which caused a reversal of the bile flow. It was probable that exaggerated blood destruction, by furnishing the liver with a larger amount of raw material, *i. e.*, hemoglobin, might bring about excessive bile formation. The possibility also existed that the poisons in their passage through the liver injured the endothelial cells of the various capillary systems of the organ, and thus facilitated the resorption of bile.

Anuria Five Full Days in a Child Three Years Old; Recovery.—Dr. W. P. Northrup of New York reported this case, a child who had suffered from scarlet fever with severe angina. For three or four days following the injection of Mulford's whole serum he had had a striking urticarial rash. At the end of twelve days there ensued a period of five days during which time the boy passed only a few drops of urine. He had no symptoms of uremia and was waterlogged. At the end of five days he began to pass urine in spurts of one drachm; the following days he passed 300 c.c., 600 c.c., 1,000 c.c., 1,750 c.c. and 2,100 c.c. He was now perfectly well. This case was rare but not unique. The probable cause of the anuria was toxic inhibition; it was probably not due to the antitoxic serum. Inflammation of the kidneys was not severe. Dr. Northrup said that the question as to whether there was any relation between the excessive urticarial skin rash, presumably an antitoxin serum rash, and the swelling of the kidney was purely conjectural. He asked whether a surgeon would at the present time suggest splitting the kidney capsule and whether one would always wait five days in a similar case.

Dr. Milton H. Fussell of Philadelphia reported a case of anuria which extended over a period of four days. There was no anasarca. The child died later of miliary tuberculosis. Sections of the kidneys were examined but nothing was found to account for the anuria.

Dr. William S. Thayer of Baltimore reported the case of a child who was absolutely waterlogged for a period of at least two months and yet there was not any abnormal sign in the urinary examination except a reduction in the quantity of the urine. He died three or four years after this attack of some other condition.

Dr. Frederick C. Shattuck of Boston asked if a reversal of the condition described by Dr. Northrup had ever been observed by him. He recalled one case in which, after the subsidence of the scarlet fever, the child had a tremendous polyuria. Nothing abnormal was found in the urine, and there was no dropsy or anything which pointed toward any nephritic trouble.

Dr. R. D. Rudolph of Toronto asked Dr. Northrup if the symptoms of nephritis appeared before the administration of the antitoxin.

Dr. William P. Northrup of New York replied in the negative. He was unable to answer Dr. Shattuck's question. In the cases that had been reported in the literature, there were a great number of weak places. In some it was reported that the patients were given tub baths daily and this admitted of a loophole even though the patients were carefully observed.

Dr. Francis F. Kinnicutt of New York asked if the urticaria was very severe.

Dr. Northrup replied that the urticaria was very severe.

Dr. Francis F. Kinnicutt of New York said that urticaria as a possible cause of the anuria appealed to him. In angioneurotic edema the mucous membranes became swollen; therefore, as an etiological factor this suggested itself to him.

Dr. Northrup of New York said that one of the best articles on this subject was by Dr. E. P. Fowler of New York on "Suppression of Urine" (William Wood & Co., New York, 1881).

Eye Affections in the Insane.—F. M. Fernández describes the affections of the eyes he found in almost 200 insane patients. Lacrymal diseases are not very common. Blepharitis, on the contrary, is abundant, owing to the prejudices of that kind of patients. Ectropion is exceedingly common, owing to the frequency with which the insane strike each other. He was surprised to find so little trachoma in spite of the increase of the disease in Cuba lately, and of the scanty sanitary conditions. Pterygium was frequent, and also corneal affections. Cataract was common, and he operated upon four cases, with fair results. He was surprised to see an immense number of cases of increased sensibility of the retina.—*Crónica Médico-Quirurgica de la Habana.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Board of Medical Examiners of Maryland.

December, 1909.

ANATOMY.

1. Bone? Composition and structure.
2. Name bones with which the temporal articulates.
3. Describe the thoracic duct.
4. Name the ductless glands.
5. Describe any one ductless gland.
6. Make diagram of transverse section of thoracic spinal cord.
7. Give general plan of circulation.
8. Describe the ophthalmic nerve.
9. Describe the middle ear.
10. Origin, insertion, action, and nerve-supply of teres major and gracilis muscles.

PHYSIOLOGY.

1. (*a*) Define human physiology. (*b*) Define physiological leucocytosis and mention some conditions in which it is found. (*c*) Give normal blood-pressure.
2. State what you know of the composition and characacter of urine, and mention the most frequent abnormal constituents.
3. (*a*) What are the sources of oxygen and carbonic-acid gas in the system? (*b*) What is the effect of each upon the blood?
4. What is meant by absorption and nutrition?
5. Where in the body is each of the following found, and what is the function of each: Pepsin, trypsin, glycogen, ptyalin, and synovia?
6. Describe the normal heart sounds and factors producing each.
7. Describe briefly the functions of the pneumogastric nerve.
8. Give the functions of the skin, and describe briefly how each function is performed.
9. Lymph: Origin, description, composition, and functions.
10. (*a*) Describe the normal pulse, and give the average rate during infancy, youth, and old age. (*b*) What is the normal ratio of the pulse to respiration?

CHEMISTRY.

1. Define (*a*) diffusion, (*b*) dialysis, (*c*) combustion, (*d*) reagents, (*e*) oxidation, and give an illustration of each.
2. (*a*) What is the reaction of normal gastric juice, (*b*) and to what is it due?
3. (*a*) Give properties, (*b*) chemical formula, and (*c*) uses of permanganate of potash.
4. Mention one chemical antidote for each of the following: (*a*) Phenol, (*b*) arsenious oxide, (*c*) sulphuric acid, (*d*) mercuric chloride, (*e*) oxalic acid.
5. Complete the following equations:
   (*a*) $BaO_2 + H_2SO_4 =$
   (*b*) $2KI + HgCl_2 =$
   (*c*) $Na_2CO_3 + CaCl_2 =$
   (*d*) $Pb(NO_3)_2 + Na_2SO_4 =$
   (*e*) $2KOH + H_2SO_4 =$
6. Describe in detail the examination of a sample of urine for the detection of sugar, albumen and bile.
7. Give (*a*) chemical formula, (*b*) properties, and (*c*) uses of iodoform.
8. Give a chemical classification of foodstuffs, with an example of each.
9. Under what circumstances are the syllables mono, di-, tri-, tetra-, and penta- used in chemical nomenclature? Give examples.
10. Describe Marsh's test for arsenic.

MATERIA MEDICA.

1. How is opium obtained? (*a*) What per cent. of morphine should the official powdered opium yield? (*b*) Name two alkaloids of opium and give doses.
2. Give the official name and composition of (*a*) Fowler's solution, (*b*) Donovan's solution.
3. Name five official preparations of mercury.
4. State the dose of infusion of digitalis, fluid extract of ergot, oleum terebinthinæ, sodium salicylate, and tinctura opii deodorati.
5. Give the official name and dose of (*a*) Epsom salts, (*b*) Rochelle salts, (*c*) Glauber salts.
6. What is incompatibility in medicine, and what are the different kinds of incompatibles?
7. Would you write potassium chlorate and tannin in the same prescription? Give reasons for your answer.
8. Define narcotics, anesthetics, and sedatives, and give an example of each.
9. Name the four principal alkaloids of cinchona.
10. Mention the three principal salts of potassium used in medicine, and give dose of each.

THERAPEUTICS.

1. Name two respiratory stimulants and two vasomotor depressants. Give doses.
2. Describe and give the indications for the use of cardiac sedatives, with an example.
3. For what purpose is diaphoresis produced? Name three diaphoretics.
4. By what methods do antipyretics act?
5. Define anthelmintics, and name some remedies of this class.
6. Explain how antitoxin produces immunity and effects cure.
7. What therapeutic uses has chloroform other than as an anesthetic?
8. What is cumulative action? Name one drug that has this tendency, and give symptoms of such action.
9. What is the important alkaloid of erythroxylon, and what is its principal therapeutic use?
10. What are the therapeutic uses of the preparations of bismuth?

PATHOLOGY.

1. Define (*a*) calcification, (*b*) neuroma and angioma, (*c*) a retention cyst. (*d*) What are the degenerative changes of arteries? (*e*) What is osteomalacia?
2. How does sarcoma differ histologically from carcinoma?
3. What pathological changes are found in Addison's disease?
4. Give pathology of tabes dorsalis.
5. Describe pathological change that takes place in the liver from chronic interstitial hepatitis or atrophic cirrhosis.
6. What pathological changes occur in acute lobar pneumonia?
7. What is diplococcus? Name two pathogenic diplococci.
8. Define (*a*) germicide, (*b*) antiseptic, (*c*) asepsis, (*d*) sterile, (*e*) disinfectant.
9. What is essential to the life of bacteria?
10. What special culture medium is required for the growth of gonococcus?

PRACTICE.

1. Define (*a*) epidemic parotitis, (*b*) difference between endemic and epidemic diseases, (*c*) dysphagia, and name some diseases in which it occurs; (*d*) Koplik's sign and Kernig's sign. In what diseases do they occur?
2. What is (*a*) percussion, (*b*) inspiration, (*c*) mensuration, (*d*) palpation, (*e*) auscultation, (*f*) succussion, (*g*) egophony.
3. Give differential diagnosis between membranous and spasmodic croup, and give treatment of each.
4. Give differential diagnosis between varioloid and varicella.
5. Give differential diagnosis between hysteria and epilepsy.
6. Give symptoms of Graves' or Basedow's disease.
7. Give causes and symptoms of ascites, and indicate how to recognize by what disease it is produced.
8. Give treatment of erysipelas.
9. Give treatment of diabetes mellitus.
10. Describe symptoms of herpes zoster and its treatment.

SURGERY.

1. What is an abscess, an aneurysm, and with what conditions may aneurysm be confounded?
2. Define peritonitis.
3. Describe operation for ligation of subclavian in its third portion.
4. Describe tonsillectomy, and how would you arrest dangerous hemorrhage after this operation?
5. Name and describe the more common errors of refraction.
6. Define glaucoma, and describe its surgical treatment.
7. Where and when, if at all, should metallic sutures be used, and why?
8. Give symptoms, signs, diagnosis, and surgical treatment (operative and non-operative) of tuberculous coxitis (hip-point disease).

9. Name several local anesthetics and mode of application.
10. Cholecystotomy: Indication, limitations, technicque.

OBSTETRICS.

1. What are the factors concerned in normal menstruation? Under what pathological condition may menstruation be absent?
2. How is external palpation applied in the diagnosis of the position of the fetus?
3. What is puerperal eclampsia? Describe the prophylaxis and give treatment.
4. Give the causes, diagnosis, and treatment of prolapse of the cord.
5. Give the causes, diagnosis, mechanism, and management of a face presentation.
6. Mention all the structures divided in complete laceration of the perineum, and describe an operation for their restoration.
7. Give the pathological anatomy, symptoms, diagnosis, and treatment of membranous dysmenorrhea.
8. Give reasons for the shortening of the round ligaments. Describe the operation.
9. Describe the structures and development of a dermoid cyst of the ovary.
10. Give the causes of icterus of the new-born.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS OF MARYLAND.

December, 1909.

ANATOMY.

1. See Cunningham's "Anatomy" (1909), pages 70 and 71; or Gray's "Anatomy" (1908), pages 41 and 34.
2. The Temporal bone articulates with the Occipital, Parietal, Sphenoid, Inferior Maxillary, and Malar bones.
3. See Cunningham's "Anatomy" 1909), page 906; or Gray's "Anatomy" (1908), page 775.
4. The ductless glands are: Spleen, thyroid, parathyroids, thymus, suprarenals, coccygeal, carotid, pineal pituitary, and lymphatic glands.
5. See Cunningham's "Anatomy" (1909), page 1210; or Gray's "Anatomy" (1908), page 1407.
6. See Cunningham's "Anatomy" (1909), page 458; or Gray's "Anatomy" (1908), page 843.
7. See Gray's "Anatomy" (1908), page 557.
8. See Cunningham's "Anatomy" (1909), page 679; or Gray's "Anatomy" (1908), page 1043.
9. See Cunningham's "Anatomy" (1909), page 748; or Gray's "Anatomy" (1908), page 1160.
10. TERES MAJOR. *Origin:* Inferior angle of scapula. *Insertion:* Inner bicipital ridge of humerus. *Action:* draws humerus downward and backward, and is internal rotator. *Nerve supply:* Subscapular nerve.

GRACILIS. *Origin:* Symphysis pubis. *Insertion:* Upper part of inner surface of shaft of tibia. *Action:* Flexes leg, rotates it inward, and adducts thigh. *Nerve supply:* Obturator nerve.

PHYSIOLOGY.

1. (*a*) *Human physiology* is that branch of science which treats of the functions of the organs and tissues of the human body in a state of health.

(*b*) *Physiological leucocytosis* is an increase in the number of the white blood corpuscles occurring under normal or physiological conditions, such as: Digestion, exercise, after a cold bath, or during pregnancy.

(*c*) The normal blood pressure in the brachial artery is between 110 and 130 millimeters of mercury.

2. *Normal urine* is a yellowish fluid secreted by the kidneys to the amount of about 1200-1500 c.c. daily; specific gravity, about 1015 to 1025; acid reaction (due to acid sodium phosphate); it has a characteristic odor and a salty taste. Its *normal constituents* are: Water, urea, uric acid, urates, hippuric acid, kreatin, kreatinin, xanthin, hypoxanthin; sulphates, chlorides, and phosphates of sodium and potassium; phosphates of magnesium and calcium; nitrogen, and carbon dioxide. The most frequent *abnormal constituents* are: Albumin, casts, sugar, blood, pus, excess of indican, bacteria, bile.

4. *Absorption* is the process by which the products of digestion are conveyed to the circulation. *Nutrition* is the sum of the processes by which the body digests, absorbs, and assimilates suitable materials brought into contact with it.

5. *Pepsin* is found in the gastric juice; it changes proteids into proteoses and peptones in an acid medium. *Trypsin* is found in the pancreatic juice; it changes proteids into proteoses and peptones in an alkaline medium, and afterwards decomposes them into leucin and tyrosin. *Glycogen* is found in the liver (also in placenta, white blood corpuscles, muscle tissue, etc.); it is a source of sugar and of energy. *Ptyalin* is found in the saliva; it changes starches into dextrin and sugar. *Synovia* is found in the joints and bursæ; it acts as a lubricant.

6. There are two normal heart sounds which follow in quick succession, and are succeeded by a pause. The first, or systolic, sound is dull and somewhat prolonged; the second, or diastolic, sound is sharper and shorter. The sounds may be expressed by the syllables *lubb—dup*. The first sound is heard best at the apex beat in the fifth left intercostal space; the second sound is heard best over the second right costal cartilage. The *causes* producing the *first* sound of the heart are not definitely ascertained; the following are supposed to be causatory factors: (1) The vibration and closure of the auriculoventricular valves, (2) the muscular sound produced by the contraction of the ventricles, and (3) the cardiac impulse against the chest wall. The *second* sound is caused by the vibration due to the closure of the semilunar valves.

7. *Function of Pneumogastric Nerve:* It supplies (1) *motor* influence to the pharynx and esophagus, stomach, and intestines, to the larynx, trachea, bronchi, and lungs; (2) *sensory* and, in part, (3) *vasomotor* influence, to the same regions; (4) *inhibitory* influence to the *heart;* (5) *inhibitory* afferent impulses to the *vasomotor center;* (6) *excito-secretory* to the salivary glands; (7) *excito-motor* in coughing, vomiting, etc.

8. The *functions of the skin* are: (1) Protection, (2) excretion, (3) secretion, (4) heat regulation, (5) absorption, (6) general sensation, (7) special sense of touch, and (8) respiration.

(1) By its mechanical covering, and also by its being an organ of sensation. (2) Very slight; and see (3). (3) It secretes sebum to lubricate the hairs, and sweat (which has several functions: excretion of water, carbon dioxide, and urea; cooling of surface of body; and regulator of body heat). (4) By radiation, and see 3. (5) Very slight, chiefly of oily substances. (6) and (7) By end organs. (8) A slight amount of carbon dioxide is exhaled.

9. LYMPH. *Origin:* There are two theories as to the formation of lymph: (1) That it is formed from the blood plasma by the processes of filtration, diffusion, and osmosis. (2) That in addition to these, the endothelial cells of the capillaries exercise some influence. *Description:* Lymph is a colorless, albuminous fluid, alkaline in reaction, with specific gravity of about 1015, containing lymph corpuscles, and coagulating when drawn from its vessels. *Composition:* Proteins (serum albumin, fibrinogen), sugar, sodium chloride and carbonate, water, urea, fat. *Function:* To provide cells and tissues with materials necessary for their growth, repair, and functional activities; and to receive and carry away their waste products.

10. The *pulse* is a wave of expansion which travels along the arteries, and is due to the discharge from the left ventricle of a volume of blood, during systole, into the already full arterial system. The points to be observed are: (1) Its *frequency;* this gives the rate of the heart beats. (2) Its *compressibility;* this denotes the force with which the heart is beating. (3) Its *tension;* this denotes the peripheral resistance, and also the state of the arterial walls. (4) Its *regularity* or *rhythm;* this denotes the regularity (or otherwise) of the heart's action in force or rhythm. The average rate during infancy is about 120 per minute; during youth, about 80; and during old age, about 60. The normal ratio of pulse to respiration is about 4:1.

CHEMISTRY.

1. *Diffusion* is the thorough mixing of liquids or gases which occurs when they are brought together. Thus, two liquids of different densities, even when at perfect rest, will soon have diffused into each other to form a single liquid whose density and composition are the same throughout. *Dialysis* is the process of separating substances from each other by placing the mixture containing them in a vessel with porous walls and immersing it in water, when the more diffusible substance will pass through. *Reagents* are substances used to produce chemical reactions; for example, see Question 6 below:

By *oxidation* we mean the act of union of oxygen with another element or compound. This process is attended by the liberation of heat, and, when it takes place rapidly, of light. The rusting of a given weight of iron is a slow oxidation, while the burning of the same in oxygen is a rapid oxidation. Only the latter produces light, while in both cases the same amount of heat is liberated.

By *combustion*, in a general sense, is meant the rapid union of the oxygen of the air with some other substance, as coal or phosphorus. In a wider sense, however, combustion may be defined as any chemical union of two substances attended by liberation of heat and light.

2. (*a*) Acid. (*b*) To hydrochloric acid.

3. Potassium Permanganate is a dark crystalline substance, yielding a red powder when broken. It is soluble in water, and gives it a red color even in very dilute solutions. It is an oxidizing agent, and disinfectant. Its formula is $K_2Mn_2O_8$.

4. One chemical antidote for *phenol*, sodium sulphate; for *arsenious* oxide, freshly prepared solution of ferric hydroxide; for *sulphuric acid*, magnesia; for *mercuric chloride*, white of egg; for *oxalic acid*, magnesia.

5. (*a*) $BaO_2 + H_2SO_4 = BaSO_4 + H_2O_2$
(*b*) $2KI + HgCl_2 = 2KCl + HgI_2$
(*c*) $Na_2CO_3 + CaCl_2 = 2NaCl + CaCO_3$
(*d*) $Pb(NO_3)_2 + Na_2SO_4 = PbSO_4 + 2NaNO_3$
(*e*) $2KOH + H_2SO_4 = K_2SO_4 + 2H_2O$

6. *Test for albumin:* "The urine must be perfectly clear. If not so, it is to be filtered, and if this does not render it transparent it is to be treated with a few drops of magnesia mixture and again filtered. The reaction is first observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral or alkaline, it is rendered *faintly* acid by the addition of dilute acetic acid and heated. If albumin be present, a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of HNO_3."

Test for sugar: Render the urine strongly alkaline by addition of Na_2CO_3. Divide about 6 c.c. of the alkaline liquid in two test-tubes. To one test-tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color.

Test for bile pigment in the urine: Put 3 c.c. HNO_3 in a test-tube; add a piece of wood, and heat until the acid is yellow; cool. When cold, float some of the urine to be tested upon the surface of the acid. A green band is formed at the junction of the liquid, which gradually rises, and is succeeded from below by blue, reddish-violet, and yellow.

7. *Iodoform* has formula CHI_3. It is a solid, yellow, crystalline substance, insoluble in water, soluble in alcohol and in ether, with a sweet taste and a peculiar penetrating odor. It is used as a dressing for wounds, sores and ulcers (particularly tubercular and syphilitic ulcers).

8. Foods are classified as follows:

I. Inorganic { Water. / Salts. (Sodium Chloride.)

II. Organic { Non-nitrogenous { Carbohydrates (Sugar). / Fats (Fat). / Nitrogenous—Proteids (Meat).

9. *Mono* denotes one; thus, CO carbon monoxide. *Di* means two; thus, H_2O_2 hydrogen dioxide. *Tri* means three; thus $C_3H_5(OH)_3$ glycerol is a triatomic alcohol. *Tetra* means four; thus, carbon is tetravalent. *Penta* means five; thus PCl_5 phosphorus pentachloride.

10. *Marsh's test for arsenic:* This test depends on the fact that arsenic hydride is formed when nascent hydrogen acts on a compound of arsenic:

$$H_3AsO_3 + 3H_2 = AsH_3 + 3H_2O.$$

A small flask fitted with thistle funnel and a delivery tube, as for the production of hydrogen, is used; pure zinc and hydrochloric acid are introduced, and after a short time the hydrogen is ignited. It is advisable to cover the flask with a cloth before igniting the gas, as an explosion may happen unless the air has all been driven out. If the materials are pure the hydrogen flame gives no deposit upon a piece of cold porcelain brought into it, but commercial zinc usually contains arsenic. When the purity of the gas is proved, a little solution of arsenite may be poured down the thistle funnel, which will produce a more rapid evolution of gas, and the flame will become larger and perceptibly colored. A piece of cold porcelain depressed upon the flame will be covered with a deposit of metallic arsenic. The films of arsenic are metallic looking in the thicker places, brownish near the edges; they are easily volatized by heat, and dissolve in solution of bleaching powder. A portion of the glass tube from which the gas is burned should be heated to redness; the gas decomposes and a deposit of arsenic appears on the tube, which may be identified in a similar way, or may be converted into crystals of oxide by cautious sublimation in an open tube.—(Fisher's *Elementary Chemistry.*)

MATERIA MEDICA.

1. Opium is obtained by incising the unripe capsules of Papaver somniferum. It should yield not less than nine *per cent.* of morphine. *Two alkaloids:* Morphine, dose gr. 1/5; Codeine, dose gr. ½.

2. (*a*) *Fowler's Solution* is liquor potasii arsenitis. Its composition is: Arsenic trioxide, potassium bicarbonate, compound tincture of lavender, and water.

(*b*) *Donovan's Solution* is liquor arseni et hydrargyri iodidi. Its composition is: arsenous iodide, red mercuric iodide, and water.

3. (1) Hydrargyri chloridum corrosivum; (2) Hydrargyri chloridum mite; (3) Hydrargyri iodidum flavum; (4) Hydrargyri iodidum rubrum; (5) Hydrargyrum cum creta.

4. Infusion of digitalis, dose 3ij; Fluidextract of ergot, dose ℥xxx; Oleum terebinthinæ, no dose; Sodium salicylate, dose gr. xv; Tinctura opii deodorati, dose ℥viij.

5.

	OFFICIAL NAME.	DOSE.
Epsom salt.....	Magnesii sulphas	3iv
Rochelle salt.....	Potassii et sodii tartras	3ij
Glauber's salt.....	Sodii sulphas	3iv

6. By *incompatibility* is understood the simultaneous administration or combination of substances not suitable for such combination. *Varieties:* Chemical, pharmaceutical, and therapeutical.

7. I would not write potassium chlorate and tannin in the same prescription; because the combination is explosive.

8. *Narcotics* are agents which produce deep sleep; as opium.

Anesthetics are agents which destroy sensation; as ether.

Sedatives are agents which reduce functional activity and diminish pain; as aconite.

9. Quinine, quinidine, cinchonine, cinchonidine.

10. Potassium iodide, dose gr. vijss; potassium chlorate, dose gr. iv; potassium bitartrate, dose gr. xxx.

THERAPEUTICS.

1. *Two respiratory stimulants:* Strychnine, dose of sulplate, gr. 1/64; and citrated caffeine, dose gr. ij. *Two vasomotor depressants:* Amyl nitrite, dose ℥iij; and aconite, dose of tincture, ℥x.

2. *Cardiac sedatives* lessen the force and frequency of the heart's action. They are used to control palpitation and overaction of that organ, also to slow the pulse in febrile conditions in sthenic subjects, especially when local inflammation is the exciting cause thereof. Most of them are direct cardiac poisons, depressing both the heart muscle and the motor ganglia. The list includes Aconite and Veratrum, also Muscarine, Pilocarpine, Saponin, Hydrocyanic Acid, Antimony, Potassium salts, and Digitalis, the last-named acting as a sedative by stimulation of the vagus center and the cardiac muscle, slowing the rate and giving regular rhythm to the action of the heart.—(From Potter's *Materia Medica.*)

3. *Diaphoresis is produced:* (1) To remove fluid from the body. (2) To remove poisons from the body. (3) To reestablish disturbed cutaneous circulation, and so to relieve congestion of internal organs. (4) To relieve the kidneys. (5) To increase the alkalinity of the tissues. *Three diaphoretics:* Alcohol, aconite, and pilocarpus.

4. The following table (from Potter's *Materia Medica*) gives the chief antipyretics, with their manner of action: Temperature depression may be done by five different actions working upon two principal lines, viz., by:

(*a*) *Lessening heat production by* { (1) diminishing tissue change. / (2) reducing the circulation.

(*b*) *Promoting heat loss by* { (3) dilating cutaneous vessels, thus increasing heat radiation. / (4) promoting perspiration, its evaporation lowering the temperature. / (5) abstracting heat from the body.

The following list of antipyretics includes a few for each of the above-named actions, to which the numbers refer in each case, viz.:

Quinine, 1.	Aconite, 2.	Antipyrin, 1, 4.
Phenol, 1.	Alcohol, 1, 3.	Antimony, 2, 4.
Salicin, 1.	Nitrous ether, 3, 4.	Cold bath, 5.
Digitalis, 2.	Acetanilid, 1, 4.	Cold drinks, 5.
	Phenacetin, 1, 4.	Wet-pack, 5.

5. *Anthelmintics* are agents which kill or expel worms inhabiting the intestinal tract. *Examples:* Oleoresina aspidii, gr. xxx; Pelletièrine tannate, gr. x; santonin, gr. j; pumpkin (pepo) seeds, ʒj.

6. *How* antitoxin produces immunity and affects cure is not known, but *theories* deduced from observed facts are as follows: "As the various pathogenic bacteria produce the causative toxins of their respective diseases, so the organic cells of the body, reacting under the stimulus of the poisons thus introduced, immediately proceed to elaborate defensive bodies, which if produced in sufficient quantity will neutralize the effects of the toxins. Residual antibodies remaining in the blood after recovery render the animal immune for a time against the disease. The immunizing and curative effects obtained by the injection of the blood serum of an immunized animal into the circulation of another animal are due either to direct chemical neutralization of the toxins themselves by the antibodies so introduced (Behring, Kitasato), or to a particular influence exerted by the antibodies upon the living cells of the organism which, being affected in two opposite directions, remain neutral to the disease (Buchner). Some authorities hold that these results are due to the conjoint action of leucytic and chemical forces. Ehrlich's side-chain theory assumes that every toxin contains toxophore molecules having direct toxic action, and haptophore molecules which combine the toxophores with a similar combining group of molecules in the tissue cell of the attacked organism. The tissue cell molecules being destroyed by the toxophores, a rapid and profuse regeneration of similar molecules occurs in side chains, and these molecules overgrowing are carried into the circulation, becoming the antitoxin, which acts by combining with the haptophores of newly arrived toxin, using up their combining power before they can reach the tissue cells."—(Potter's *Materia Medica*, etc.)

7. Besides being an anesthetic, chloroform is a rubefacient, an anodyne, an antipruritic; it is administered internally as a stomachic, in dyspepsia, to disguise nauseous drugs, in diarrhea, in irritating coughs and bronchitis.

8. *Cumulative action* is the property which some drugs have of producing more or less sudden and violent action, after single and successive doses have been taken with no untoward effect. *Example:* Digitalis; this produces fast and irregular pulse, gastroenteritis, small pulse, low blood pressure.

9. The important alkaloid of erythroxylon is cocaine; its principal therapeutic use is as a local anesthetic.

10. Preparations of bismuth are used: (1) *Externally*, as dusting powders for wounds, sores, some skin diseases; (2) *internally*, in vomiting, diarrhea, gastritis, gastralgia, and as an intestinal antiseptic; (3) also in sore mouth, conjunctivitis, granular lids, coryza, mercurial ptyalism.

PATHOLOGY.

1. (*a*) *Calcification* is a pathological process in which certain tissues are infiltrated with calcareous particles (salts of calcium and magnesium). (*b*) *Neuroma* is a tumor consisting almost entirely of nerve tissue. *Angioma* is a tumor consisting of blood-vessels bound together by a small amount of connective tissue. (*c*) A *retention* cyst is a cyst which results from the retention of a normal secretion (as a sebaceous cyst); (*d*) Fatty, calcareous, hyaline, and amyloid degenerations. (*e*) *Osteomalacia* is a disease characterized by progressive softening of the bones.

2. *Carcinoma* is derived from the epiblast or the hypoblast; possesses a stroma, in which are both blood-vessels and lymphatics; metastasis occurs by the lymphatics.

Sarcoma is derived from the mesoblast; it has no stroma and no lymphatics; metastasis occurs by the blood-vessels which are in contact with the cells.

3. See French's "Practice of Medicine" (1907), page 539; or Osler's "Practice of Medicine" (1909), page 756.

4. In *tabes dorsalis* the posterior columns of the spinal cord and the posterior nerve roots are involved. The posterior columns of the spinal cord are gray and shrunken, and show considerable overgrowth of connective tissue in the columns of Goll, Burdach, and Lissauer; this process extends upward from the lumbosacral region; the posterior nerve roots degenerate and become atrophic. The meninges over the affected parts become opaque and adherent. Some of the cranial nerves may also atrophy, notably the optic, but also the motor oculi and vagus. The process is destructive and progressive; it is not a simple wasting, although the nerve fibers are atrophied, but it is characterized by irritation, changes in the axis cylinders, overgrowth of the connective tissue, and sometimes congestion; the spinal ganglia may be affected.

5. In *atrophic cirrhosis:* The liver is shrunken and indurated, rough, and of a pale or yellow color; a growth of new connective tissue is disposed in broad bands which run in various directions, and by their contraction divide the liver into numerous irregular lobes. Many acini may be affected at one time. The capsule may be thickened, or adherent to the diaphragm. Jaundice is slight, and comes on late; ascites is pronounced and may occur early.

6. See French's "Practice of Medicine" (1907), page 154; or Osler's "Practice of Medicine" (1909), page 170.

7. A *diplococcus* is a form of bacteria made up of two cocci attached to each other (in pairs). Two pathogenic diplococci: *Diplacoccus pneumoniæ* and *Diplococcus intracellularis meningitidis.*

8. (*a*) *Germicide* as an agent capable of destroying bacteria. (*b*) *Antiseptic* is an agent capable of preventing or restraining putrefaction. (*c*) *Asepsis* means freedom from pathogenic germs. (*d*) *Sterile* means containing neither microorganisms nor spores capable of development. (*e*) *Disinfectant* is an agent which restrains infectious diseases by destroying or removing their specific poisons.

9. Most bacteria require proper temperature, generally at or near that of the body; oxygen is generally needed, those that cannot live without it being called aërobic, and those that can grow without it, anaërobic; nutriment of a proper kind, containing both organic and inorganic material; a slight degree of moisture; a medium of slightly alkaline reaction; and rest. Individual bacteria may require modifications of the above essentials.

10. Human blood serum.

PRACTICE.

1. (*a*) *Epidemic parotitis* is inflammation of the parotid gland (or mumps), occurring in a large number of people at the same time. (*b*) An *endemic* disease is one which is more prevalent in certain localities than elsewhere; an *epidemic disease* is one which attacks a large number of persons in the same locality in rapid succession. (*c*) *Dysphagia* means painful or difficult swallowing; it occurs in peritonsillar abscess, tonsillitis, cancer of tongue, pharyngitis, etc. (*d*) *Koplik's sign* is the presence of small red spots with a bluish-white center on the inner surface of the cheeks, found in measles prior to the development of the eruption on the skin. *Kernig's sign* is inability to fully straighten the leg after both thigh and leg have been flexed; it is found in cerebrospinal meningitis.

2. (*a*) *Percussion* is a method of diagnosis, and consists in striking a part with a view to determining the condition of the underlying organs by the sound elicited. (*b*) *Inspiration* is the act of breathing in. (*c*) *Mensuration* means measuring. (*d*) *Palpation* is a method of diagnosis, and consists in feeling or pressing over an organ with fingers or hands. (*e*) *Auscultation* is a method of diagnosis, and consists in listening to the sounds of the heart, blood-vessels, or respiratory apparatus. (*f*) *Succussion* is a method of diagnosis, and consists in shaking (slightly) the patient or some viscus. (*g*) *Egophony* is a form of vocal resonance in which the voice sounds tremulous and bleating.

3. *Spasmodic croup* generally comes on suddenly, at night. There is no appreciable fever, no previous malaise or sickness, and often the patient is asleep again by the time the physician arrives. There is frequently a thick, tenacious mucus, but neither Klebs-Loeffler bacilli nor streptococci are present. It is entirely a local disturbance.

Membranous croup is either laryngeal diphtheria or a streptococcus infection. In either case there is a prior stage of malaise, accompanied by chills, fever, and sore throat. The fever may become very high. A membrane forms, in which are found the Klebs-Loeffler bacilli or streptococci.

For treatment, see French's "Practice of Medicine" (1907), pages 647 and 195; or Osler's "Practice of Medicine" (1909), pages 599 and 207.

4. In *varicella* the symptoms come on gradually; there is no prodromal fever; no pain in the back; the eruption appears on the first day, comes in crops, disappears on stretching the skin, and is not shotty.

In *varioloid* the symptoms come on very suddenly; there is fever; severe pain in the back, and headache; the eruption appears on the third or fourth day, as papules, becoming in turn vesicles and pustules.

5.

EPILEPSY.	HYSTERIA.
1. No apparent cause.	1. Cause, emotional.
2. Sudden and rapid onset.	2. Onset gradual, usually after some mental excitement.

EPILEPSY.	HYSTERIA.
3. Aura generally present.	3. Globus hystericus or palpitation.
4. Consciousness lost.	4. Consciousness generally preserved.
5. Pupils generally dilated.	5. Pupils normal.
6. Tongue often bitten.	6. Tongue never bitten.
7. Patient very liable to hurt himself.	7. Patient not liable to hurt himself; may injure others.
8. May be involuntary bladder and bowel discharges.	8. Never.
9. Of short duration.	9. Duration longer.

6. See French's "Practice of Medicine" (1907), page 548; or Osler's "Practice of Medicine" (1909), page 766.

7. See French's "Practice of Medicine" (1907), page 871; or Osler's "Practice of Medicine" (1909), page 589.

8. See French's "Practice of Medicine" (1907), page 221; or Osler's "Practice of Medicine" (1909), page 213.

9. See French's "Practice of Medicine" (1907), page 944; or Osler's "Practice of Medicine" (1909), page 420.

10. See French's "Practice of Medicine" (1907), page 995.

SURGERY.

1. An *abscess* is a circumscribed collection of pus in a cavity of new formation.

An *aneurysm* is a pulsating sac containing blood communicating with the lumen of an artery; it may be confounded with abscess, cyst, soft tumor.

2. *Peritonitis* is inflammation of the peritoneum.

3. See Rose and Carless' "Surgery" (1908), page 333; or Da Costa's "Surgery" (1908), page 410.

4. See Rose and Carless' "Surgery" (1908), page 868.

5. The more common errors of refraction are: Myopia, hypermetropia, and astigmatism. *Myopia* is a condition in which the anteroposterior axis of the eye is abnormally long, and parallel rays are focused in front of the retina. *Hypermetropia* is a condition in which the anteroposterior axis of the eye is abnormally short, and parallel rays are focused behind the retina. *Astigmatism* is a condition in which, owing to a greater curvature of the eye in one meridian than in others, the refractive power of the eye varies.

6. *Glaucoma* is a diseased condition of the eye especially characterized by increased intraocular tension. Surgical treatment is *iridectomy:* "Having first secured a lid speculum in position, a fold of conjunctiva, near the cornea and opposite the place where the incision is to be made, is seized by fixation forceps. A keratome is entered through the cornea at the scleral border, the point being kept nearly perpendicular to the sclera until it has reached the anterior chamber, when the handle is depressed so as to bring the blade parallel to the iris. The blade is then pushed forward until it has made a wound sufficiently large for the purpose of the operation; still depressing the handle, the blade is withdrawn slowly, and iris forceps are thrust through the wound closed, and opened in the anterior chamber to seize the iris. The iris is then drawn out of the wound, and as much of it as desired is excised by fine iridectomy scissors held firmly against the eyeball and parallel to the wound. The stump of the iris is then carefully returned to the anterior chamber, no portion of it being allowed to become incarcerated in the corneal incision. The delicate McClure iris scissors are the best for cutting the iris, but they are rather expensive, and not always obtainable. The eye should be thoroughly cocainized, and the operation should be done under antiseptic precautions; after the operation the eye should be thoroughly irrigated, a light bandage applied, and the eye kept closed until the corneal incision has become united. The incision may be made with the Graefe knife instead of the lance-shaped keratome."—(Gould and Pyle's *Compend.*)

7. See Rose and Carless' "Surgery" (1908), page 232.

8. See Rose and Carless' "Surgery" (1908), page 679; or Da Costa's "Surgery" (1908), page 552.

9. See Rose and Carless' "Surgery" (1908), page 1318; or Da Costa's Surgery (1908), page 1046.

10. See Rose and Carless' "Surgery" (1908), page 1061; or Da Costa's "Surgery" (1908), page 965.

OBSTETRICS.

1. See Williams' "Obstetrics" (1909), page 81; or Hirst's "Obstetrics" (1909), page 57.

Menstruation may be absent, owing to absence or imperfect development of the generative organs; also to stenosis, obstructions, or atresia of the genital tract; also to operative removal of the uterus or its appendages. Other causative factors are: Acute infectious diseases, anemia, chlorosis, obesity, drug habits, alcoholism, overstudy, lack of exercise, exposure to cold, and various emotional causes.

2. See Williams' "Obstetrics" (1909), page 211; or Hirst's "Obstetrics" (1909), page 389.

3. *Puerperal eclampsia* is an acute morbid condition, occurring during pregnancy, labor, or the puerperal state, and is characterized by tonic and clonic convulsions, which affect first the voluntary and then the involuntary muscles; there is total loss of consciousness, which tends either to coma or to sleep, and the condition may terminate in recovery or death. *Preventive treatment:* (1) The amount of nitrogenous food should be diminished to a minimum; (2) the production and absorption of poisonous materials in the intestines and body tissues should be limited and their elimination should be aided by improving the action of the bowels, the kidneys, the liver, the skin, and the lungs; (3) the source of the fetal metabolic products and the peripheral irritation in the uterus should, if necessary, be removed by evacuating that organ. *Curative treatment:* (1) Controlling the convulsions (by chloroform, veratrum, or chloral); (2) elimination of the poison or poisons which are presumed to cause the convulsions; (3) emptying the uterus under deep anesthesia, by some method that is rapid and that will cause as little injury to the woman as possible.

4. See Williams' "Obstetrics" (1909), page 842; or Hirst's "Obstetrics" (1909), page 625.

5. See Williams' "Obstetrics" (1909), page 274; or Hirst's "Obstetrics" (1909), page 409.

6. In *incomplete laceration of the perineum* any of the following tissues may be lacerated: Skin, mucous membrane of fourchette, constrictor vaginæ, transversus perinei, and lavator ani. In *complete laceration* the sphincter ani and the anterior surface of the rectum are involved, in addition to the structures named above.

For *repair,* see Williams' "Obstetrics" (1909), page 325; or Hirst's "Obstetrics" (1909), page 868.

7. MEMBRANOUS DYSMENORRHEA. *"Pathological anatomy:* When complete the membrane is a hollow cast of the interior of the uterus; it is the shape of an isosceles triangle, the base of which corresponds to the fundus of the uterus. At each of the truncated angles there is an opening, the small ones at the base indicating the position of the uterine ostia of the Fallopian tubes, and the larger apical opening marking the site of the os internum. A menstrual decidua is usually 2.3 centimeters in length and 2 millimeters in thickness. The inner surface is shaggy, as is best seen when the membrane is floated out in water. Histologically, the membrane consists of recent blood-clot, characterized by the presence of a large excess of leucocytes; fragments of organized tissue are found, consisting of small round cells with a small amount of delicate fibrous stroma, and sometimes portions of shed and partially disintegrated epithelium. No glands are found, nor are the large decidual cells characteristic of the decidua of pregnancy present. The condition is best described as one of exfoliative menstrual endometritis. *Symptoms:* The patient complains of severe intermittent pain, beginning with the onset of the menstrual period and reaching a maximum just before the expulsion of the membrane, after which the pain usually ceases. The membrane may come away whole, in several pieces, or in numerous shreds, and is usually discharged within forty-eight hours of the commencement of the menstrual flow. *Diagnosis:* The membranous cast must be distinguished from the decidua that comes away in cases of tubal pregnancy, or from the unimpregnated horn of a gravid uterus, and from the products of early abortion. The histological appearances will usually be decisive; in addition to which the history will generally serve for a diagnosis. In cases of deciduæ associated with pregnancy within or without the uterus there is always a history of one or more missed periods, except in some few cases of tubal gestation. The hemorrhage in cases of membranous dysmenorrhea is limited to the usual few days, while in cases where the member is decidual it may go on for one or several weeks. When the case has been under observation some time the regular painful discharge of membranes at monthly intervals is absolutely characteristic. *Treatment:* No drugs affect the formation of the membrane, although pain may be relieved by this means. The incidence of pregnancy sometimes effectually arrests the membranous formation, but not always. The best results are obtained from curetting, which affords at least a temporary relief; but it may require to be repeated."—(Sutton and Giles' *Diseases of Women.*)

8. The round ligaments are shortened when the uterus is retroverted, or retroflexed, and there are no complications. See Hirst's "Obstetrics" (1909), page 914; or Rose and Carless' "Surgery" (1908), page 1278.

9. *Ovarian dermoids:* Dermoids are "tumors furnished with skin or mucous membrane occurring in situations where these structures are not found under normal conditions." Ovarian dermoids may be lined with skin throughout, or only over a very small area. The skin may have hair, sebaceous glands, sweat glands, mammæ. There may be teeth, muscle, bone, horn, nails; very rarely brain-like tissue. The cavity of a dermoid cyst is generally filled with fluid fat.

10. The cause of icterus of the new-born is not known. It is found most often in premature and weakly infants, and in those born in maternity hospitals. The following theories have been held as to its etiology: "(1) *Obstruction to the outflow of bile* by (*a*) plugs of mucus in the common bile duct; (*b*) partial blocking of the bile ducts by desquamated epithelium, the result of hyperemia and catarrh of the ducts following on the changes in the circulation which take place at birth; (*c*) congenital narrowing of the bile ducts; (*d*) inability of the ducts to carry off the secretion of bile, which is considerable at first; and (*e*) delayed ligature of the cord. (2) *Pressure on the ducts from without* by (*a*) the portal and hepatic veins becoming distended in consequence of the changes in the circulation following birth; (*b*) swelling and edema of Glisson's capsule, the result of engorgement of the umbilical and portal veins—hence the jaundice is hepatogenous. (3) Closure of the umbilical vein, which leads to such a lowering of blood pressure in the capillaries of the liver that reabsorption of bile takes place. (4) The ductus venosus remains open and thereby allows some portal blood, which contains bile, to pass through it and enter the inferior vena cava."—(From *Aids to Diseases of Children.*)

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION	
Alabama*	W. H. Sanders, Montgomery	Montgomery	July 12
Arizona*	Ancil Martin, Phoenix	Phoenix	July 4
Arkansas	F. T. Murphy, Brinkley	Little Rock	Nov. 8
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco	Aug. 2
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	July 5
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	July 12
Delaware	J. H. Wilson, Dover	Dover	June 21
Dist. of Col'bia	Geo. C. Ober, Washington	Washington	July 12
Florida*	I. D. Fernandez, Jacksonville	Palatka	Nov. 9
Georgia	T. H. Goss, Athens	Atlanta	Oct. 11
Idaho*	W. F. Howard, Pocatello		Oct. 4
Illinois	J. A. Egan, Springfield	Chicago	June 9
Indiana	W. T. Gott, Crawfordsville	Indianapolis	July 12
Iowa	Louis A. Thomas, Des Moines.	Des Moines.	
Kansas	F. P. Hatfield, Olathe	Topeka	June 14
Kentucky	J. N. McCormack, Bowling Green	Louisville	July 5
Louisiana	F. A. LaRue, 211 Camp Street, New Orleans	New Orleans	Oct 18
Maine	F. W. Searle, Portland	Portland	July 19
Maryland	J. McP. Scott, Hagerstown	Baltimore	June 21
Massachusetts*	E. B. Harvey, State House, Boston	Boston	July 12
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Ann Arbor	June 14
Minnesota	W. S. Fullerton, St. Paul	St. Paul	June 14
Mississippi	S. H. McLean, Jackson	Jackson	Oct. 11
Missouri	Frank B. Hiller, Jefferson City	Jefferson City	June 13
Montana*	Wm. C. Riddell, Helena	Helena	Oct. 4
Nebraska	C. A. Carr, Lincoln	Lincoln	May 23
Nevada	S. L. Lee, Carson City	Carson City	Nov. 2
N. Hampshire	Henry C. Morrison, State Library, Concord	Concord	July 6
New Jersey	H. G. Norton, Trenton	Trenton	June 21
New Mexico	J. A. Massie, Santa Fe	Santa Fe	July 11
New York	C. F. Wheelock, Univ. of State of New York, Albany	New York / Albany / Syracuse / Buffalo	June 28
N. Carolina	B. K. Hays, Oxford	Wrightsville	June 15
N. Dakota	H. M. Wheeler, Grand Forks	Grand Forks	July 5
Ohio	Geo. H. Matson, Columbus	Columbus	June 13
Oklahoma*	F. P. Davis, Enid	Guthrie	July 12
Oregon	B. E. Miller, Portland	Portland	July 5
Pennsylvania*	N. C. Schaeffer, Harrisburg	Philadelphia / Pittsburg	June 21
Rhode Island*	G. T. Swarts, Providence	Providence	July 7
S. Carolina	H. H. Wyman, Aiken	Columbia	June 14
S. Dakota	H. E. McNutt, Aberdeen	Watertown	July 13
Tennessee	C. A. Abernathy, Pulaski	Memphis / Nashville / Knoxville	May —
Texas	M. E. Daniel, Honey Grove	Austin	June 28
Utah	R. W. Fisher, Salt Lake City	Salt Lake City	July 4
Vermont	W. Scott Nay, Underhill	Burlington	July 12
Virginia	R. S. Martin, Stuart	Richmond	June 22
Washington*	T. C. McFadden, Seattle	Spokane	July 5
W. Virginia	H. A. Barbee, Point Pleasant	Charleston	July 11
Wisconsin	J. M. Beffel, Milwaukee	Madison	July 12
Wyoming	S. B. Miller, Laramie	Laramie	June 22

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of May 28, 1910:

	Cases	Death
Tuberculosis Pulmonalis	542	166
Diptheria	461	40
Measles	1,331	26
Scarlet Fever	582	27
Smallpox	3	1
Varicella	185	—
Typhoid Fever	36	5
Whooping Cough	49	3
Cerebrospinal Meningitis	2	3
Malarial Fever	—	—
Totals	3,191	271

The Treatment of Cancer.—F. Durante goes over all the methods for the treatment of cancer without surgical operation that have been advocated in modern times, and finds them all wanting as far as a radical and permanent cure are concerned. Among the methods of treatment that are considered are the biochemical methods, the use of erysipelas germs to combat the cancer tissues, as proposed by Coley, cancer vaccines, serotherapy, the *x*-rays, radium, and fulguration. Not one of these agencies which have at first promised such good results has stood the test of time. The growths have gone on developing after being retarded in some instances for a time, or recurrences and metastases have taken place. Those cases that have seemed to be permanently cured he refers to incorrect diagnosis. The superficial epitheliomata are easily influenced by several of these remedies, but the deep carcinomata are unconquerable by any of them. He denies the selective action of rays and fulguration on the cancer cells, while he admits that physical methods act as a strong stimulus on cellular reproduction, disorganization of protoplasm, and molecular degeneration, when they did not produce an eschar.—*Il Policlinico.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended May 27, 1910.

		CASES	DEATHS
CHOLERA			
India, Rangoon	April 3–9	..	2

NATURAL SELECTION AND OUR VISCERA.

BY R. G. ECCLES, M.D.,

BROOKLYN, N. Y.

A THEORY that makes intelligible many otherwise incoherent facts, and is not antagonised by any known fact is either true or so close an approximation to truth that it is a valuable and suggestive aid toward reaching truth. If the number of facts, that it puts a reasonable meaning into, accumulates with our advance in knowledge, conviction of its truth is certain to grow upon unbiased people. When there is no rival theory, having any scientific standing, the very least that common sense can demand is its provisional acceptance. The theory that natural selection is the chief agent in the production of all biological adaptations now occupies this position. It is without a rival, has explained multitudes of adaptations that are meaningless in its absence, and has put intelligibility into thousands of facts that were unknown to its original propounder. To Prof. Darwin this cumulativeness of evidence was its prime recommendation and Prof. Mendola tells us that "it is he who above any scientific worker of his time, taught us the value of cumulative evidence in establishing a new theory." Of the theory of natural selection Darwin wrote: "Now this hypothesis may be tested—and this seems to me the only fair and legitimate manner of considering the whole question—by trying whether it explains several large and independent classes of facts."[1] To Asa Gray he wrote: that he could not "possibly believe that a false theory would explain so many classes of facts" as natural selection did.[2] Evidently Darwin's old teacher, Adam Sedgwick, was, for some reason, mentally unable to appreciate the value of this kind of evidence, for he wrote to his former pupil: "You have deserted * * * the true method of induction, and started us in machinery as wild, I think, as Bishop Wilkin's locomotive that was to sail with us to the moon."[3] Tyndall must have come in contact with men like Sedgwick when he wrote: "There are men, and by no means the minority, who however wealthy in regard to facts, can never rise into the region of principles; and they are sometimes intolerant of those who can."[4] It is certain that Haeckel was not of this type for he wrote: "When we come to the application of this law, and seek to determine with its aid the origin of the various species of organisms, we are compelled to frame phylogenetic hypotheses that have essentially a deductive character, and are inferences from the general law to the particular cases. But these special deductions are just as much justified and necessitated by the rigorous laws of logic as the inductive conclusions on which the whole theory of evolution is built."[5] Sticklers for induction refuse to follow Darwin and Haeckel because they use deduction, but what sorry spectacles such sticklers would make should they adopt their one-sided principle in every-day life. Induction is imperative until the law or theory is established with considerable acceptable evidence, but that once reached, then the deductions or implications are its substantial fruits. The heuristic purpose is the chief purpose of a generalization inasmuch as it guides with a large degree of safety where experiment may be impossible. It also foreshadows the results of experiments and economically leads the investigator to the point where he can make discoveries. One of Darwin's important deductions was that "we may conclude that every detail of structure in every living creature is either now or was formerly of use directly or indirectly through complex laws of growth."[6] For half a century external and visible adaptations have been studied in the light of natural selection. Protective colorings, mimicry, curiosities in the forms of flowers aiding crossfertilization, and many strange adjustments to the external environment have been sought for, discovered, and explained. No effort of a serious nature has been made toward the explanation of visceral adaptations along these lines. Physiology has refrained from drawing Darwinian deductions and so Haeckel tells us that "the development of physiology during the last fifty years has been much more one-sided than that of morphology. It has not only failed to make much use of the comparative method which has given such great results in morphology, but it has also neglected evolutionary principles. Hence, in the last few decades morphology has far outrun physiology, though the latter is apt to put on superior airs in regard to its rival."[7] Bacteriology, protozoology, and pathology have also far outrun physiology in progress, but they have dragged the latter into the by-ways and highways of evolution in defiance of its attitude toward deduction. With prophetic vision the late president of Harvard University recently declared that, "in the future medical science must include the study of causes and consequences, which will carry the student through a large portion of the animal and vegetable kingdoms and particularly into the habits and habitats of their minute parasite forms."[8] He evidently sees that medical science is bound, before long, to be evolutionized. Pathology, through evolutionary ideas, is destined to revolutionize medical studies, and it is the belief of this writer that, as we now go to physiology for explanations of pathological conditions, it will not be long before we discover it necessary to explain the whys and wherefores of physiology by pathology. Disease seems to have preceded as a selective agent, and perhaps more, every new physiological level in the evolutionary ascent. The "every detail of structure in living creatures," referred to by Darwin, will probably be found to show their uses as protective against disease germs.

Already "the study of the protozoa has had its effect on every part of biology that is concerned with questions of historical descent," as has been declared by Prof. E. B. Wilson. He also tells us "that these creatures may have something to teach us in every department of thought into which evolutionary considerations enter," and that "the bacteria must look to their laurels with so formidable a competitor in the field," for "it is within the bounds of possibility that the discovery of the causal relation between protozoa and disease may one day rank with the greatest of those that general biology owes to the study of these simple animals."[9] It is among the protozoa that we find the most thorough specialization in regard to the food requirements of parasites. Their relations to their hosts and to the organs of their hosts is one of the most curious features in their lives. A thorough study of these relationships promises for the future the knowledge that we need in order to establish a scientific system of therapeutics. To discover why microorganisms select specific tissues to the exclusion of all others is to discover how to control their powers of proliferation and how to evict them with our remedies. Until we have a Darwinian science of medicine we cannot hope for a knowledge of the substances that attract and repel, evict and destroy, the various disease germs. It is through these peculiar tissue adaptations that we have secured our first glimpse of the immense antiquity of disease and of the great importance of parasitism in phylogeny. Of the protozoan class, sporozoa, Prof. Minchin tells us that, "as a general, though by no means universal, rule, each species of sporozoan is parasitic on a particular species of host, or on a limited number of allied species and is usually confined to definite organs or tissues of that host. Except for a brief period of their developmental cycle, they cannot exist apart from the very definite and limited environment to which they are exclusively adapted."[10] Prof. Calkins says of them: "These infect all animal forms from protozoa to man; one group lives in the digestive tract and the cavities of the body (*Gregarinidia*); another in the cells of the digestive organs (*Coccididea*); another in the muscle cells and lymph surrounding them (*Myxosporidida, Sarcosporidida*); and still another in the blood corpuscles and in the blood plasma (*Hemosporidida*)."[11] It will become evident to the reader on weighing the meaning of such facts that such a distribution cannot be fortuitous. It could only result from design or ages of natural selection. Take, as an illustration, a coccidian that, during its trophic stage, has its home within the cytoplasm of a cell. Why does it push the nucleus out of its way "often indenting or compressing it," while on the other hand, the *Cyclospora caryolyptica* enters into and destroys the nucleus? The latter "owes its specific name to its intranuclear habitat, which in this case seems to be an invariable characteristic."[12] The so-called Leishman body, found in kala azar, after making its way into the cytoplasm of some nucleated cell is able to multiply at the expense of the contents of the cytoplasm and "as multiplication goes on the cell increases in size and the nucleus is often displaced to one side."[13] Is it not fairly certain that these peculiar characteristics are evidences of an unadaptability, in the avoided or rejected tissues, for the respective organisms that avoid them? If we are consistent believers in natural selection are we not compelled to conclude that, as these different types of sporozoa "cannot exist apart from the very definite and limited environment to which they are exclusively adapted," that all connecting links between them have perished through lack of fitness? Are we not compelled to credit to the selection of the fit all such adaptations? When a protozoologist can tell us just what kind of animal and in what tissue of that animal we must look in order to find a given species of sporozoan, and in what other animal and organ we can find some other different species, such a distribution cannot be a matter of chance. It is surely more than accidental that the *Sarcosporidia* "with the rarest exceptions" confine their depredations to "the striped muscles?" Chance cannot be charged with always carrying *Coccididæ* to epitheliel cells and never to blood cells while taking the *Hemosporidia* to blood cells instead of to epitheliel cells.[14] "Liver cells, muscle cells, even heart cells, may all be destroyed by some form or other of protozoan parasite."[15] "In vertebrates the kidney is very often attacked (by *Eimeria nova*); in other cases among this phylum (*Coccidia*) it is not infrequently the spleen, and even in a few instances the testes, which is selected by coccidian parasites—never, however, the ovary—so that in this respect the predelections of *Coccidia* are the opposite of *Myxosporidia,* which frequently attack the ovary but never the testes."[16] Though fortuitousness may well be charged with carrying the resting forms of sporozoans into the intestinal tracts of their hosts, and though "the so-called 'selection' of locality" may be "a matter of mere passive resistance on the part of the parasite, that part being 'selected' where they are not destroyed by the reactions of the host, and where conditions of life are most satisfactory for nourishment and security,"[17] we must admit that the destructive reactions of the host have been determined by the evolutionary forces that produced the host. How else can we explain the parallelism of the phylogenetic changes of the totality of hosts with the totality of parasites? How happen these to both correspond—branch with branch—unless both have evolved, side by side—or rather, for much of the time, within and without each other?

If we next turn our attention to the bacteria we will find that they, too, are restricted—though in a less degree—to certain parts of the host. Prof. W. H. Park says: "Let us rub very virulent streptococci, typhoid bacilli, and diphtheria bacilli into an abrasion on the hand. The typhoid bacillus produces no lesion, the diphtheria bacillus but a very minute infected area, but the streptococcus may give rise to a severe cellulitis or fatal septicemia. Now place the same bacteria on an abrasion on the throat. The typhoid bacillus is again harmless; the diphtheria bacillus produces inflammation, a pseudomembrane, and toxemia, and the streptococcus causes an exudate, an abscess, or a septicemia. Finally, introduce the same bacteria into the intestines, and now it is the typhoid bacillus which produces its characteristic lesions, while the streptococcus and diphtheria bacillus are usually innocious. If we tried in this way all the parasitic bacteria we would find that certain varieties are capable of developing, and thereby exciting disease, only on the mucous membrane of the throat, others of the intestines, others of the urethra; some develop only in the connective tissues, or in the blood, while others, again, under favorable conditions, seem able to grow in or upon most regions of the body."[17] Prof. Roger has pointed out that injections of anthrax bacilli behave differently on reaching different

organs. "A quantity of anthrax bacilli," he says, "sixty-four times that which is fatal by the peripheral veins is completely annihilated by the liver." If *Staphylococcus aureus* is used instead of anthrax a somewhat similar effect occurs. If, however, we use streptococci these find in the liver excellent conditions for multiplication. Should we, on the contrary, direct the streptococci to the lungs they would there be likely to meet destruction. "The lung then represents a protective organ against streptococcus; it fulfils a rôle analagous to that exercised by the liver against *Bacillus anthracis* or *Staphyloccocus aureus*, except that it destroys pathogenic agents with less energy."[18] But neither bacteria nor protozoa have a monopoly of this habit of preference for certain localities in which to live. Metazoan parasites have the same habit and the various parasitic fungi that invade the higher plants show similar preferences. Emerson tells us that "Line in nature is not found," and this appears to be quite true in respect to parasitism. So narrow, indeed, is the dividing line between the saprophytic and the parasitic bacteria, that it has been bridged experimentally. "It is certain," says Prof. J. B. Pollock, "that among the fungi as well as among the bacteria, forms that for the most part live only on dead organic matter, that is, as saprophytes, may under certain special conditions become adapted to a parasitic life. They thus become the producers of new diseases. Though for the most part supposed new diseases are only a wider distribution of old diseases it is entirely possible for new diseases actually to originate by physiological adaptation. This has been proved in the production of plant disease experimentally."[19] With the changes of time any such new habit would become fixed and obligatory, for the old food that the parasite had deserted would become poisonous to it. With protozoa it has repeatedly been proven, experimentally, that becoming habituated to an abnormal food caused the original food to become fatal unless gradually restored. But what is the meaning of all these differences of toxicity of different organs for different parasites, and how happens it that, as protective devices, they are all so inadequate? Not one of them shows perfection. They all taper into absolute nonprotection, so far as some pathogenic germs are concerned. Says Prof. Wm. H. Welch: "The acceptance of the explanation of physiological adaptations furnished by the doctrine of organic evolution helps us * * * in the study of pathological adaptations" but, he says, on another page, "the teleological conception of a useful purpose in no case affords an explanation of the mechanism of an adaptive process."[20] Everywhere, in a study of disease processes, the fact has to be faced that they all utterly fail at some point where we, if we could have had our desires, would have improved them. In every one of them we have a complete explanation in natural selection. In not one of them have we the slightest intimation of special design—unless natural selection, itself, is designed. The parasites have kept pace with the protective appliances and, in order that they might live, natural selection has, apparently, selected them in accordance with their ability to break through the barriers of poisonousness that were heaped up against them. The work has extinguished neither, but compelled the one to match the other just as the warships and forts of contending nations have had to keep pace with each other. As war has been the active cause in building up and perfecting of forts and Dreadnoughts, so disease has apparently been the active agent in building up the chemical structures which constitute our organs.

With the failure of poisonousness as a protective device against parasites natural selection seems to have provided us with a supplemental device. Variation having failed to supply sufficient poisonousness for selection to work upon evidently showed itself as a fitness in another direction. By increasing the sizes of organs beyond the actual, immediate requirements it has stayed, but not stopped, the fatality of disease. In the case of our lungs, "life may continue," says Prof. Meltzer, "though a great part of the lungs be destroyed, if only the disease that caused the destruction came to a standstill. We know that in some cases of pneumonia one lung can be entirely consolidated without seriously impairing the process of ventilation. Furthermore, a patient whose thorax was freely opened to evacuate a one-sided pleural abscess has, after the opening, less dyspnea than before. In empyema as in pneumonia, it is essentially the infection and intoxication with their reactions which cause the apparent disturbance in the respiratory mechanism, and not so much the mechanical interference with the ventilation of the corresponding lung. Since the classical experiments of Regnauld and Reiset many investigators have stated that compression of one lung or a unilateral pneumothorax exerts very little influence upon the respiratory exchange of gases. Hellin reported, recently, a series of experiments in rabbits in which the right lung was completely removed. The right lung of the rabbit has four lobes, and is much larger in volume than the left; that means that more than one-half the lung tissue was removed. Most of the animals survived the operation and some lived a year or longer. * * * We see, then, that the normal process of respiration can be carried out with at least one-half of the lung."[21] If we only need one-half of the lung capacity which we possess, why has nature compelled us to carry around so much, apparently, useless weight? Why is the strain of supplying this extra lung structure with digested food placed upon the digestive organs? Why are the excretory organs thus forced to assume the extra work of getting rid of such waste? We have not far to look for a satisfactory reply. Let us ask what would happen to multitudes of animals if they were brought into the world with only enough lung tissue to serve them during perfect health? In an attack of pneumonia, tuberculosis, or any other disease that interfered with the function of the lung, would such animals be able to live a single day? The prompt destruction that would occur would quickly exterminate them. Is not, then, this excess of lung an adaptation to check the speedy ravages of disease? Is it not evident that an increase in the size of a lung, or the addition of another lung, when lungs were first used to aerate the blood, would be of decided selective value? Under the strain of pulmonary diseases natural selection would, necessarily, have been at work. Either it would seem to have supplied this extra lung tissue or it came by miracle. Prof. Adami tells us that "We know from experiment that three-quarters of the liver, for example, may be removed from the healthy animal with no pronounced disturbance of the bodily functions, that whenever one-fifth or less of the pancreas is left in the dog it may be weeks before diabetes shows itself, that only when fifteen-sixteenths of the thyroids are removed may the dog succumb.

In this enormous reserve of material and force may truly be said to lie the secret of the continued existence of living beings."[22] What, if not disease, could these adaptations be selected by? In each of the organs referred to disease is of selective value along the path they have come. Given heredity, with sufficient time, and disease with variations would surely seem to be all that is needed to do the rest. Concerning our kidneys we are told that "one kidney can be removed with entire impunity, if the other kidney is normal. The amount and the composition of the urinary secretion remains practically unaltered and this even soon after the removal of the kidney. That can only mean that normally the kidney has an abundance of tissue which can do at a moment's notice at least twice the normal amount of work. From the experimental work of Tuffier, Bradford, and others, we know that at least two-thirds of both kidneys may be removed without serious detriment to the animal's life and to the secretory function of the kidneys. We know that the average quantity of urine, as well as the normal quantities of its various constituents may be greatly reduced without any visible detriment."[23] From the viewpoint of natural selection the surplus kidney is only enough to have succeeded in tiding its possessors over the dangers of disease, long enough to enable them to have sufficient progeny to take their places in the procession of life. Anything short of this would have meant extermination. The necessities of the past, and not the needs of either the present or the future, had everything to do with its amount. Our humanitarian instincts would cause us to wish for more in many instances in which it could lengthen the life of some dear friend. None of us have any too much. Our protection, with the surplus, still remains imperfect, but no more so than we would expect it to be if natural selection has been its banker. But this increase in the sizes of the various organs, which disease seems to make necessary, requires another balance. "No great change is possible," says Prof. Brooks, "without the coordinated modifications of all the correlated features."[24] Increase in the sizes of lungs, liver, kidneys, and other organs means more work for the stomach to do their digesting, the kidneys to do their excreting, etc. Each increment of increase in size must be balanced by another increase through added work. This, in turn, reduces the proportion of reserve needed to hold disease at bay. Another addition will be required to balance this. Should environing conditions increase to a still greater extent the danger from disease, increase in organ size would continue to be of selective value. A growing increase in the sizes of organs would mean a growing increase in the sizes of the animals that possessed such organs. Is it possible that growth in size, from ameba to mastadon, has resulted from continuous adjustments toward disease? It looks that way. The controlling tendency that would hold back from giantism would be the food supply. In failure of supply the over-large animal would perish. Anything that would restrict the quantity or quality of available food would favor the production of dwarfs. The larger an animal, other things being equal, the better should be its chance for life in the presence of ample food and under the menace of disease. The smaller an animal, other things being equal, and under the conditions mentioned, the shorter should be its life. Small animals appear to be, as a rule, short lived, but they make up for this by such devices as resting stages, alternation of generation, and ability to multiply with great rapidity. In such ways they tide over the vicissitudes of cold and heat, drought and famine, etc.

In the organs so far considered, all of them required, under the most favorable of circumstances, some fraction of their tissue to make the life of the possessor possible. We now come to the consideration of an organ that, from one point of view, seems to be almost superfluous. In 1876 Prof. Czerny, of Heidelberg, Germany, removed the entire stomach of a dog, kept the animal alive until 1882 when it was shipped by him to Prof. Ludwig, of Leipzig. Ludwig and Ogata were studying the physiology of digestion and asked Czerny to let them have his dog for examination. On receiving the dog they killed it and examined its digestive organs. It was in good health and had then lived for more than five years without a stomach."[25] In 1895 Prof. Schuchardt excised the stomach of a patient, leaving only a minute fraction of three fingers in width at the pyloric end. This patient lived two and a half years after the operation, and was during this time perfectly well."[25] In 1897 a Zurich surgeon, named C. Schlatter, exhibited a patient at a medical congress, in Otten, from whom "he had completely extirpated the stomach." This was eight weeks after the operation and in the mean time she "had put on 4.4 kilos in weight."[25] The hazardous character of experiments of this kind keeps them from frequent repetition but the mere fact of success, if only in one, would evidently mean that the peculiar function performed by the stomach is not, directly, of life and death value. That it must have a function of extreme importance is evident to every Darwinian, otherwise its survival in all sorts of animals, and with no signs of any tendency to atrophy, would be unaccountable. Its digesting function—so far as digestion alone is concerned—could, apparently, be dispensed with. As a storage reservoir, for the gradual supply of food, its benefit is evident but not absolutely indispensable. As a protection against the constant introducing of pathogenic microorganisms it seems to be the chief guard of the body. As a place for the "splitting up of the proteins into numerous larger and smaller cleavage products" for the "presentation of the largest possible surface of attack to the trypsin," as stated by Abderhalden, and for thus hastening digestion and getting the food quickly away from theft by parasites, it is doubtlessly also beneficial.[26] Above all else, to which all the other functions seem subsidiary, is the part it takes in defending the body against the growing adaptations of disease germs. On masticating our food we insalivate it. Before the days of millers and cooks this task was a more difficult one than now. On entering the stomach the food is alkaline and contains the diastase ptyalin. Under normal conditions this alkaline, ptyalinised mass digests, in the warm stomach, for about three-quarters of an hour. Then it is rendered acid by the gastric juice, and continues acid for three or more hours. On reaching the duodenum it becomes alkaline again, to, once more, become acid lower down in the digestive tract. Pavlov and Parastschuck have shown us that the glands of Brunner, most probably secrete an enzyme which, like pepsin, acts in an acid medium.[26] It is thus evident that parasites, on gaining entrance to the alimentary canal, run the gauntlet of exposure to (a) alkali, (b) acid, (c) alkali, and (d) acid, successively. To be compelled to repeat-

edly readjust metabolism to diametrically opposite conditions must seriously hamper proliferation, where it fails to bring about destruction. Germs normally accustomed to acid habitats cannot be at home in alkaline ones and those used to acid surroundings are far from being favored by alkaline. The successive steps of digestion, when considered in relation to the germs, show a still more pronounced protective character. The first step, in the digestion of bread, grain, etc., is the dissolving away of the starchy covering of the vegetable albumin, and this means the laying bare of all germs that happen to be enmeshed in the starch. In mastication multitudes of germs must be ground into the food-mass that could only be reached by such a preliminary diastatic fermentation. The first step in the digestion of protein is the dissolving away of the covering and binding connective tissue of meats. With the teeth this is torn apart, but again the microorganisms are ground into the mass during mastication. Only by the removal of the connective tissue can there be safety from disease through digestion. We should remember in this connection that "connective tissue is scarcely attacked at all by trypsin, while it is readily digested by means of pepsin in acid solution"[26] For meat to reach the duodenum without the removal of the tough fibers of connective tissue would, evidently, be hazardous to life, when pathogenic germs happened to be thus shielded. Primitive man, before the use of fire, must have swallowed blood with his meat. But "blood serum and serum globulin are not attacked by trypsin, although both are digested without difficulty by gastric juice."[27] Without stomach digestion we can see that here again would have been a serious menace to life through disease infection. Enmeshed in serum and in serum globulin pancreatic digestion could not have coped with the germs. That hungry savages and many kinds of beasts do not hesitate swallowing putrid food is well known. If pepsin, like ptyalin, could be destroyed by the germs of putridity, the protective power of the stomach against disease would be very materially impaired. It has, however, been experimentally demonstrated that "a putrid solution of pepsin in distilled water one month old digests fibrin as readily as a fresh solution."[28] Instead of germs being able to destroy pepsin it, in conjunction with hydrochloric acid, seems to be able to destroy pretty effectually most invading microbes. "The gastric juice," says Adami, "is particularly active in destroying bacteria. The number taken in at each meal must be great * * * nevertheless, a few hours after food the duodenum may be found quite sterile."[29] Bunge tells us that "the antiseptic action of the gastric juice was noticed more than a hundred years ago by Spallanzani. He found that by moistening meat with gastric juice he could prevent decomposition for many days. But when, *ceteris paribus*, water was used instead of gastric juice, an unbearable putrid odor was speedily developed. A snake had swallowed a lizard. After sixteen days Spallanzani opened the stomach; the lizard was half digested, but gave no odor of decomposition."[30] That the function of the gastric juice, or at least the hydrochloric acid which it contains, is more than that of being a digestive agent is seen in the now well-known fact that it is poured out when pure water is introduced into the stomach.[31] Unless this is protective against germs, it would be hard to conjure up any other reason for its occurrence. The ingestion of honey or syrup is also met by a prompt outpouring, by the stomach wall, of acid. When ordinary food, that needs digesting, is introduced there is no such promptitude in its appearance. These other substances are all likely to carry infective material and the rapid appearance of the acid is a decided fitness. We are told by Bunge that "a strong point in favor of the view that the antiseptic action of the gastric juice constitutes its chief importance is found in the fact that, in a whole series of the lower animals, the commencement of the alimentary canal secretes a fluid very rich in mineral acid, but containing no ferment, and having no special action on the food. This important fact was first noticed by the zoologist Troschel."[32] As milk is in a fluid condition, and so able to proceed down into the intestines for digestion, what can be the meaning of the curdling by rennet? It contains nothing that tryptic digestion is not quite able to dispose of. The writer can see but one important fitness in this that could have had selective value. The germs of putrefaction and of disease, one or other, or both of which this fluid is always pretty certain to contain, are, by the coagulation, solidified into a mass that must be liquefied again before proceeding on its journey. During this liquefaction it is usually sterilized and thus made safe. This, then, is one of the most interesting and useful of the adaptations of digestion. As the food passes from the stomach into the duodenum it goes through the pyloric orifice, not as a total, but in a sifted or selected order. The partly digested carbohydrates pass through first, the partly digested proteins then follow, and finally the fats.[33] The latter are usually retained long after the others, particularly if in abundance. Is there anything of selective value in this? We all know how a duck's feathers behave when water is poured upon them. What about germs coated with fat in respect to the 0.3 per cent. hydrochloric acid sulution? This is largely water and would behave much like water as a hinderer of the action of the gastric juice. Fat sterilization would require longer than that of any other part of the food, and so we find that it is retained longer, so as, most probably, to be partly hydrolyzed by lipose. In this sterilizing of food the cell walls of the bacteria and the coverings of the sporozoa must be penetrated before they can be destroyed. Wells tells us that "numerous investigators have shown that the insoluble bacterial cell wall consists chiefly of chitin."[34] We have already learned that "a few hours after food the duodenum may be found quite sterile." It is, therefore, certain that the chitin is, somehow, dissolved during stomach digestion. Little seems to be known about the digestibility of chitin, notwithstanding its great importance to pathology and the simplicity of such an investigation. Being chiefly composed of glucosamin it is likely that the double action of the ptyalin and the pepsin digestion may be concerned in its solution. Should this prove to be the case, it will be the more interesting as an adaptation against disease. But, notwithstanding the many devices that act as barriers to the passage of parasites into the intestines, some get there. The protection here, as elsewhere, is imperfect. There is no evidence of anything more than such protection as would be expected from natural selection. A designed or purposeful protection should be far more perfect than any of these display. In the case of intestinal sporozoans the adaptations are peculiarly faulty in that they appear to demoniacally favor the parasites rather than the hosts. The very devices

of digestion that have been selected as protective have, by variations favorable to the parasites, become injurious to their hosts, for "only in their proper host do the digestive juices have the effect of liberating the sporozoites without harming them."[35] If such an adaptation is preordained by purpose what can be thought of it? If not at all digested they would pass through without doing harm. If wholly digested they would be harmless. It is the partial digesting that makes them dangerous. Turning our attention to the malarial parasite and the mosquito we learn that "Ross and Grassi found that certain genera of mosquitoes, *e.g. Culex sp.,* are incapable of fostering the human parasite, while all species of the genus *Anopheles* are particularly susceptible."[36] Why is it that an *Anopheles* can take acute enteritis from our malarial parasites when the *Culex* cannot? It is a matter of digestion. Prof. Minchin tells us that "if a human being suffering from malaria is bitten by an *Anopheles* mosquito * * * the mosquito draws into its stomach various stages of the parasite along with the blood. * * * All stages of the schizogonous cycle are digested. * * * The gametocytes alone are able to resist the action of the digestive juices. * * * The maturation of the gametes and their subsequent conjugation take place in the stomach of the mosquito. * * * If a malarial patient be bitten by a mosquito of any other genus than *Anopheles* * * * then not only the schizonts, but also the gametocytes, are digested by it. *Culex,* on the other hand, is the intermediary for the *Hemoproteus* of birds, and when it bites a bird infected with this genus of parasite, it digests all the stages except the gametocytes. *Culex*, in fact, stands in the same relation to the malarial parasites of birds, as *Anopheles* to those of man. Should an *Anopheles,* on the other hand, bite a bird infected with *Hemoproteus,* it will digest every stage of the parasite, gametocytes and all."[37] If due to natural selection all this is just as might be expected. If due to any other cause it baffles human understanding. Let the gametocytes of human malaria vary but slightly in the chemistry of their envelopes and, if the variation made them digestible to *Anopheles* mosquitos, human malaria would quickly disappear from the earth. Let them vary in a way that would defy the digestive powers of *Culex* mosquitos and almost every part of the earth would become dangerous for man. On how slight a turn does human comfort thus depend! The merest change in the covering of the gametocyte of a parasite or the slightest alteration in the gastric juice of an insect could thus increase or decrease the population of the earth to a most alarming extent. How few of us realize the slimness of the thread of fate.

It was long thought that the sole use of digestion was the conversion of insoluble into soluble foods. This we now know was a mistake. Food of all kinds, like the words and sentences on this page, are built up of elementary molecules—the alphabet of bodily, living structure. The number of these biological letters in protein is—as far as yet known— not far from the number of letters in the alphabet. Every living body is put together in a way much like that of a book with its sentences and ideas. Our food—in the condition in which we eat it—bears almost exactly the same relationship to our bodies that a galley of used type does to a printing office. Until it is completely, and perfectly, distributed it probably cannot be reused. Every letter must be separated from every other in order to be in fit condition for setting up again. Mann tells us that "the albumin, taken as food, is converted in the alimentary canal of the higher animals by means of the four proteolytic ferments, pepsin, trypsin, erepsin, and arginase into primary crystalline dissociation-products, the amino-acids, etc., which are then absorbed in this form."[38] It is thought by some physiologists that a small residue of protein may be left undissociated, just as if some printer, in order to be economical, would save whole words of type from a form he was distributing, because these words occurred with considerable frequency in the new book that was to be set up from them. Should some crazy printer try to go too far in this kind of economy the reader can imagine what sort of book he would produce should the words occur throughout its pages in utter disorder. In what is known as anaphylaxis some such event transpires within the body but this we will have to deal with more at length in another paper. As a protection against such a disaster "the intestine forms a solid barrier between the heterogeneous compounds in the food and the homogeneous building material for the blood and tissues, the composition of which has been established by the entire development of the given animal species."[39] "The whole problem of protein metabolism," say Rosenau and Anderson, "seems to be an adjustment in the sense of a defense. The power to assimilate and use foreign protein is not achieved without a certain amount of violence to the body."[40] The history of the phylogenetic development and differentiation of protein, through reaction against parasites, gives us the key to the seeming mystery of the need of any such defense, and that will be considered at another time. There is at least one form in which heterogenous protein is constantly being carried into the circulation undigested. Strange to say that form is the very last one that could have been suspected by physiologists or pathologists, reasoning from current belief among them. Reference is here made to what is known as Stöhr's phenomenon. It was first shown by Stöhr that phagocytes constantly leave the circulation, enter the intestines, pick up bacteria, and carry them back into the circulation with them. The current opinion of medical men has been that bacteria can only gain access to the blood through some lesion, or by virtue of some weakening influence that permits them to pass through the intestinal wall. Prof. Adami tells us that it is wrong "to imagine as it is too often taught that the hindrance to the entrance of bacteria into the tissues is, under all circumstances, complete in the healthy individual. A certain number of microbes is always gaining admission—nay, is being actively introduced by the cells of the organism. But under such circumstances they do not cause infection. In health they tend to be destroyed very soon after their reception. The evidence that this is the case is now overwhelming. * * * That such leucocytes as have escaped into the lumen of the gut and have returned can and do pass into the blood stream has been demonstrated with admirable precision by Prof. A. B. Macallum."[42] Metchnikoff tells us that "the digestive organs are furnished throughout with a defensive apparatus against microorganisms; this consists in an accumulation of lymphoid tissue in the form of patches or groups of solitary glands—the tonsils, Peyer's patches, and the solitary glands of the intestines. These organs produce a large number of phagocytes which are

able to come in close contact with the microorganisms."[43] The reader will notice that these very glands are active centers of diseases. Of the first named we have been told that they—the tonsils—constitute "the battlefield in which the first fight occurs between bacteria and the leucocytes."[44] Another writer says: "Certain it is that there is a growing clinical and experimental evidence that the tonsils are the portals of entry for the infectious material in a wide range of diseases, among which are pericarditis, myocarditis, endocarditis, arthritis, chorea, neuritis, adenitis, glandular fever, nephritis, pleurisy, tuberculosis, iritis, phlebitis, osteomyelitis, various other streptococcus and staphylococcus septicemias, Hodgkin's disease, and possibly even certain forms of leukemia."[45] This looks like a terrible impeachment of the tonsils as protective organs. From the viewpoint of natural selection it simply means that these are the enemies we now have to fight, that they have varied in ways that overcame our resisting powers, that in this fort the phagocytic soldiers battle with them until compelled to surrender, or until death has overcome them, and that our resisting power is, most emphatically, a very limited one, under these conditions. To look at protection as a designed purposefulness is to be compelled to conclude that, for man, the purpose must have become a very faulty affair. The position of the tonsils might lead us to conclude, as the author just quoted has done, that the tonsils must be the portals of entry of all the diseases let loose from Pandora's box. The fact is that these may be the last of a chain of forts to be conquered. The disease may, or may not, have entered by this portal. "Experiments have proved that bacteria and colored substances; such as carmine, etc., injected into the blood reappeared in the tonsils and were discharged by them into the palatal cavity. Bacterial infection of the tonsils might therefore be produced either by an immigration of bacteria from the mouth into these organs or by their emigration from the circulation."[46] This taking of bacteria and other noxious substances from the blood, by the tonsils, and discharging the same into the digestive tract seems to be quite as important a function as the taking up of bacteria, by the phagocytes of the tonsils for immediate destruction. As we have seen the stomach can dispose of a lot of them. The using of bacteria, as food, by the leucocytes is a hereditary trait that can be best considered when we come to discuss anaphylaxis. That there are two distinct types of phagocytes should not be lost sight of by the reader as this division of function among them corresponds to a division of labor that has become strongly differentiated in our digestive apparatus. "The cellular army of defense," says Meltzer, "is made up of two types; the microphages, the polynuclear leucocytes whose abode is in the bone marrow; and the macrophages, the large mononuclear cells which have their barracks in the lymph nodes and lymphoid tissue. According to Opie one of the effectual weapons of these warriors is their intracellular proteolytic ferments. But the ferment of the microphage is active in an alkaline medium, while that of the macrophage requires for its activity an acid medium."[47] Adami speaks of these as "two broad groups of phagocytes, each having the power of acting more particularly upon one set of substances; the microphages (polymorphonuclear leucocytes, eosinophiles, etc.), and the macrophages (hyaline leucocytes, endothelial cells, and fixed phagocytes);" the former he finds "more particularly active in opposing the bacteria of acute disease, the latter those of chronic disease."[48] In their methods of digesting, these two kinds of phagocytes represent gastric and duodenal activity. We have found that one of the most important functions of the digestive apparatus is that of destroying disease germs. We here discover that acid and alkaline digesting phagocytes perform similar functions. Let us now inquire the origin of digestion and of the digestive tract. Prof. E. Ray Lankester informs us that "the lowest multicellular animals provided with a digestive sac or gut, such as the polyps, have that sac lined by digestive cells which have the same ameboid character as 'phagocytes,' and actually digest to a large extent by swallowing or taking into their individual protoplasm raw particles of food. Such particles are inclosed in a temporary cavity, or vacuole, into which the cell protoplasm secretes digestive ferment and other chemical agents. Now there is no doubt that such digestive vacuoles may burst and so pour out into the polyp's stomach a digestive juice which will act on food particles outside the substance of the cells, and thus by the substitution of this process of outpouring of the secretion for that of ingestion of food particles into the cells we get the usual form of digestion by juices secreted into a digestive cavity."[49] It thus appears that digestion had its beginning in a process much like that pursued by the phagocytes of the tonsils. Finding their foes too much for them it became necessary to eject them and have them digested outside of rather than within their protoplasm. We certainly could not wonder at this if, at any time, they found foes such as the protozoa have to contend with. Dr. E. Penard, in a recent illustrated article which appeared in the new German microscopical journal, *Mikrokosmos,* states that a rotifer, *"Proales latrunculus,* sp.n., which lives parasitically within and on the heliozoon, *Acanthocystus turfacea* * * * allows itself to be engulfed in the usual rhizopod fashion by its unsuspecting host, but no sooner has the envelope closed on the rotifer than it expands its ciliary wreath and proceeds to eat up everything it can find in the larder, then it attacks the protoplasmic walls and feeds on these. A terrible struggle now goes on between the host and its prey, which usually lasts about six hours and nearly always ends in the death of the rhizopod. * * * In the summer of 1904, Dr. Penard found nearly half of all the *Acanthocystos turfacea* afflicted with this parasite."[50] The long continued selective action of such parasites as the *Proales latrunculus* would soon extinguish a colonial group of protozoa unless variation steadily brought to their aid some such device as the sac, or digesting pocket, of a gastræa animal, into which they could be injected and digested. From such a sac, or gastrula, Haeckel tells us, the intestinal tract of the higher metazoa was produced.[51] His theory explains so perfectly the many facts of embryology and comparative anatomy, bearing on this question, that most zoologists have accepted it as a true generalization. The polyp, or hydra, which Professor Lankester refers to in the quotation given, is a favorite animal for illustrating that branch of the animal kingdom known as the cœlenterata, or animals that possess a hollow space for an intestine. To the student of embryology it is known as one of the simplest of the two-layered or diploblastic animals. Its outer skin-layer is the primitive example of the ectoderm and the invaginated layer, that constitutes the in-

terior of its gut, is one of the simplest of endoderms. Unlike animals higher in the scale, up to and including man, it has no middle layer or mesoderm. To compare its simple structure with the complexities of our own is to see what evolution has done for us in differentiating our many tissues. Prof. C. S. Minot declares that, "The importance to pathologists of a thorough knowledge of the genesis of the tissues from their germ layers can hardly be emphasized too strongly" and, as he has given one of the best classifications ever made, it is here reproduced for the reader's benefit.[52]

CLASSIFICATION OF THE TISSUES (Blastoderm).

A—Ectodermal (Epiblast)	B—Mesodermal (Mesoblast)	C—Entodermal (Hypoblast)
1 *Epidermis*	1 *Mesothelium*	1 *Notochord*
a Epidermal appendages	a Epithelium of peritoneum pericardium pleura urogenital organs	2 *Epithelium of*
b Lens of eye	b Striated muscles	a Digestive tract
2 *Epithelium of*	2 *Mesenchyma*	Esophagus
a cornea	a Connective tissue	Stomach
b olfactory chamber	Smooth muscle	Liver
c auditory organ	Pseudoendothelium	Pancreas
d mouth	Fat-cells	Small intestine
(oral glands)	Pigment cells	Yolk-sack
(enamel organ)	b Blood	Large intestine
(hypophysis)	c Blood vessels	Cecum
e anus	d Lymphatics	Vermix
f chorion	e Spleen	Rectum
Fetal placenta	f Supporting tissues	Allantois
g amnion	cartilage	(bladder)
3 *Nervous system*	bone	b Pharynx
a Brain	g Marrow	Eustachian tube
optic nerve		Tonsils
retina		Thymus
b Spinal cord		Parathyroids
c Ganglia		Thyroid
d Neuraxons		c Respiratory tract
		Larynx
		Trachea
		Lungs

There is one very important thing shown in this table which my readers should not overlook. That is, the fact that the brain and spinal cord are produced by the same layer as the skin. Phylogenetically our whole nervous system is but an improved and sensitized skin. It came, by successive variations, from the skin of our polyp-like ancestors. Tucked away in the cavities of skull and spinal vertebræ our brains and spinal cords look like anything other than their original progenitor—the skin. The embryo, by epitomizing our evolutionary history in its development, tells the tale of the humble origin of our noblest tissue. As the skin is now, and always appears to have been, an organ whose chief function is that of resisting the aggressions of parasites, the nervous system should show its relations, in function, to its ancestral tissue. The skin always has been the most completely exposed part of the body in relation to pathogenic microorganisms. We learn that "the cutaneous sensory fibers are distributed through the whole length of the dorsal half of the brain wall as far forward as the superior colliculus. The roof of the midbrain is still in part a primary cutaneous sensory center, even in man. This gives the strongest morphological support to the account of the evolution of the cutaneous, auditory, and visual primary and secondary reflex centers and the cerebellum out of a primitive longitudinal column or zone whose functions were at first simple cutaneous sensory."[53] If we stop to consider how intimately connected with the skin the brain must be we will see that even now a very large part of its work is that of protecting us from disease germs. Think of the sensitiveness of the skin at every minute point of its surface, to pain from injury. It cannot be pricked with the finest needle without giving forth its cry of danger. But danger from what? Surely a needle prick is not of selective value in itself. Without infection from slight wounds natural selection could have had no chance to give us so pain-sensitive a skin. But all this pain—pain that travels from every minute fraction of an inch of the entire surface of the body—exists or is produced in the brain. The nerves of touch that make us sensitive to contact, the nerves of heat that make us sensitive to high temperatures, the nerves of cold that make us sensitive to low temperatures, the nerves that regulate perspiration and thereby the temperature of the body-cavity, the nerves that produce itching, the nerves that produce tickling, all are mechanisms that, directly or indirectly, warn of danger from germs. It is impossible to discover selective value in any of them if disease is left out of the problem. Indeed, so much of the brain is concerned with the regulating of the skin, that "Dubois, the Dutch anatomist, stimulated by the work of Snell, has brought forward evidence for the view that when, within the same order, several species of mammals similar in form, but differing in size, are compared with one another, the weight of the brain is found to be closely correlated with the extension of the body surface, and by inference with the afferent system of neurons."[54] If a relationship so close as this exists between the neurones of the brain and of the cutaneous surface then an exceedingly large part of the brain must have been selected because of the benefit derived from them in warning of disease. Even if it is less perfect than Dubois imagines the fact that he thought it probable is evidence of a very profound relationship. If we leave the consideration of the skin and turn directly to the question of the evolution of the cerebral cortex we learn that it formerly "was olfactory in function, the hippocampal formation" being its earliest appearance.[55] In the lower mammals the sense of smell appears to be of intense importance. Prof. Bardeen states that "In reptiles and fishes it makes up half the brain" and "the earliest cortical relations are with the sense of smell only."[56] In its beginnings the sense of smell probably had to do solely with the selection of food. It was of life and death value that some such device be selected in order to be able to discriminate between wholesome and unwholesome food. Things that had to be avoided as dangerous, such as decomposing bodies, would kill off all animals that failed to take a dislike to them through their smell. Only those lived that developed such a sense of dislike. Food that was good would be selected because of a pleasant flavor. It is not generally known that flavor, even in ourselves, is connected with our nerves of smell and not of taste. As the organ of smell became more and more sensitive it would come to be used for other purposes. Smell, then, was, most likely, protective from disease so that the earliest of sensory activities of the brain, as it developed from skin, continued to intensify and improve the mechanism of immunity. If we now inquire about its latest achievements we learn, from Prof. J. A. Lindsay, that "it was in the interest of the developing organism that the centers presiding over the mechanism of speech * * * should be located in one, rather than in both hemispheres. It is entirely in accord with this theory that the right side of the cerebrum should contain potential speech centers, and that these should be capable of successful and adequate development when the centers on the left side are destroyed by disease."[57] Look where we will, among all the adaptations of our

viscera, and at every turn and from every viewpoint we find that natural selection, through parasites, is the only theory that seems capable of putting meaning into them. Without this theory there is but chaos and darkness before us.

ON SOME ERRORS IN THE SEARCH FOR THE GONOCOCCUS IN THE VAGINITIS OF CHILDREN.

By IRA VAN GIESON, M.D.,

NEW YORK.

FROM THE RESEARCH LABORATORY, N. Y. CITY DEPARTMENT OF HEALTH.

When a subject has been worn as threadbare as that of the microscopic detection of the gonococcus, it seems incredible that the simple procedure of collecting the exudate in vaginitis and spreading it on a slide for microscopic examination of the gonococcus could be so faulty as often to defeat the very purpose for which it is undertaken. Nevertheless, this is a fact. It has been supposed that the transference of the exudate from the vestibule or the vagina to the slide by means of a cotton swab, such as is used in taking cultures from the throat, would be thoroughly reliable; that is, when the secretion is spread on the slide the presence or absence of the gonococcus would indicate the presence in or the absence of the organism from the vagina.

At the Willard Parker Hospital, in the scarlet fever, diphtheria, and measles wards, and in the other hospitals of the Department of Health of the City of New York, we have for years taken this procedure at its face value, supposing that it gave accurate information in determining the question of the gonococcus in its important influence in our management of this prevalent, troublesome, and persistent malady in little children. Now it turns out that the method is far from providing a certain means of detecting gonococcus, and frequently fails in cases without appreciable discharge. When a method is not fully reliable it is time for the substitution of one which is more certain and trustworthy. The new pipette method proposed here is so simple that it seems like making much of a small matter in according it any extended text. But the method deals with a troublesome and a rather common malady, and as it often happens that important phenomena are disclosed and handled with methods of trivial operation, no apology is needed for a seemingly inconsequential procedure if it helps us better to detect and to manage an intractable and easily transmissible disease.

Under any circumstance specific vaginitis in children is serious. From one standpoint it is perhaps less so than in adults, in that the uterus and tubes are seldom involved; however, it is in other respects far more serious because of the danger of ophthalmia. But everyone knows that in hospitals, especially in those for contagious diseases, the disease is particularly vicious because of its liability to spread through the wards unless the greatest vigilance is exercised. We have to be on guard constantly to catch the patient at the very inception of the disease, indeed with the detection of the gonococcus to anticipate its appearance, and equal care is imperative in not sending a child home prematurely, to infect its companions.

When vaginitis is fully developed the gonococcus determination is hardly necessary to tell us what is going on. Nor when pus is pouring out of the vagina or urethra does anyone need a microscope to know what to do or to make a diagnosis, for he would only be making sure of what he already knew. To be sure, the microscope will give the secondary information as to whether the discharge is nonspecific or the contrary. In such cases, when

the aid of a miscroscope is to a certain extent a laboratory refinement, the swab device works very well, as indeed anything else which will get the exudate spread out uniformly on the slide. The method is excellent when the disease is so obvious that its application is hardly necessary.

This whole matter of the detection of the gonococcus, regarded from a practical standpoint, becomes of real value in the very beginning and the declining stages of the discharge. These are the stages where the greatest danger of widespread infection exists for the simple reason that they are not heralded and placarded with the obtrusive cardinal manifestation of the malady, namely, the discharge. Here we are absolutely dependent upon the microscope, and here where it is important to single out vaginitis cases on admission to the hospital, to apprehend the incipient cases, to detect the gonococcus when the secretion is only faintly purulent or scanty and hidden in the vaginal fornices or otherwise not obvious, here it is that the device with the swabs sometimes leaves us in the lurch.

Whether the vaginal exudations without the gonococcus, the non-specific vaginitis cases are infectious or not is exceedingly difficult to determine without inoculation experiments. From time to time we find a profuse nongonorrheal vaginitis in which the leucocytes contain several small bacilli with tapering ends lying side by side. Apparently this form is infectious. Occasionally there are also nonspecific cases in which there are intracellular cocci, but distinctly smaller than the gonococcus. And rarely a discharge is met in which the leucocytes show no bacteria of any kind. The only organisms present are extracellular and seem to be merely the ordinary saprophytes of the healthy vagina. This form of vaginal discharge seems to be due to a simple catarrhal exudate accompanying at times measles and scarlet fever. The products of inflammation complicating the course of these exanthemata pass into the vagina and sweep out with them the ordinary vaginal bacterial flora.

The most sensible plan, I think, in the examination of these nonspecific and nondescript discharges is, that while a negative report may be given as far as the gonococcus is concerned, in the question of isolating these children, we should be guided more by the general structural appearance of the exudate than the matter of the bacterial content, because we cannot tell whether these several bacteria associated with the nonspecific cases are infectious or harmless. It is difficult to describe or lay down any set rule regarding the structural appearances of the smear which indicates a dangerous or suspicious discharge, but one learns from experience that a certain preponderance of leucocytes, or an exudate almost entirely purulent, justifies the diagnosis from mere vaginal hypersecretion (from uncleanliness for instance), and the recommendation of isolation, even though the gonococcus is not present. A few leucocytes scattered among a large content of vaginal epithelial scales, although the smears may be laden with various kinds of bacteria have no special significance. In the routine microscopic vaginal examinations at the Department of Health hospitals (comprising at times several hundred children) I have followed this plan of dealing with the nonspecific or indifferent discharges, largely according to the structural appearances of the exudate, reporting, for instance. "Gonoccoccus absent: recommend isolation and observation for several days from the largely purulent character of discharge and slight relative content of desquamated vaginal epithelium." Considering the volume of vaginal discharge, both benign and infectious, and the catarrhal conditions in measles and scarlet fever that we have to contend with, this policy has worked out very well. It places one on the safe side with many children having discharges which are not gonorrheal, but nevertheless if infectious a menace to the ward. If the discharage is benign no harm is done to the child in isolation. From what has been said it is apparent that adherence to a rigid rule in the absence or presence of gonococcus in the determination of this question of vaginal discharges may bring about diagnostic blunders in two ways. The observer might find organisms indistinguishable from gonococci in a vaginal secretion without the structural earmarks of a true vaginal inflammation and so condemn a child with mere profuse secretion to the vaginitis ward, and on the other hand, he might, in reporting the absence of the gonococcus, leave an infectious child in the ward. Some judgment must be exercised independent of, or at least in conjunction with, the question of the morphology of bacteria in these secretions. The structural character of the secretion must be taken into consideration, and at times this is just as important a factor as the bacterial determination.

The reason for the frequent failure of the dry swab method is quite simple. Unless the discharge is profuse, the exudate on the absorbent cotton is caught in its interstices, and the result is that much of what we wish to have on the slide is retained by the cotton. Not infrequently in thin, serous, and scanty discharges nothing but fluid is expressed from the swab to the slide, while abundant gonococci remain in the leucocytes sticking tenaciously within the meshes of the cotton fibers. In attempting to release the exudate in the preparation of the smear, the swab is rubbed and pressed about on the slide; the cellular contents may be torn off the cotton fibers with considerable mechanical injury so that the structure of the material on the slide, especially the leucocytes, is highly distorted and most unfavorable for the detection of the gonococcus. Quite frequently also it is difficult to spread the exudate evenly and uniformly on the slides with the swab; thus the cells are heaped on top of each other and conceal the gonococci. Occasionally the narrow vaginal orifice in children wipes the surface layer of the exudate off the swab as it is being removed.

The intact leucocyte cell body is the *sine qua non* in the diagnosis of the gonococcus. Without this we lose the foothold of certainty. This is especially true of the vaginal secretion, which brings in difficulties not encountered in discharges from the male urethra. In the vaginal discharge we cannot take the free cocci into account, because while the male urethra exudate contains as a rule no adventitious bacteria and only those of a specific or nonspecific urethritis, the vaginal discharge and the healthy vagina often contain among them cocci which cannot be distinguished morphologically from gonococci.

If one were to make the diagnosis on the presence of free gonococci-like organism, many children, healthy as far as vaginitis is concerned, would be wrongly put in the vaginitis ward. These smears with distorted pus cells are, therefore, misleading and often quite worthless. It is truly astonishing to discover that hundreds and hundreds of gono-

cocci may be lost or concealed in the smears from these cotton swabs or retained on the cotton. It should not be understood that the deformity of the leucocytes is characteristic of all swab smears. It occurs extensively, however, in quite a large proportion of them when the secretion is very thin or viscous, and especially when the swab is allowed to dry in the air momentarily, or through a conjunction of both factors. Occasionally the volume and consistence of the exudate are such that the film is in good condition and offers the proper conditions of accurate diagnosis.

Besides these drawbacks, it is questionable whether the swab device is wholly harmless. No one would think of using a similar procedure in the male urethra, because it would denude the epithelial layer and damage the lining membrane. The introduction of a dry cotton swab into an inflamed and sensitive vagina, twisting it about to collect the exudate, must injure the lining walls if only to a slight extent. And since as we are told the deeper layers of the epithelium and the membrane on which it rests act as barriers against invasion of the gonococcus into the circulation or the lymph spaces and its propagation to remoter parts, this aspect of the procedure is hardly a negligible factor. In the final and healing stages of vaginitis it is also important not to interfere with the restitution of the epithelium.

A very much better way to obtain the exudate is to collect it in glass tubes so that one can see what the content of the vagina is, and incidentally not lose it in transferring it to the slide. For this purpose ordinary medicine droppers are the most convenient; they are about the length of the average child's vagina and manipulation of the rubber bulb collects the secretion. Occasionally the sharp cutting edge of the dropper needs rounding off in the flame. The tubes, of course, may be sterilized and used over again, kept in bichloride solution before being applied, and the children are hardly aware of their introduction, which is more than can be said of the swab. Sometimes the pus is so scanty that instead of filling the lumen of the tube it sticks to the sides of its walls and cannot be transferred to the slide. In such instances it is well to fill the tube with a drop or two of water, or, better, a 1-5000 bichloride solution before introducing into the vagina, and by compressing and expanding the bulb make an emulsion of the exudate. The advantage of this is that the whole vaginal contents are obtained where the secretion is scanty, the bichloride fixes the cellular elements at the same time, and they are in perfect form when dried on the slide. Salt solution is less preferable, for it seems to contract the leucocytes. Exceptionally in very young children, or where the vaginal entrance is very small, it is necessary to draw out the tubes to a finer caliber, although when partly filled with the bichloride solution they need only be inserted into the ostium and the exudate washed out into their lumen.

This method is perfectly adapted to the study of structural cellular details of the exudate, which under the generic title of the "cytodiagnosis" of urethral and vaginal discharges came into prominence some two or three years ago. Up to this time observers had largely restricted their study of these exudates to the detection of the gonococci. The advance of the technique of staining blood and differentiation of the various white blood cells, and their constituent granules suggested a similar study in urethral and vaginal discharges. Pappenheim, Janowski, Joseph, Palano, Posner, and several other observers took up the subject and tried to turn the study to a practical account in diagnostic and prognostic value. They found various types of leucocytes, such as mast cells, eosinophiles, small and large lymphocytes, globular nucleated polymorphonuclear leucocytes, vacuolated, and other types of degenerated cells, and attempted to show that the prevalence or absence of one or another type of these various cells corresponded to some particular phase of the disease and hence was of diagnostic value. At the request of my friend, the late Dr. Robert W. Taylor, I went over this subject, not only in the male urethral inflammations in various stages, but also in vaginitis, using the various methods of blood smear technique, and feel quite sure that while the subject may be exceedingly interesting from a theoretical standpoint, it does not work out at all in practical diagnostic value, for the results are too irregular and contradictory. Thus the eosinphiles are liable to occur in the early stages, but they occur at times equally well in the late and chronic stages, and so on, with various other constituents of the exudate. There are but two signs indicative of particular phases in gonorrhea, and even these are rather vague and indefinite, namely, the presence of red blood-cells, indicating a beginning stage of gonorrhea, and the appearance of considerable epithelium, mucus, and the decrease of the leucocytes, showing that the process is nearing its end stages, which is a good deal like saying that the shower is over when the rain drops cease falling.

In contrasting these two methods at Dr. Park's suggestion I followed several cases in the vaginitis wards, systematically controlling the swab smears with tube method; sometimes immediately afterwards, sometimes twenty-four hours later. Here are the results as regards the absence or presence of the gonococcus indicated respectively by the minus and plus signs.

These tables need no comment. It will be seen that in many instances where the swab method has given a negative decision the gonococci are, nevertheless, present, as shown in the smears from the medicine droppers. In Table No. 1 the dry swabs gave positive results in 6 out of 9 cases. In Table No. 2 the suggestion of moistening the swab was carried out, giving slightly better results. These children ranged between the ages of one and six or eight years, and the results in each case were con-

trolled by staining with Gram's method. It is the custom at these hospitals to examine all of the suspected children twice a week for gonococci and all cases on admission. I have tried not to fall into the rather natural tendency of accentuating the value of a measure by exaggerating the defects of what it is designed to correct, for the swab smears have always been taken by the interne physicians of the hospitals,* and represent, I think, on an average the results obtained in hospitals in general when the method is used. Perhaps the swabs might have been taken more carefully, especially if one had in mind their imperfections and the tables are not wholly fair, but the procedure is certainly inferior to and less reliable than that of tubes. This is especially to be emphasized when the gonococci are very few in number, for they may be lost entirely in the swabs even when moistened.

A striking instance of the value of the new method is the case of Katie L., 5 years old, admitted with scarlet fever. The swab smears were negative. While the child was still on the examination table I was astonished to find fully half of the medicine dropper tube (plus two or three drops weak bichloride solution) filled with pus hidden in the vaginal fornices and which was reeking with gonococci. There was hardly any external evidence of the discharge, and this child, if we had relied on the swab method result, would have been sent into the ward to infect other of the inmates.

Another interesting case is that of Ellen F., 3 years old, who had been in the diphtheria ward some three weeks. This ward, on the sixth floor of the Willard Parker Hospital, contained 24 children. Ellen had no discharge, no signs of vaginitis, no gonococci on admission or any other time as far as could be determined, when suddenly, on March 27, 1909, a discharge developed. The swab method failed, but the medicine dropper disclosed abundant pus cells with gonococci. No other children had vaginitis in the ward, and a question of great interest arises: How did Ellen develop a specific vaginitis three weeks after admission when the examination was negative and when there were no cases in this ward to infect her?

These cases are not very rare and their consideration, which is beyond the confines of this paper, seem very important not only for study of gonorrheal infection in particular, but for the rôle of pathogenic bacteria in general. Apparently the explanation in consonance with the theories of the present day is that such children are gonococcus carriers; that such gonococci do not provoke any pathogenic action in these particular children until some complicating congestion or light catarrh, incident to diphtheria and certain of the exanthemata, provides the suitable opportunity. We hope, during the ensuing year, to see if, by an accurate method of examination of admission cases, this can be substantiated, and to learn whether these children belong to the class of bacterial carriers, as we have come to know them in connection with typhoid fever, diphtheria, etc.

This investigation will not only require the washing out of the vaginal contents into the bichloride tubes, but probably also depositing the cells, before transferring to the slides, by the centrifugal machine, since the scanty collection of cells will be dispersed in a considerable volume of fluid.

*So far as I can learn, the swab method is quite universal in the various hospitals in New York City, which contain any considerable number of children.

A third instance of the accuracy of the tube method worth mentioning, perhaps, is that of a declining discharge of a girl of 15 years. An unequivocal decision of the question of the gonococcus was highly important because medicolegal consideration involving the matter of criminal assault entered into the case. The physicians to whom the gonococcus determination was referred were unable to settle this question one way or the other, because smears prepared in the conventional way from absorbent cotton swabs showed such mutilation or destruction of the leucocytic cell bodies that no intracellular gonococci were found, and they declined, quite properly, to make a diagnosis on the presence of free "coffee bean" diplococci amid the variegated bacterial flora.

As a matter of fact gonococci were present, but exceedingly few in number, as was disclosed by flushing out the vaginal fornices with a tube filled with a few drops of 1-1000 bichloride solution, These smears showed the classical indubitable picture of groups of gonococci within the bodies of perfectly preserved leucocytes.

The swab procedure is equally bad in determining the nature of inflammation or discharges from the conjunctiva. This is so very important that it needs no elaboration. Among other forms we are constantly meeting with simple catarrhal conjunctivitis in measles and scarlet fever, diphtheritic conjunctivitis, and at times an inflammation accompanied by the pneumococcus, Morax-Axenfeld, or Koch-Weeks bacillus, but we never can be sure without the microscope, whether the case may not be one of gonorrheal ophthalmia.

I know of at least one case of very early gonorrheal ophthalmia in which the swab method utterly failed to show the very few gonococci present disclosed by the tube procedure. Exudates from the conjunctiva should be allowed to flow into capillary tubes. If such exudates are thick and viscous they may be drawn up into the tube by a piece of attached capillary rubber tubing and expressed on the slide and emulsified with weak bichloride solution to make the smear spread thin and uniformly. The same may be said of the examination of cases of otitis and discharges from the ear, sinuses, etc.

A trivial suggestion in the staining of the smears, although very likely gratuitous, may be of service to those having occasion to make these determinations in large numbers. The fixing of the smear may be discarded. The film can be flooded with almost any of the polychrome solutions, washed in water and examined while wet under the cover glass or afterwards dried for permanent keeping. In fact, the washing in water may be omitted and a drop or two of the polychrome solution, if not too opaque, may be allowed to flow in a capillary sheet over the film underneath the cover glass and the examination made directly. An advantage of this is, besides saving time, that the gonococci appear to swell slightly and approach more nearly their size and shape in the living condition, which is of service in comparing them with a gonococcus-like organism somewhat smaller in size.

Tuberculosis in Australia.—The death rate per 10,000 from tuberculosis in Victoria, Australia, has fallen from 14.58 in 1890 to 9.58 in 1907, and in Melbourne and suburbs from 20 in 1890 to 11.6 in 1907. The fall is attributed to the aggressive campaign against this disease, including the registration of tuberculosis cases, the erection of institutions for treatment, and the general improvement of sanitary and working conditions.

THE THERAPEUTIC POSSIBILITIES OF DIRECT BLOOD TRANSFUSION.*

By JOHN A. HARTWELL, M.D.,

NEW YORK.

PROFESSOR OF CLINICAL SURGERY, CORNELL MEDICAL COLLEGE; ATTENDING SURGEON, BELLEVUE HOSPITAL, AND ASSISTANT SURGEON TO PRESBYTERIAN HOSPITAL, NEW YORK CITY.

"Judiciously employed, transfusion will surely form a valuable, often life saving, resource; injudiciously employed, it will surely become discredited." This is the closing paragraph of Crile's book on transfusion, and it emphasizes admirably the lesson taught by the more than five hundred carefully written pages of his work.

That this procedure has, by the efforts of many men, been put upon a safe basis as a therapeutic measure, is a matter of the utmost importance. It is still too early to estimate its full value, or comprehend its possible dangers, but it is a subject worthy of the fullest discussion, and each bit of experience coming to the individual is worthy of report, whether the result has been successful or unsuccessful.

Crile's work was published last year, and so completely covered all the ground, that it is proper to quote his conclusions:

"Transfusion, when properly safeguarded, may be safely done. In pernicious anemia, toxemia, certain drug poisons, leukemia, acute hyperthyroidism, carcinoma and uremia, it has been of no value. In tuberculosis and chronic infections it has certain value. In human sarcoma there is some evidence of value, though it is not yet proved. In pathological hemorrhage it is of marked value. If done in time, transfusion is specific in acute hemorrhage. In suitable cases it seems to be almost specific in the prevention and treatment of shock."

From this we see that whenever there is a secondary anemia of vital centers, whether from hemorrhage, or from disturbance of the internal circulatory mechanism, we have in transfusion a means of treatment which is superior to any other. On the other hand, in all forms of disease, with the possible exception of tuberculosis and some other chronic infections, its use has been attended with very little success. This is what would be expected, reasoning on *a priori grounds*. In the first instance, transfusion surely and inevitably replaces the biological elements, the absence of which is producing the pathological condition. In the second instance, the blood acts, if it act at all, by altering biological processes, and this is a matter of great uncertainty and of the utmost complexity.

In using a transfusion, we may, however, hope to bring about such alteration through the bactericidal power of the introduced serum, through the addition of immune bodies, through the activity of the healthy phagocytes or through the introduction of unknown substances existing in the blood of a normal person, which have become vitiated in the patient. That such a hope has little justification in experience up to the present time is disappointing, because in many conditions the knowledge we possess of certain pathological processes and their antagonism by the living organism would seem to argue strongly in favor of transfusion as a therapeutic measure. The pyogenic infections are cases in point. A living bacterial organism here gains admission to the body of an individual, and, finding a suitable medium, rapidly develops. The body defences of the individual come to the rescue, and the bacteria may be destroyed with the return to health of the individual, with or without surgical intervention. In case this defense is not sufficient, the bacteria increase still farther, and the death of the individual may result.

That this defense lies to a great extent in the blood is an established fact. The serum contains bodies which act either as inhibitors to the life of the bacterium, or as activators to the blood phagocytes, or as neutralizing agents to the toxins, in any case making less the evil effects of the bacterial activities.

The usual clinical study of the white blood cells gives us valuable evidence of the way the battle is going, and in many cases a proper prognosis can be arrived at in this way. This, interpreted, means that under the stimulation of the invading organisms, the circulating cells become more numerous and more potent when the contest is turning in favor of the body cells, and less so when they are being overwhelmed by the microorganisms. Experimentally, and clinically also, there is indisputable evidence that the serum contains bacteriolysins. When, therefore, we are confronted by a patient suffering from an infectious process, we might with reason hope to aid his defenses by means of a transfusion. And could we obtain as a donor one who had recently recovered from the same infection, we would have further ground for hope by the possibility of introducing immune bodies with the elements of the normal blood. The agglutination of the typhoid bacilli by the serum of a patient recovered from this disease is an expression of this process. This reaction may exist in the serum over long periods in some instances. Since practically every typhoid patient shows the presence of the bacillus in the blood, a transfusion from a person recovered from typhoid ought to exert a very beneficial effect. In those cases especially where the outcome depends on the power of overcoming a toxemia, that is, in such patients as show the so-called typhoid condition, a transfer of a blood containing typhoid agglutinins should be of value.

The work of Hiss and Zinsser with the watery extracts of leucocytes is also worthy of note in this connection. They found that such an extract of the leucocytes, obtained in the exudate from a rabbit's pleura under the influence of aleuronat, had a decided influence in saving the life of animals receiving an ordinarily fatal dose of various living microorganisms. This favorable influence, too, they believe was slightly increased if the rabbit yielding the leucocytes was first rendered immune to the particular organism.

Further investigation showed that this property was not bactericidal, but what they termed endoantitoxic that is, due to an antitoxin which existed within the leucocyte, and was given up only upon its destruction. This last they inferred because living leucocytes in similar bulk seemed not to possess the efficiency of the extract. These experimental findings were put to the clinical test, and in epidemic meningitis, pneumonia, and later erysipelas, (Lambert) they seemed to be of value.

These results, taken in conjunction with the well-known bactericidal power of whole blood, would seem to indicate that transfusion should exert a beneficial influence on these and allied conditions. Hiss' observation that only the extracted leucocytes were useful, would not be a counter indication, since

*Read before the Surgical Section of the New York Academy of Medicine April 1, 1910.

the life of the leucocyte is short, and hence the large number introduced by means of a transfusion would soon, in their death, give rise to the same endoantitoxin. The fact remains that, clinically, both acute and chronic infections, with the possible exception of tuberculosis, have not shown themselves amenable to such treatment. It must be remembered, however, that the total number of cases in which it has been tried is small, and in most of these the conditions were unfavorable, transfusion being used only as a last resort.

Certainly this problem is worthy of further experimental and clinical study, and the writer feels that, notwithstanding the unsatisfactory results up to the present time, transfusion as judged from experimental findings, should be a valuable aid in the treatment of septic conditions. In chronic infections it ought to be possible to increase the efficiency of the donor's blood by subjecting him to a treatment of vaccine made from the infecting organism. The writer attempted this in one instance, with the result reported below.

The possibility of an hemolysis taking place under such conditions must be borne in mind, as also the danger that the donor might become, at least locally, infected.

An attractive problem at the present time is presented in the possible efficiency of transfusion in cases of malignant disease. In discussing this, however, it is necessary to emphasize the inherent difficulties present because of our vague ideas concerning the pathogenesis of neoplasms.

The theory concerning this which has the greatest amount of fact to substantiate it, is the one which attributes neoplastic growth to a lawless development of body cells which are in some way released from their normal constraining influences.

For our purposes, two factors in this theory are of especial importance. First, the control which one group of body cells, through their function, exerts over the growth of other groups, and, second, the part that altered nutrition plays in the development and growth of tumors. It is these factors which hold out a partial explanation of the spontaneous regression of tumors, of their regression under experimental conditions, and of the immunity to tumor growth which seems to be conferred when such regression has occurred.

Medical literature has contained in the past instances of the spontaneous cure of cancer in the human subject, and about fifteen of these seem to be well authenticated.

Wehr in 1883 first described the spontaneous regression of lymphosarcoma in dogs. Since then, and mostly within the past five years, similar observations have been made by others, not only in the dog, but in rats and mice.

Gaylor and Clowes observed the spontaneous cure of mice inoculated with the Jensen tumor. They found that these mice were much more immune to future inoculation than were normal mice. This immunity could be conferred by injecting mice with the serum of cured animals. On the other hand, Loeb found that a regressing tumor of a rat, if planted in another part of the same animal's body, would grow rapidly. Investigation by other authors also failed to find any evidence that the serum of immune animals contained anything which is inimical to the growth of tumor cells. Beebe and Crile showed that dogs could be cured of lymphosarcoma by exsanguinating them and transfusing them from a dog who had spontaneously recovered from this tumor, and dogs so cured were thereafter immune. But recently Beebe has demonstrated that the immune blood of one dog does not confer immunity to the donor in a transfusion, unless the latter have a growing tumor at the time of the exchange. Finally, it must be emphasized that many animals of a given species are naturally immune to neoplasms which grow rapidly and fatally in others of the species. And within very narrow limits the neoplasm which grows well in one species, will refuse to grow in another species.

A complete summary of the work done along these lines is found in Ewing's Harvey Lecture, "The Cancer Problem," and this is strongly recommended to the careful study of any one interested in the subject.

While these experimental findings are contradictory and to some extent inexplicable, they demonstrate two facts. First, that a susceptible animal may be rendered immune to malignant growths, after which its body fluids contain something that inhibits malignant growth in other animals of the same species; and second, that this immunity differs from that existing toward infections, and is probably due to the development of an unfavorable soil for the growth. Application of these facts to the problem of human cancer is very tempting, and in transfusion the method of their application may exist.

Hodenpyl's recent experiences in bringing about a cure of cancer by the injection of the peritoneal exudate from a person spontaneously recovering from cancer is the first practical step in this direction. Spontaneous cures of cancer in the human subject are so rare, and the coincident factor of obtaining a body fluid from such a person without detriment to himself, is so much rarer, that the advantages to be gained from this precise method must of necessity be very limited. The fact, however, is clinically established that cancer can be eradicated from the human subject by the aid of some material produced in another human recovering from cancer. Applying to this fact the results obtained by Gaylor and Clowes, and Beebe and Crile, we may justly hope that patients so cured will have in their blood elements which will retard the growth in a third patient. Furthermore, every surgeon can recall cancer cases in which he has perforce done what he considered an incomplete operation, and yet a permanent cure has resulted. Such a patient may have recovered by virtue of his natural resistance, which only needed to be relieved of a part of its burden to become effective. Such a patient may therefore be an immune, and his blood may have curative value.

That we have no definite knowledge of the nature of these elements, or of the exact way in which they accomplish the result, does not detract from their practical efficiency. There are many important considerations, however, which must be borne in mind in putting into practice such therapeutic measure. Beebe and Crile found it necessary to exsanguinate completely or almost completely the dog suffering from lymphosarcoma, before the transfusion of an immune blood, in order to get the best results. Of necessity, then, a most vigorous bleeding of the immune donor must be practiced to replace the lost blood of the donee. Neither of these can be done in the human subject, for obvious reasons. Gaylord has shown that a tumor which is regressing will take on new growth if its host is bled or otherwise depressed. Therefore we must be certain that

our cured donor is completely cured, otherwise his gift of blood to another sufferer may result in a recurrence for himself. One such clinical experience was personally reported to me, in which a patient with apparent stationary cancer was used as a donor. His cancer immediately entered on a much more malignant phase.

Weil and others have shown that normal blood is markedly hemolyzed by the serum of a cancer subject. It may be that in the same way the red cells of the immune person would be destroyed. This has not proved to be so, however, in the animal experiments. This aspect of the use of transfusion has been presented to you because the cancer problem is such a serious one, and our means of combating it are, after all, so meagre that any phase which has a sound basis on experimental and pathological evidence is worthy of careful consideration. But let us consider it judiciously, and let us not run into the error of discrediting what may be of value, by a careless or injudicious application of it. The writer has used transfusion thirteen times in eight patients. One of these was done for acute hemorrhage in a ruptured ectopic pregnancy, prior to doing the laparotomy. The rupture had occurred about twenty-four hours previously, and on admission to the hospital the patient was in a very critical condition. The pulse was soft and thready; the respiration was shallow and rapid; the hemoglobin registered, 39 per cent. (Dare). The woman's husband was used as the donor, the radial artery being inserted into an arm vein. The flow continued for about twenty minutes, when the donor showed evidence of the hemorrhage and the patient's hemoglobin registered 62 per cent.

The ruptured ectopic was then operated on, and an uneventful recovery followed. Two other infusions, one for Dr. Eliot and one for Dr. Hawkes, were made as preparation for radical operation in case of malignant disease. In each the immediate result was satisfactory, and the major operation was exceedingly well borne, which had seemed doubtful without the aid of transfusion. Three cases were done for sepsis, one being acute and two being chronic. In none was any permanent good accomplished, all of the patients ultimately dying. One of these cases, in a patient of Dr. Bovaird in the Presbyterian Hospital, is worthy of a moment's consideration. He was a young man suffering from septic endocarditis, with a streptococcus blood infection which had produced a marked secondary anemia, the blood examination being: Hb., 49 per cent.; red blood cells, 2,800,000.

On the first occasion one sister was used as the donor. The artery-in-vein method was used, and a very satisfactory flow resulted. After the operation the blood examinations gave the following:

Second day—Hb., 70 per cent.; red blood-cells, 3,260,000.

Third day—Hb., 70 per cent.; red blood-cells, 3,250,000.

Sixth day—Hb., 62 per cent.; red blood-cells, 3,220,000.

Seventeenth day—Hb., 49 per cent.; red blood-cells, 2,880,000.

The immediate result was therefore very satisfactory, but the good was not sustained.

The second transfusion from another sister exactly duplicated the first. At the end of four weeks a third transfusion was attempted, but the technique was faulty, owing to the difficulty of utilizing the saphenous vein. No arm vein was available, as the previous transfusions and the many blood cultures taken had damaged all of them. The failure here was particularly disppointing, because the first donor was being used, and she had been prepared over a period of three weeks by receiving vaccines made from the patient's infecting organism. The small amount of blood transfused had only a transient effect for good, and the patient died some weeks later, when autopsy showed large infected vegetations on the heart valves and infected thrombi in many organs.

The seventh patient was suffering from osteosarcoma of the femur. He was transfused twice, a friend being used as the donor. One operation was entirely satisfactory from a technical standpoint, one only partially so. Neither showed any result in altering the progress of the growth, and later he consented to amputation.

The remaining patient was under the care of Dr. Freeman, of Orange, suffering from a pernicious anemia in an advanced form. She was transfused four times, twice with complete success, twice only partially so. A marked improvement resulted each time, but the introduced blood was slowly hemolyzed, and at the end of a few weeks she was back again at the starting point. Death finally resulted. The condition of primary anemia is a tempting one to treat by transfusion. A consideration of its pathology, however, forces one to the conclusion that such treatment can accomplish nothing. The destructive agent to the red cells is not removed by the operation, and the introduced cells undergo dissolution. In a certain number of cases, however, an anemia which presents a picture closely allied to a primary anemia, is in reality secondary to some remediable cause. In such cases, a transfusion, while in no sense curative, might tide the patient over a critical period, and thus be the indirect means of preventing a fatal outcome.

The one patient in the eight who derived a permanent benefit was suffering from hemorrhage. Her life was probably saved by the operation, as she would have hardly withstood the necessary laparotomy without the transfusion. As before stated, however, the failures in other conditions do not make a hopeless outlook, and the operation of transfusion holds out a promise of benefit in septic cases, and a possibility in malignant growth.

The septic cases reported above are not a fair test of any therapeutic measure, as they were all in what might well be accepted as a hopeless stage of the disease, at the time of operation. A wider appreciation of the value of transfusion ought to result in a greater success than has heretofore attended it, if the use of it is not so long postponed.

Undoubtedly one of the factors tending toward its not being more generally used, is the difficulty of its technique. Dr. Crile reports no operative failure in a large series of cases, but this has not been the fortune of many of us. His success proves, however, that the difficulties can be overcome, and it makes it imperative that those of us who have faith in its efficiency, should make ourselves as proficient in its performance as he has become. The papers of the evening dealing with methods are therefore very timely.

A second difficulty that has arisen in the experience of some of us has been the obtaining of a donor. Usually a relative can be secured, but this is not always possible. The unfortunate appearance in the public press of a story attributing the death of a working man to his having acted as a donor to

his friend, will still further add to this difficulty. It is therefore important to report that the facts in this case, after careful investigation, do not in the least justify such a conclusion. His death could not be even indirectly considered as resulting from the giving of his blood. It is only just, however, that we should give every care to the comfort and well-being of a donor, and that he should be fully informed concerning the amount of inconvenience that may be expected as the result of the operation.

27 East Sixty-third Street.

BENIGN OBSTRUCTION OF THE PYLORUS.

By JONATHAN GODFREY WELLS, M.D.,

NEW YORK.

INSTRUCTOR OF DISEASES OF THE STOMACH AT THE NEW YORK POST-GRADUATE HOSPITAL AND MEDICAL SCHOOL.

Benign obstruction of the pylorus, while not so very rare, occurs much less frequently than obstruction from malignant disease. The obstruction may be caused from within the lining of the pylorus, in the wall, or from pressure from without. Of the causes we may mention, ulcer and its after effects, pylorospasm generally due to erosion or fissure, hypertrophic gastritis, effects of strong acids or alkalies, pressure on the external surface of the pylorus, syphilis, tuberculosis, gallstones, foreign bodies, and a few others chiefly of interest as pathological rareties. The more important of these will be taken up later.

Before describing the symptoms, it might be well to consider the effects of an obstruction on the tissues of the stomach. The obstruction in practically all cases is a gradual process, being only very slight at first, and gradually increasing until complete stoppage occurs. This gradual process naturally incites the stomach to greater activity, increasing the strength and frequency of the peristaltic movements. This overwork brings about an hypertrophy of the muscle, especially of the fibers near the pylorus. This hypertrophy takes place in nearly every case of benign obstruction, except in those cases where the stomach is already the seat of marked myasthenia. This stage of overexertion and hypertrophy of the muscles gradually passes into that of complete loss of muscular power and atrophy. This is brought about by the overwork, the poor circulation within the stomach wall, the unhealthy condition of the mucous membrane, and the poor general health. The secretion of gastric juice is, as a rule, increased, the time of secretion prolonged, or it may be continuous.

There is also often an increase in the acidity. If the case is far advanced there may be a marked decrease in the acids and ferments or they may be absent. In cases preceded by chronic gastritis we find a subacidity or an absence of acid from the first. The previous conditions of the secretory organs and the cause of the obstruction materially modify the character of the gastric juice. The mucous membrane becomes very susceptible to injury and bleeds easily. The size of the stomach may remain normal or nearly so for some time, especially if the muscles are strong enough to force food through the pylorus, or if the vomiting is frequent. The wall finally becomes stretched and may extend down to the pelvis. We rarely see the same degree of dilatation in obstruction due to malignant growths. Where the stomach is the seat of an ulcer or there has been a perigastritis, we may have irregular dilatation, due to cicatricial tissue.

The signs and symptoms may be divided into those referable to the alimentary tract, and those of the general system. Those of the alimentary tract may be divided into those of the stage of muscular overwork or compensation and those of retention. These two divisions may be fairly well defined, in some cases, while in others the first division is practically absent. The symptoms of one gradually pass into those of the other. Peristaltic increase is characterized by crampy pain and the sensation of something alive and moving in the stomach. Cramps may be very frequent and severe and are generally worse shortly after eating. They are relieved somewhat or entirely by the emptying of the stomach. The pain often radiates to the back and chest. Vomiting during this period may occur only occasionally, or may take place shortly after each meal, or but once a day. This symptom depends primarily on the extent of the obstruction and secondarily on the cause. The other symptoms at this period are largely those of the causing factors.

When the dilatation and stagnation are marked the muscular contraction and cramps decrease and become more spasmodic. The sensation of fullness and pressure and distress after food increases as the disease advances until, as a patient expressed it to me, he felt as if he had a fifty-pound lead weight in his stomach all the time. The vomiting, as I stated above, at first may occur only once every few days, but later takes place nearly every night or morning, or after eating, especially of a meal containing solid foods or alcoholic drinks. The amount vomited at first is small; later it may amount to two quarts or more and contain food taken days and weeks previously. When the dilatation becomes excessive and the muscular power weak the stomach may not be able to empty itself and there may remain a considerable residue always in the stomach. During this period the vomiting becomes less frequent and really amounts to an overflow which takes place principally when the patient lies down. The complete cessation of vomiting is a grave symptom. The crampy pains of the first stage are absent or materially decreased late in the disease and are replaced by a dull, more or less steady pain which at no time may be severe, but causes the patient considerable anxiety. All pain and cramps may be practically absent in a case from the very first. Neuralgic pains are severe in some cases, especially those due to ulcers or erosions, but may occur in cases in which we are reasonably sure no ulceration exists. The peristaltic unrest unaccompanied by cramps may extend well into the stage of retention and stagnation and cause the patient more uneasiness than all his other symptoms. This unrest is frequent in benign stenosis, but rather rare when malignancy is the cause.

The appetite is good or may be increased so long as the muscular power of the stomach is fairly good, but as retention and stagnation increase, the appetite decreases and in advanced cases is lost. On the other hand thirst generally increases as the condition becomes worse as there is practically no absorption from the stomach and little fluid passes into the intestines, so that the thirst is a fair indicator of the degree of the obstruction. The bowels become markedly constipated, the movements being hard, small, and dry; the greater the obstruction the dryer and smaller the stool. Pyrosis at times may be marked and very frequent. Belching occurs practically in all cases and the gas expelled may be very

offensive depending upon the variety of fermentation and character of the decomposing food. Decomposing food or gases forced into the intestines may cause diarrhea, but more often bring about fermentation without diarrhea and the patient has added to his already large number of symptoms those of intestinal fermentation. Dizziness is present in all cases and may be very marked. Headaches are frequent, but are probably more severe in cases with intestinal fermentation.

The general manifestations are those of lack of nutrition. They depend on the amount of food passed into the intestines, upon the amount of water lost by vomiting, and upon diminished absorption. The loss of weight depends directly upon the completeness of the obstruction. The patient first loses the fatty tissues, later the albumen of the muscles, so that a state of extreme emaciation supervenes. The patient complains of weakness, dyspnea, and sleepiness, tires after slight exertion, and the extremities, especially the legs, become cold and numb. The skin becomes dry, scaly, and sallow. While these patients become extremely emaciated they do not have the cachexia which goes with malignant disease. In the final stages tetany may develop; this may be very slight or severe and terminate life quickly. In any case it is a very grave complication and generally terminates fatally.

Having briefly reviewed the subjective symptoms we will turn our attention to the objective signs, which are obtained by inspection, palpation, percussion, auscultation, transillumination, tube-palpation, duodenal bucket (Einhorn), and lastly the analysis of the stomach contents.

Inspection in advanced cases yields important results as we can often see the greater curvature throughout nearly its entire extent, lying below the umbilicus; occasionally peristaltic or rarer antiperistaltic waves may be observed. By percussion the extent of the dilatation may be fairly accurately defined.

Occasionally by palpation we are able to feel the thickened pylorus, or other causes of obstruction, and also the peristaltic movements which may cause a decided stiffening of the stomach wall for a few moments. This stiffening is peculiar to pyloric stenosis and is only felt during the period before the muscles become exhausted. Transillumination, inflating with air, and tube-palpation are also of value in determining the size and position of the stomach.

One of the latest means of determining the patency of the pylorus is the duodenal bucket of Einhorn. This consists of a small gold bucket, similar in shape to the stomach bucket, attached to a silk cord. The bucket is placed in a capsule and swallowed by the patient and not withdrawn for twelve hours. Its contents are examined for pancreatic ferments and if found, we are reasonably sure it has passed into the duodenum, thus proving the pylorus is still patent. If the obstruction is due to an ulcer we may obtain a blood stain on the silk cord, thus giving us a clue as to the site of the ulcer. Auscultation is of little importance.

The examination of the stomach contents yields very important results. By simply examining the material vomited, or withdrawn, we are often able to find out that food has remained in the stomach for a day or more. We also obtain definite information as to the extent of the obstruction by the quantity vomited or withdrawn. If this simple method gives unsatisfactory results we wash out the stomach in the afternoon and have the patient eat a meal of steamed rice, or some other easily detected substance, and then withdraw the stomach contents the following morning and if rice is still present in considerable quantities we are sure an obstruction is present. After marked retention and stagnation have taken place the stomach content is very characteristic. It smells like sour beer, especially when hydrochloric acid is present and contains copious remnants of food in a partial state of decomposition. These remnants may be from food taken several days previously. It may have a decided odor of sulphuretted hydrogen, which odor rapidly disappears if the contents are exposed to the air. Blood is frequently present, especially in cases with ulceration. The stomach contents if placed in a beaker will divide into three layers, an upper frothy, a middle clear, and a lower layer composed of the solid materials. Occasionally, we find bile in the contents, and if it is constantly present it speaks for a stenosis of the lower duodenum. Chemical analysis usually shows a decided increase in the total acidity. By microscopic examination we find yeast cells, sarcinæ, blood cells, and numerous bacteria. Sarcinæ find a favorable medium for growth in the stomach contents which contain hydrochloric acid but do not thrive so well when hydrochloric acid is absent and a large amount of lactic acid present. When lactic acid is present in considerable amounts we often find the lactic acid bacilli.

The urine is often alkaline, the amount small and of a high specific gravity; the greater the obstruction the less urine is passed. We possess, in the amount of urine passed, a fairly accurate measure of the degree of the insufficiency of the pylorus. The chlorides are decreased in grave cases and acetone is occasionally found.

An exact diagnosis of the cause can be made in a considerable number of cases, especially when due to ulcer, hypertrophic gastritis, and pylorospasm. When due to ulcer we can usually obtain a history of ulcer dating back a considerable length of time, or the history of an ulcer cured perhaps years before. With the evident ulcer symptoms accompanied by hemorrhage from the stomach and followed sooner or later by signs of obstruction, our diagnosis is easy. Without the above symptoms our diagnosis as to cause may be impossible.

The hypertrophic form generally occurs in early adult life and has a history of chronic gastritis dating back for some time. It is subject to numerous remissions and exacerbations. The gastric juice is decreased or absent and lactic acid may be present. The diagnosis between ulcer and spastic stenosis, I believe, can only be a tentative one in many cases, as both are characterised by cramp-like pains, and marked gastralgia, especially at the height of digestion. But if we have a patient giving a history of more or less constant pylorospasm followed by retention, without hemorrhage, we may decide against ulcer. The hypertrophic form is the most amenable to treatment. The diagnosis of stenosis from acid or strong alkalies is made entirely by the history. When we are in doubt as to the cause it is well to give potassium iodide to find out if syphilis is at the bottom of the trouble. A decided history of gallstones followed by pyloric obstruction should make us think of obstruction in the duodenum from a large stone or pressure on the duodenum from a gall-bladder distended with stones. In many cases we are unable at first to make a differential diag-

nosis between the causes, or even whether the obstruction is benign or malignant.

A history dating back a considerable time, a fair general condition, without cachexia, an increase of hydrochloric acid, stomach contents which are not fetid in character, symptoms which have been intermittent in character, that is, remissions followed by exacerbations, and retention for a few days, followed by emptying of the stomach through the pylorus, all point toward a benign growth, but are not positive, as we occasionally get all these symptoms in cancer. Finally, in a considerable number of cases, we have to wait and see if proper treatment brings about more or less permanent relief. In cancer cases the improvement is of short duration.

The prognosis is unfavorable, especially when the obstruction is due to organic changes. The cases of hypertrophic gastritis often respond well to treatment and at times are relieved permanently. The ulcer cases may be relieved for months or even years, but ultimately arrive at that condition where an operation is necessary.

The complications of the condition are few, among the most important are hemorrhage, tetanus, and rupture of the stomach.

The treatment consists largely of the proper diet and lavage. The character of the diet depends on the completeness of the obstruction, the cause, and the general health of the patient. The most satisfactory method of feeding is to give four or five small meals, the food to be fluid or semisolid, as milk, gruels which have been strained, prune pulp, eggs boiled two and a half minutes or raw, and other substances of like character. If the pyloric obstruction is partially patent, we may give solid food finely divided. We must also be governed by the state of the gastric juice, with hydrochloric acid present in fairly large quantities the patients digest proteins well. When hydrochloric acid is absent, proteins are best given predigested. Butter is the best form when the natural acid is present. The amount of fluid taken should not exceed 1,500 cubic centimeters. When the vomiting is excessive, the pain marked, or the signs of complete retention are present, or hemorrhage frequent, we should feed by the rectum for a week or two. When the amount of urine falls below 800 cubic centimeters, we should give normal saline solution by rectum. Lavage is of the greatest importance, as a means for keeping the stomach free from decomposing foods and relieving the overexertion of the muscles and also for the relief of pain and distress. The addition of alkalies or antiseptic to the wash water is of practically no value. The time for lavage is governed somewhat by the extent of retention and the symptoms. As a rule the early morning is the time of choice, but on account of pain, nausea, and a decided desire to vomit, it may have to be washed out at any time during the day. In very advanced cases lavage may be demanded twice a day. A proper abdominal bandage should be applied. The medical treatment is largely directed toward stopping fermentation; for this purpose I believe chloral hydrate the most satisfactory. Opium in some form may be required for the pain. Vomiting, if not relieved by lavage, will not be relieved by medicine. The bowels are best moved by oil injections.

The question of when to operate depends largely on the character of the obstruction and its completeness. The social condition of the patient may also have a decided voice as to the time of operation. If he is so situated that he can have the proper diet and rest, operation may be postponed, but if he cannot have the proper medical treatment, operation should be performed early. In the large majority of cases the medical treatment should be directed toward getting the patient in as good a condition as possible for an operation. If in doubt as to whether the case is benign or malignant, advise operation before the patient has arrived at that stage in which neither the patient nor operator have a fair chance.

CEREBROSPINAL MENINGITIS OF FULMINATING TYPE;

ACCOMPANIED BY ACUTE OTITIS MEDIA SIMULATING MASTOID INVOLVEMENT.

By SAMUEL HORTON BROWN, M.D.,

PHILADELPHIA.

Sporadic cases of the infectious fevers always present unusual symptomatology and consequently are not infrequently confused with other more common affections. Meningeal complications being not uncommon in the course of ear disease, it is usual to attribute the former to the latter, but the case I am about to report illustrates the necessity of constant vigilance in all cases if embarrassing circumstances are to be avoided.

In this case, the patient was a robust working man of about 29 years of age, who had never been sick enough in his life to require the attention of a physician for anything of any duration. He had had headaches from time to time and occasional colds. At the beginning of this last illness he was seized on a Sunday afternoon with a bad headache and pain in the right ear. The latter increased in severity until he felt compelled to call in a physician, and it was my privilege to see the man late that night. The symptoms all pointed to a condition of acute otitis media with slight mastoid involvement and treatment appropriate to that condition was prescribed. He was advised not to return to work on the following day but to consult his family physician, a colleague of mine, or in his absence to avail himself of my services.

During the early morning hours the tympanic membrane ruptured and a few drops of pus were discharged. His intense symptoms were relieved, but he consulted my confrère in the morning and returned to work that afternoon. Early in the evening he again complained of headache, and it progressively increased in severity until my colleague was again called and prescribed something which relieved him temporarily. Very early the next morning I was asked to see the man, as he was said to be in convulsions. Upon examination he was found to have a high fever, there was no discharge from the ear, he was semiconscious, and having convulsions in rapid succession without intermissions of more than a few minutes. The seriousness of the man's condition was very obvious, and the only treatment that suggested itself, in view of the history of ear trouble, was the opening of the mastoid. Accordingly, at my suggestion, he was removed to the German Hospital and operated upon the same day by Dr. Barton Potts. Before beginning the operation it was thought advisable to make a lumbar puncture, which was done and the cerebrospinal fluid was examined subsequently.

This examination showed the presence of the *Diplococcus intracellularis* in great numbers.

Pending the report from the pathologist, the operation proceeded, and the right mastoid was opened. The bone was found extremely dense and there were very few granulations and scarcely any pus. The left mastoid was also opened but nothing of interest found. The patient continued to have convulsions after the operation and eventually lapsed into coma and died within twenty-four hours. The patient's condition was so far advanced by the time the report was returned from the laboratory that resort to Flexner's serum was out of question. The postmortem examination showed cerebrospinal meningitis with purulent exudate at the base of the brain most marked on the left side.

The infection doubtless was secondary and its point of access was through the diseased middle ear. The history of contagion could not be obtained. Why such a severe grade of infection should attack one in so robust health affords considerable speculation. The condition was negative in all respects except those mentioned. The entire illness consumed but seventy-two hours and was attended by most marked suffering. Whether the early use of antitoxin would have been of value is questionable.

1901 Mt. Vernon Street.

A NEW GASTROSCOPE.*

By MAX EINHORN, M.D.,

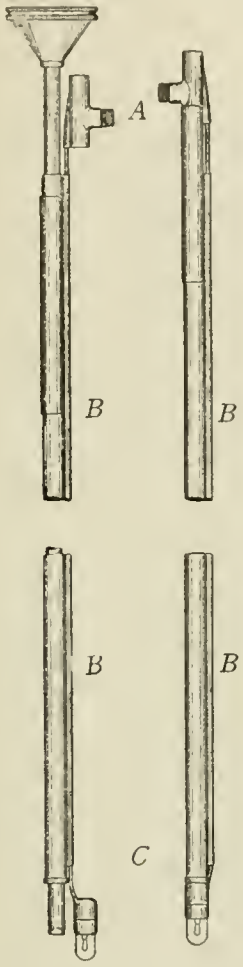
NEW YORK.

The gastroscopes which had been used thus far, have a lamp at the end and an optic arrangement above the lamp on the side of the instruments. It is, therefore, possible to obtain merely a lateral view of the organ, namely, of that piece lying opposite the window. It appeared to me that it would be of advantage to modify the instrument in such a manner that the lamp end piece could be pushed out of the way when inspecting. For then a view straight down would be possible.†

In December, 1901, I had Wappler & Co., of this city, construct a gastroscope on this principle for me. The instrument consists of a hollow metallic tube at the upper part of which there is an adjuster (A), and at the side of which is a groove (B), containing a rod with a lamp on its end (C) (lamp carrier). This rod can be moved up and down, and can also be rotated. At its upper part the rod contains an attachment for current connection.

When inserting the gastroscope the lamp just closes up the opening of the tube and serves as an obturator. The adjusting piece is pushed upward and holds the lamp carrier and the tube together in such a manner that no change in position between the rod and tube is possible. When the lower part of the instrument has reached the stomach, the adjuster is slipped downward. The lamp carrier is pushed somewhat down and rotated to the side. In this manner the lamp is taken away from the lower end of the tube and the latter free for use. A direct view of a very minute piece of the stomach wall is now immediately made possible. The field of vision is considerably enlarged by inserting telescopes into the metal tube—one with a lens at its end permitting inspection of the entire area straight forward, the other with a side window, allowing vision of the side of the stomach opposite the window.

The accompanying figure illustrates the above arrangement. The Electrosurgical Company of Rochester constructed a similar gastroscope for me



about five or six years ago. I have used this gastroscope on patients at my office as well as in the German Hospital, off and on, for several years. At some future date I shall write on this instrument and its application, more fully.

20 East Sixty-third Street.

*Demonstrated at the meeting of the German Medical Society of New York on May 2, 1910.

†Elsner has very recently described a similar instrument in the *Berliner klinische Wochenschrift.*

Vaccination and Smallpox in Germany.—In a pamphlet issued by the Council on Defense of Medical Research of the American Medical Association, Dr. Schamberg of Philadelphia says: "Since the law of 1874 went into effect in Germany there have been no epidemics of smallpox in that country. The disease is frequently introduced by foreigners, particularly on the frontier, but smallpox can find no foothold. In 1899 there occurred in the German Empire, among 54,000,000 people, only 28 deaths from smallpox; these occurred in 21 different districts, the largest number in any one district being three. Not a death from smallpox occurred in a large town. In 1897 there were but five deaths from smallpox in the entire German Empire (54,000,000 population). Furthermore, for a period of thirteen years, in a population comprising two-fifths of the total inhabitants of Germany, there were only five instances of death from smallpox in successfully revaccinated persons. Germany has taught the world how to utilize Jenner's great discovery so as to exterminate epidemics of smallpox. The German Vaccination Committee of 1884, referring to the influence of the compulsory vaccination law, said: 'The remarkable and persistent decline in Prussia since 1875 can be due only to the vaccination law of 1874, because all other conditions remain the same in the two other countries (Austria and Germany). The only difference is that in Prussia the revaccination of all school children at the age of twelve years was made compulsory in 1874.'"

THE CUTANEOUS REACTION IN LEPROSY.

STUDIES of immunity have brought forth many facts of great scientific value, but as yet we have not been able to gauge correctly their true importance. For example, in some ways it has been somewhat disconcerting to discover that when an animal has been injected with certain foreign protein substances, under some circumstances, instead of becoming resistant to the protein the animal in its reaction may become more susceptible. This hypersensitiveness in the case of guinea-pigs has been shown to last a year and even longer and may be present as long as the animal lives. Von Pirquet observed in 1907 that if the skin of a tuberculous patient was scarified and moistened with a drop of Koch's old tuberculin, within from twelve to forty-eight hours, an urticaria-like swelling or a papule surrounded by a reddened area appeared. In the case of a positive reaction a slight reddening appears in about twelve hours and the swelling and redness reaches its maximum in from twenty-four to forty-eight hours, lasting four or five days or longer.

Oscar Teague of the Biological Laboratory, Bureau of Science, Manila, published in the *Philippine Journal of Science,* October, 1909, No. 5, Vol. 4, a preliminary report of a similar cutaneous reaction in leprosy. Wooley, in April, 1907, suggested that, since the lepra bacillus had not been grown on culture media, nodules obtained from a leprous patient be extracted in a salt solution and the resulting extract be used as a vaccine in treatment. Teague recognized that it was but a short step to use such an extract in an attempt to obtain a cutaneous reaction in lepers such as von Pirquet had observed in tuberculosis. It was hoped that in this manner an aid to diagnosis of doubtful cases of leprosy might be obtained. As the bacillus of leprosy is more like the tubercle bacillus than other pathogenic organisms, extracts were prepared in a similar way to that employed in the preparation of old tuberculin. Four different extracts were made as follows: (1) from nodules taken from living lepers; (2) from the nodulous skin of a dead leper; (3) from the spleen of a dead leper; (4) a control from the skin of a cholera corpse. The material thus obtained was cut into small pieces, or ground in a mortar in case of the spleen, and extracted in 5 per cent. glycerin. It was then heated on the water bath until the volume was reduced to about one-tenth of the original. Fifty lepers were vaccinated with these extracts, a control vaccination with the extract of skin from the cholera case being made in each instance. In two or three cases there was a doubtful reaction, but otherwise the vaccinations were in all respects like the controls.

These experiments, it is needless to say, were of great interest, and as the consensus of opinion with regard to von Pirquet's cutaneous reaction seems to be that it is a specific reaction for tuberculosis, further experiments as to leprosy on similar lines in Manila will be attentively followed. The hypersensitiveness produced in some circumstances by the injection of certain toxic substances may be employed usefully from a diagnostic standpoint, and thus the hypersensitive reaction as the immunity reaction may be utilized in medicine.

CONSTIPATION IN INFANCY.

THE regulation of the passage of fecal material through the colon of the newborn infant, and its final evacuation, is more purely a reflex than is the case in the adult, in whom a voluntary psychic element is added to the physiological. In most properly fed infants Nature produces rhythmic contractions of the rectal wall resulting at fairly regular intervals in the normal evacuation of the bowel. So long as this rhythm is maintained and recurs at least once and not more than four times a day, the bowels are said to be regular. When, however, any influence interferes with the rhythm of the process, either diarrhea or constipation results. The former is usually due to direct irritation from undigested food or intestinal intoxication. The latter may be due to one of many causes. Aside from the cases of disturbance of the central nervous system and mechanical obstruction to the gut, which as a rule are obvious, many more obscure factors have been mentioned in explanation of chronic constipation of infancy. Much stress has been laid upon the anatomical peculiarities of the child's colon, its proportionally greater length, and increased convolutions.

Another far too common cause of constipation in the infant is the indiscriminate and unintelligent use of castor oil, the action of which, though purgative at first, is to produce after the first cleaning out an obstinate constipation.

In *The Practitioner* for May, 1910, Pritchard of London lays stress upon the unfortunate results following the administration of this drug in infants, especially during the first few days of life, calling attention to the natural rhythmic nervous impulse which produces defecation. He emphasizes the fact that such reactions of the nerve centers depend upon past experiences, and their regularity is due to the establishment of a habit. Meconium, owing to the physical properties, is just sufficiently lubricant and stimulating to call forth the proper number of movements a day, and thus is given the basis for the physiological rhythm of nerve impulses, which, after a few repetitions, becomes a habit, and thus insures to the baby, in the absence of other disturbing factors, regular and normal

stools. If, however, before this habit is firmly established, a purgative dose of castor oil is administered, the whole rhythmic nervous mechanism is upset; not only by the complete emptying of the bowel is the stimulus for future movements removed, but when meconium or fecal matter does again appear its irritating action is so meager, compared to that of the oil, that the nervous center takes little or no cognizance thereof, the feces remain overtime in the rectum, and the nervous rhythm is either completely destroyed or so lengthened that the intestinal contents become dry and hard and constipation inevitably results. After quoting Still's statement, that he knows of no drug which is responsible for more chronic constipation in infancy than castor oil, Pritchard says, "I would go even further and say that I know of no series of doses of purgative medicine which are responsible for so much constipation at any time of life as the single dose of castor oil which cleans out meconium from the bowel of the newborn infant."

This theory of Pritchard's is distinctly ingenious and fits in well with clinical observation. The use of castor oil in the infant, except where a single clearing out is required for an acute intestinal infection, is certainly a most harmful procedure, but one whose drawbacks are not in the least recognized by the lay public, and not sufficiently widely appreciated by the medical profession. It is an easy matter, requiring but little thought, to tell a mother whose baby has not had a movement for two days to give it a good cleaning out with castor oil. It is a very different matter, requiring much mental exertion during the following weeks or months, to again establish the regular rhythmic cycle of intestinal evacuation which is necessary for a proper functional activity of the digestive system.

THE STRESS AND STRAIN OF LITERARY LIFE.

Brain exertion, or rather undue mental effort, induces fatigue, possibly to a greater extent than does excess of physical exertion. Like the muscles, the brain is liable to fatigue, and mental strain will affect injuriously the digestion and will bring about changes in the blood and consequently will injure the circulatory system. In *Cassel's Magazine* for May, Sir Malcolm Morris discourses instructively in regard to the bad influence the mental stress and strain of literary life may exert on the body. A man who engages in literary or journalistic work at high pressure draws largely upon the fount of vitality, and in most cases will suffer for his recklessness in the long run. Brain work carried to the point of fatigue for a continued period will, in most instances, cause actual waste of tissue, and will produce various phases of dyspepsia, not infrequently culminating in chronic intestinal autointoxication, bringing in its train neurasthenia in its many manifestations. One of the main causes of mental strain brought to the breaking point is night work with lack of sleep. Want of healthy exercise and unsuitable diet are other important contributory causes. Eyestrain also is a factor of considerable importance when considering the ill health of many literary men. The fact also must be taken into account that at the commencement of their careers, and sometimes throughout their careers, literary men are forced to contend with poverty with its accompaniments of anxiety and worry, and are unable either to work or to live in the manner best fitted to conserve their health.

To take a few examples of well-known literary men, Carlyle's name is one of the first to suggest itself. He was notoriously of the bilious type; his bilious temperament tinged all his writings and saturated some of his work. Moreover, he is said to have been an injudicious eater, and perhaps smoked more than was good for him. However, his constitution was sound, for he lived to a green old age. Darwin, again attained old age, although he was a martyr to headaches which, according to George M. Gould, were wholly due to eyestrain. Spencer was another indefatigable worker, who suffered much from dyspepsia, but who reached an age beyond the ordinary span of life. Tolstoi is a conspicuous example of the literary man who, while taking full toll of his brain powers, has lived on the whole a healthy life. Mark Twain, throughout his life of seventy-five years, enjoyed fair health; he worked hard, and played hard, his sole excess being in the consumption of cigars. Anthony Trollope was most probably the best example of a well-known writer who lived by routine, that is to say, so far as his literary output was concerned. He wrote so many words a day, no more no less, and spent the remainder of his time in exercise and amusement.

There have been literary men of genius who have absolutely killed themselves by burning the candle at both ends. Balzac was undoubtedly one of these. He would work unceasingly for days and nights at a stretch, consuming large quantities of black, strong coffee, and he would amuse himself in the same strenuous manner. Poe is another man who committed suicide in a somewhat similar way, although there was maybe a strain of degeneracy in his mental and physical make-up.

The list of celebrated literary men who have shortened their days by mental stress and strain is long, and the list of unsuccessful and mediocre literary men who have done the same thing is far longer. As a rule, those who have made a name are not compelled to use their brains to excess and need not deny themselves rest and amusement, but those who have failed must do both.

The Use and Abuse of Gastroenterostomy.

During the thirty years since the operation of gastroenterostomy was first performed the use of this lifesaving procedure has increased tremendously, and the technique has undergone radical changes until now in many clinics at whose heads are men with especial reputations as gastric surgeons, it is at least a weekly, and at times a daily, happening to have one or more patients put upon the table for this operation, and in such clinics the mortality in benign cases has dropped to the inconsiderable figure of one or two per cent. First used only in cases of organic obstruction of the pylorus, the indications have increased until by many men

the operation is performed as a routine in cases of ulcus ventriculi, gastric dilatation, gastroptosis, tetany, infantile pylorospasm, and as a palliative measure in many cases of carcinoma. During the past decade, especially during the first few years of the new century, the operation became almost a fad, and in some quarters the opinion seemed to prevail that this radical operation was a panacea for each and every form of indigestion. That experience, however, has not warranted this extreme idea is emphasized in an article in the *American Journal of the Medical Sciences* for May, 1910, in which Deaver, while insisting that gastroenterostomy is, when properly indicated, one of the most valuable of surgical procedures, warns against its indiscriminate use, especially in cases of the various forms of gastric neurosis. There is no class of patient that is more anxious to have an operation performed upon himself than the neurotic, especially when the neurasthenia has taken upon itself the symptoms of indigestion, and abdominal pain or discomfort, and there are many sad instances of men and women, often themselves members of the medical profession, who are traveling from one gastric surgeon to another, pleading with each to open the abdomen and so change the course of the alimentary tract that their sufferings may be relieved. In such cases a laporotomy will at times discover some organic lesion which is amenable to surgical treatment, but much more frequently such interference only aggravates the existing symptoms. In such cases, showing the classical symptoms of neurasthenia, it is far safer to refuse operation entirely, or at least after an exploratory laparotomy to back out, after as little interference as is necessary to confirm the diagnosis. In such a case the continuation of the operation is nothing better than meddlesome surgery, and its results, as Deaver says, are nothing short of a catastrophy. The warning is thoroughly timely and coming from a man with an established reputation as an abdominal surgeon, it carries no small weight. While the knife is of inestimable value in the cure of a gastric disorder located in the hypogastrium, it is rarely of use, and is often an abuse, in the treatment of one whose origin is in the cerebrum.

Intestinal Fermentation and Cancer.

Since Fischer in 1906 reported the powerful action of scarlet-red in stimulating the growth of epithelium, this chemical compound and others, closely related thereto, have been the subject of considerable study, both from the clinical and the experimental aspect. Not only have local superficial applications of the substances been found to stimulate the healing of indolent ulcers by rapidly covering the granulations with epithelium, but from the experimental side, also, injections into animals have caused epithelial proliferation in the course of a few days, the resulting epithelial new growth being of a type which, microscopically, is indistinguishable from carcinoma. Recently, furthermore, Stober reported similar results from the injection of scarlet-red and of its component, amidoazotolus, into a man, the inoculation having been made a few days before amputation of the part so treated. In the *Münchener medizinische Wochenschrift* for May 3, 1910, the same author and L. Wacker add one more link to the chain of evidence of the chemical stimulation of epithelial proliferation. These authors deemed it advisable to repeat these experiments, but instead of using purely synthetic compounds, to use more or less closely related substances formed in the animal body under normal and pathological conditions. They naturally turned their attention to such chemical compounds as are known to be in excess in cases of carcinoma in man. The association of intestinal fermentation with its resulting increase of indol and skatol in the feces and urine has long been observed, and has formed the basis of several theories as to the etiology of cancer. The present writers, therefore, inoculated indol, skatol, and the simpler compound, pyridin, into the ears of rabbits. Within fifteen days definite epithelial new growths were found at the site of injection. Those produced by pyridin were the least typical, those from indol and skatol were more so, while those which resulted from an injection of indol followed by skatol were the most striking of all. The micropathology of these new formations was indistinguishable from that of squamous cell carcimona; all the signs of rapid growth, formation of cell nests, and invasion of the surrounding tissue were in evidence. These findings are distinctly of interest, and will probably be used as evidence by those who believe in the intestinal origin of cancer.

News of the Week.

Optometry Course at Columbia University.—The astounding announcement is made by Columbia University of the establishment of a course in optometry, to begin September 28, 1910. The new course is made a part of the department of physics and is, it is needless to say, independent of the medical school. The course is to be for two years, and graduates will receive certificates from the university's board of extension teaching. The lecturers who are to teach the various phases of optics and optometry have been selected from the members of the faculty in the department of physics, with the addition of several special lecturers who are practical optometrists. This news would be funny, were it not so serious. It is bad enough that the State gives these persons the legal right to fit glasses without being able to test the eyes properly and without the necessity of a knowledge of the relation of ocular to general pathology. It is worse to give them the moral support of a quasi degree from a great university.

Yellow Fever in Italy.—A despatch from Lugo, Italy, dated June 1, reported thirty cases of yellow fever and nine deaths within a few days.

No Hookworm Investigation in Texas.—Owing to a failure of agreement between the Rockefeller Commission and the State Board of Health of Texas, it is stated that the former will carry on no work in the State of Texas.

The State Civil Service Commission will hold examinations on June 25, 1910, for the following positions: Second Assistant Physician, State Hospital Service, $1,500 to $2,000 and maintenance. Trained Nurse, State Institutions, open to men and women, $420 to $600 and maintenance. Applications should be filed on or before June 18, 1910. For detailed circular and application blank, address State Civil Service Commission, Albany, N. Y.

Vital Statistics for New York State.—The State Department of Health's bulletin for April gives a birth record of 16,557 and a death record of 12,835.

The morbidity record for contagious diseases was headed by measles with 9,931 cases. Other infectious diseases were scarlet fever, 4,412; tuberculosis, 3,969, and typhoid fever, 332.

Columbia University Commencement.—At the commencement exercises of Columbia University held June 1, 1910, the degree of Doctor of Medicine was conferred upon seventy students of the College of Physicians and Surgeons. The honorary degree of Doctor of Science was conferred upon Dr. William James Mayo of Rochester, Minn.

The New York Homeopathic Medical College and Hospital held its fiftieth anniversary in New York recently. The semicentennial was made the occasion for a reunion of the alumni, and in the neighborhood of 700 attended.

The Western Reserve University.—The medical department of the Western Reserve University has recently absorbed the Cleveland College of Physicians and Surgeons. Announcement has been made of the donation by Mr. H. M. Hanna of the sum of $250,000 to the endowment fund of the medical school.

Charitable Gift.—Nathan Snellenburg of Philadelphia has made a gift of $5,000 to the Jefferson Hospital for the endowment of a free bed in memory of his son, Milton L. Snellenburg, who died in that institution several months ago.

"The Tuberculosis Preventorium for Children" has applied for incorporation in Manhattan. The purpose of the organization includes the management of the present institution at Farmingdale, N. J., and the founding of other similar farms, as the need for them becomes evident.

Memorial to King Edward in Pittsburg.—At a meeting held in Pittsburg on June 5, and attended largely by Englishmen living in that city, the sum of $25,000 was subscribed towards erecting a memorial to the late King Edward VII. The committee in charge recommended that the money be used for a King Edward Memorial Building, to be a part of the proposed tuberculosis hospital in Pittsburg.

The Hungarian Hospital Association has applied to the New York State Board of Charities for approval of its certificate of incorporation. The purpose of the association is the maintaining of a hospital at which Hungarian patients can be treated by those who know their language.

The Hempstead Hospital, which has been built by Mrs. O. H. P. Belmont, will have a house staff composed entirely of women physicians. The hospital will be general in character.

The Sea Breeze Fresh Air Home at Coney Island opened for the season June 1, 1910.

The New York Academy of Medicine is desirous of adding to its library the reports of the committees that have been appointed from time to time to investigate questions of public health. Harbor pollution, the alcohol question, the prevention of tuberculosis, the prevention of occupational diseases, the sanitation of tenements, the sanitation of workshops, the effect of prolonged hours of labor, the social evil, and congestion of population are some of the topics about which information is desired. The Academy is not starting any investigation of its own; it is only trying to get the reports of past and present investigations undertaken by others. The Academy of Medicine will be very glad to receive copies of reports of this nature, and also any information concerning the appointment, the organization, and the work of committees or commissions engaged in this research.

Dinner to Dr. Ladinski.—A dinner was given June 1, 1910, in honor of Dr. L. J. Ladinski, president of the Medical Board of the Beth Israel Hospital in New York. A loving cup was presented to the guest. Announcement was made that Mr. Max Ruben had donated $5,000 toward the building fund of the hospital.

Sir Felix Semon, Physician Extraordinary to the late King Edward VII, is on a visit in America. He landed at San Francisco from Japan, May 28.

Dr. Charles A. Hodgetts of Toronto, Canada, has been appointed medical advisor to the Public Health Committee of the Dominion Commission or Conservation.

Dr. Edward Payson Fowler of New York City has given his valuable medical library, consisting of more than a thousand volumes, to the New York Academy of Medicine.

The Canadian Society of Superintendents of Training Schools meeting at Toronto, May 25, elected the following officers: *President,* Miss Mackenzie of Ottawa; *Vice-Presidents,* Miss Brent of Toronto, and Miss Stanley of London; *Secretary,* Miss Scott of Toronto; *Treasurer,* Miss Robinson of Galt; *Auditors,* Miss Matheson of Toronto, and Miss Young of Montreal. Next year's meeting will be held in Niagara Falls, simultaneously with that of the Canadian Hospital Association.

Sir Francis Seymour Haden, the founder and president of the Royal Society of Painter Etchers, who died in London, England, June 1, 1910, was for many years a practising physician. He was born in 1818, graduated from the University of London and the Sorbonne in Paris, and received the M. R. C. S. in 1857.

Obituary Notes.—Dr. Samuel L. Dutton of Chelmsford, Mass., died May 27, 1910, aged 75 years. He was a graduate of the Harvard Medical School in 1860, and was a member of the Middlesex District Medical Society, the Massachusetts Medical Society, the American Medical Association, and the Loyal Legion.

Dr. Francis X. Weil died at York, Pa., on May 20, at the age of 69 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1869 and was a member of York County Medical Society and the Medical Society of the State of Pennsylvania.

Dr. Calvin Anderson of Madison, N. J., died suddenly of heart disease, May 26, 1910, aged 69 years. He was a graduate of the College of Physicians and Surgeons of New York in 1865, a member of the Morris County Medical Society and the Medical Society of New Jersey, and attending physician to the All Soul's Hospital in Morristown. At the time of his death Dr. Calvin was serving his second term as Mayor of Madison.

Dr. Richard J. Egan of New York died at his home, May 24, 1910, aged 46 years. He was a graduate of the New York University Medical College in 1886.

Dr. John Dolway Wilson of London, Ontario, died at his home, May 16, 1910, aged 52 years. He was a graduate of Trinity Medical College in Toronto in 1882. Dr. Wilson was an ex-mayor of the City of London.

Dr. William A. Mogk, formerly of Ann Arbor, Mich., was found dead in the Sand Canyon near

Bakersfield, Cal., May 18, 1910. He was a graduate of the University of Michigan in 1898.

Dr. Thomas Frank Flowers of Atlanta, Ga., died May 22, 1910. He was a graduate of the Atlanta College of Physicians and Surgeons.

Dr. William Krause died at Philadelphia on May 30 as a result of poisoning by illuminating gas. He was 64 years old and was graduated from Jefferson Medical College in the class of 1884.

Obituary.

HENRY GRANGER PIFFARD, M.D., LL.D., New York.

Dr. Piffard's death, which occurred from pneumonia on Wednesday of this week, removes one of the best known of the older generation of New York physicians. He was born in Piffard, Livingston County, N. Y., on September 10, 1842. He was educated in one of the military schools in Sing Sing, and from there went to the University of the City of New York, whence he was graduated in 1862. He received the degree of M.D. from the College of Physicians and Surgeons in 1864, and then served for eighteen months as interne in Bellevue Hospital. He was professor of dermatology in the Medical Department of the New York University for thirty-five years, having been appointed to the chair in 1875. He served about fifteen years as surgeon to the City Hospital, then known as Charity Hospital, and on retiring was made consulting surgeon to that institution. He wrote a number of works on subjects connected with dermatology, and was a frequent contributor to periodical medical literature. He was particularly interested in recent years in radiology and the newer applications of electricity in therapeutics. Dr. Piffard was a man of engaging personality, quaint humor, and rugged honesty, who had a host of friends in spite of his fearless and sometimes blunt speech. He was polemical by nature and was always ready for a discussion, the warmer the better, but retired from it, whether victor or vanquished, on the best of terms with friend and foe. The medical profession of New York has lost a member whom it will sorely miss.

ELIZABETH BLACKWELL, M.D.

Dr. Elizabeth Blackwell died at her home in Hastings, England, June 1, 1910, aged 89 years. Born in England, Dr. Blackwell came to America with her father at the age of 11 years in 1832. In 1845, determining to study medicine, she applied to many of the American medical schools for admission, but was refused, until finally the Geneva Medical College admitted her. In 1849 she was graduated at the head of her class, being the first woman to receive a medical degree in America. Later she studied in Paris and London. In 1851 Dr. Blackwell began practice in New York in the face of strong opposition. In 1854 she founded the New York Infirmary for Women and Children, and in 1868 the Woman's Medical College of the New York Infirmary for Women and Children. During the Civil War Dr. Blackwell was influential in organizing the National Sanitary Aid Association. In 1869 she returned to England, practising in London and Hastings. There she founded the National Health Society of London, and assisted in organizing the London School of Medicine for Women.

Correspondence.

FORTY-THIRD ANNUAL MEETING OF THE CANADIAN MEDICAL ASSOCIATION.

(From Our Regular Correspondent.)

Toronto, June 3, 1910.

Although several sections were held on the morning of June 1, the day on which the annual meeting of the Canadian Medical Association was opened, and to which reference will be made later, the meeting was formally opened at the general sessions in the convocation hall of Toronto University on the afternoon of June 1. It may be said that the faculty of the university gave the use of its handsome, convenient, and commodious buildings to the association, which, needless to say, afforded every advantage for such a gathering. The addresses of welcome were given by Hon. Dr. Pyne, Minister of Education for Ontario, representing the provincial government; Acting Mayor Ward, representing the city of Toronto, and by R. A. Falconer, president of Toronto University, representing the university. The chair was taken by the retiring president of the association, R. J. Blanchard of Winnipeg, Man. Dr. Adam H. Wright of Toronto, the new president, was inducted and made his opening speech. This speech was humorous and apropos and dealt with the general practitioner. Dr. Wright gave it as his opinion that the family physician was by no means dying out, but was very much alive and kicking. The speaker delivered himself of some very decided views in regard to present-day methods of manufacturing the general practitioner, and said that the modern medical student was too much crammed. He said that while our college professors were studying methods in medical education many of our general practitioners were watching the situation with a very deep and intelligent interest, and a large number of them perhaps thought that it was unwise to endeavor to stuff a quart of material into a pint pot. Many of them also believed that our teachers should teach less in order that our learners might learn more. A certain proportion favored Fletcherization because of their belief that the intellectual pabulum given to our students should be properly digested and thoroughly assimilated. Dr. Wright held that the physician of the present day was too greatly machine made and he poked fun at the methods of up-to-date surgeons who are wont to array themselves in a night cap, a mask, a night gown, mittens, and top boots when about to operate in a well-equipped hospital of the day. He ended by saying that men of the Lister type were needed to teach our students and practitioners. Some of our shining lights nowadays, in hospitals and in medical societies, appeared to aim at giving exhibitions of their own skill instead of imparting some practical knowledge to the every-day doctor, knowledge that would help him while working in the country or in the backwoods, where theatrical costumes can scarcely come into general use. After some general business had been dispatched, the report of the Toronto Milk Commission, or rather of the Milk Commission appointed in June, 1908, by the Canadian Medical Association, was presented by its chairman, Dr. Charles J. C. O. Hasting of Toronto. The report is in book form and is a somewhat voluminous review of the work done by the commission during the past year. According to the chairman, the objects of the campaign for purer milk have been sought through an investigation of the part played by milk in the causation of infant mortality, in the spread of communicable diseases, and as a cause of tuberculosis. Stress was laid on the vital importance of a pure milk supply, especially for babies, and statistics were quoted to show the high rate of infant mortality among infants fed on raw dairy milk. This is the second commission that has reported in Canada recently on the milk question. The former commission was appointed by the Government of Ontario, and its findings showed that the milk supply of Ontario generally was unsatisfactory and that that of Toronto was distinctly bad. The report presented to the association seems to demonstrate that the milk supply of Toronto is at any rate rapidly improving, and it is predicted that before midsummer at least one-half of the milk consumed in Toronto will be a clean and safe food for human use. However, the report fully bears out the statement made in the former report that the milk supply generally in Canada is capable of vast improvement, and concludes with these words: "In view of the facts here presented, is

it too much to hope that our federal, local, and municipal legislatures will realize that human life is at least worthy of as much consideration as is farm stock and agriculture?" A marked feature of the report was the belief expressed in the efficacy of pasteurization as a means of safeguarding milk from contamination. Reference is made to the installation of a pasteurizing plant in the Children's Hospital, Toronto, the gift of Mr. J. Ross Robertson. Number of gallons pasteurized per day is fifty gallons. The average bacterial count of milk supplied to the hospital in the week just before the installation of the pasteurizing plant was 11,400 per c.c., while the count for six days after pasteurization was 36, 64, 18, 8, 50, and 64, respectively. A remarkable showing and presumably strong evidence in support of pasteurization.

The next speaker was Dr. Charles E. North of New York City, who devoted the time at his disposal chiefly to explaining the objects of the New York Milk Committee. He said that the Canadian Medical Association had a far wider scope than that of any American milk commission of which he was cognizant, and then he went on to say that New York City had the worst milk supply of any city of this continent. He accounted for this unfortunate state of affairs mainly for the reason that inspection was obviously insufficient. There were 40,000 dairy farms to be inspected, and the inspectors were, of course, too few in number to be of much practical use. Again, New York is supplied with milk from great distances, another reason for rendering inspection at the source of supply more or less futile. Dr. North, at some length, elucidated the objects of the New York Milk Committee. He confessed that he had little hope that certified milk would prove itself of any great value in New York City or in other very large cities. For one thing, the price of such milk was prohibitive to many people. He also confessed himself skeptical as to the elimination of tuberculosis among cows—at least, if it were possible, it would be a very long time in coming. He, too, pins his faith to pasteurization of milk in default of being able to insure the supply pure at the source. He pointed out that in New York, among the profession generally, there was scant trust in the merits of pasteurization, but this did not alter his opinion on the matter. Naturally it was needful to procure a clean milk before pasteurizing, but, given this, a properly pasteurized milk was a healthy food for infants. He did not think its nutritive properties were injured by the process. He had made experiments by injecting raw and pasteurized New York milk into three hundred guinea-pigs; half of those injected with raw milk had died, one injected with pasteurized milk commercially treated had died, and none injected with certified milk had died. The last two speeches made in this discussion were, from many points of view, the most interesting and the most instructive, and neither of these was by a medical man.

Professor A. McGill, Dominion Analyst, insisted upon the necessity of specific definitions of pasteurized milk being given. The scientific and the legal ones must be made alike. However, it was of little use to define pasteurized milk according to the processes it underwent legally, if there were no recognized scientific methods of discovering by tests whether these processes had been used. They could discover the bacterial contents in those milks and go on that basis if that were made the legal definition. Inspection of every plant would be very difficult and expensive in order to discover whether the processes had been followed. J. G. Rutherford, Veterinary Director-General of Canada, in the course of his remarks, said that any abnormality in the cow relating to its health or its diet was liable to give rise to changes in the qualities and properties of milk, and so affect those who drank it. He gave a list of several articles of diet which, if partaken of by the cow, would injuriously affect the health, and especially of children, of those who drank the milk. He also mentioned various complaints to which cows are addicted which should preclude the use of the milk from cows in such condition as a food. Mr. Rutherford holds very strong views as to the spread of disease by milk, and is a firm upholder of the theory that milk transmits tuberculosis to human beings and thinks that tuberculosis should be attacked in the cow, as the stamping out of the disease among cattle would remove one of the great sources among human beings. Dr. J. C. Fagin of British Columbia told of the good results which were flowing from their system of dairy inspection and by the agency of the tuberculin test the percentage of the effective stock was on the increase. The main feature of the symposium seemed to be the belief that it is idle as yet to hope for good results from inspection—at any rate, such results that will insure to large towns a pure milk supply. In the case of very large cities like New York inspection can effect but little. As milk cannot be obtained there on a large scale from sources free from contamination, pasteurization must be used. The sense of the meeting in Toronto appeared to be that pasteurization does little or no harm to the nutritive qualities of the milk.

In the evening of June 1 another general session was held in convocation hall, when the address in medicine was delivered by Dr. W. P. Herringham, physician to St. Bartholomew's Hospital, London. The address was a singularly clear exposition of the onset, course, and treatment of chronic diffuse parenchymatous nephritis. Dr. Herringham is a really good speaker, with the gift of lucidity, and, though he had chosen, as he said, a humdrum subject, he rendered it peculiarly illuminating to his audience. He said that in England acute nephritis was of rare occurrence. He had met with one case of primary nephritis due to exposure in a boy of fourteen. The disease usually commenced in an insidious manner and he gave examples drawn from his own experience of certain phases of the malady. The first case described was that of a well-grown, well-nourished girl of twenty-three years, who outwardly had little appearance of disease save a slight puffiness under the eyes. Her retinæ were natural and heart normal, but urine was passed in enormous quantities. Albumin in small quantities was found in the urine. Iron was ordered and change to a dry climate. At the present time she did not appear to be materially worse, although she had had albuminuria for seven years, and undoubtedly the kidneys were structurally diseased. Some beautiful plates were displayed on the screen showing lesions in glomeruli. However, as the speaker pointed out, such lesions were not the only lesions, nor was the presence of albumin in the urine the only symptom. Lesions occurred of the tubular epithelium. But the greatest damage effected by an attack of nephritis was the delicacy of constitution left and the liability to recurrence. It was impossible to wholly repair the damage, but relief could be administered. There was, the speaker pointed out, a very considerable amount of ignorance as to the exciting cause of nephritis. It was frequently a sequel to scarlet fever, influenza, and pneumonia. It was caused by septicemia arising from bacilli or toxin acting perhaps upon a lowered general system. It was due to zymotic disease or chill, although such a claim appears to somewhat beg the question, and no one who had had much experience of nephritis could support that position. To look for the cause in toxemia by false metabolism or in intestinal autointoxication might comfort both patient and doctor, but did not give a satisfactory explanation of its relapse and spread. A patient suffering from chronic Bright's disease resembled in many respects a town of which the drainage system was out of order. The fact that diet was an important feature in the treatment of the disease was emphasized, and as an example of the good influence upon health of a spare diet the case of Luigi di Conari was referred to, who fared well and lived to a green old age on twelve to fourteen ounces of food a day. The nitrogenous constituents of food threw more work upon the kidneys than did the carbohydrates and hydrocarbons, and therefore in the diet of a patient with Bright's disease the former constituents should be limited. On the other hand Dr. Herringham did not advocate the restriction of the diet to fish or special foods. Light, ordinary diet did not increase the quantity of albumin and he had found that patients did better on flesh food than on milk food. The diet then might be composed of fish, poultry, or flesh of any kind, as he did not recognize any distinction between the different forms of flesh except in fiber, which, in itself, of course, had some influence on the digestion. After all, appetite was the best digestive. While strict moderation should be observed with regard to quantity of food taken, there was no need for like precautions as to variety. Alcohol was not indicated in these cases, but even here justice might be tempered with mercy and those who had been accustomed to the use of alcohol might be allowed a small quantity of beer with their meals. Tea, coffee, and cocoa were irritants to the kidneys, as were also condiments, and even common salt was not well tolerated in some cases. Exercise and fresh air were beneficial, but the effects of exposure should be guarded against,

and warm clothing should be worn, and especially around the loins. If due precautions were taken, patients with chronic nephritis might live for years. In cases of chronic nephritis in which urine was scanty, in order to avoid uremia excretion of urine must be encouraged. For this purpose milk is sometimes efficient, but oftentimes diuretic drugs must be employed. Saline diuretics, citrates, carbonates, etc., act by stimulation. Cardiac drugs, digitalis, squills, act by directly stimulating the voluntary muscles of the heart and arteries, and the alkaloids, which stimulate the cardiac tissues and renal cells. Of these Dr. Herringham was of the opinion that caffeine and theobromine were the best. Such alkaloids as tea, coffee, or cocoa acted favorably on occasions. But the beverage to which the patient was unaccustomed should always be employed. For instance, if tea were the customary beverage, coffee should be used, and so on. For cardiac weakness cardiac tonics should be administered, and if saline diuretics did not effect their object alkaloids should be given a trial. The blood symptoms were often very difficult of control. When the bleeding was copious patients might be laid prone on their faces, but the remedy was generally ineffective because it was almost impossible to retain them in this position for a sufficient length of time. When hematuria was persistent resort should be had to iron, gallic acid, hamamelis, ergot, and sometimes to oil of turpentine, but there were cases in which the hematuria could not be stopped. Attention was drawn to the manner in which renal disease differed in its course. Although of the same origin, from a certain point the disease branched off into two forms, presenting clinical features almost as distant as the two poles, and seemingly quite distinct forms of disease. Those with the typical large white kidney died from asthenia as a rule, while those with small, contracted kidney, generally young, died very frequently from acute uremia. The main object in bad cases was to attempt to increase the flow of urine. In this connection Dr. Herringham deprecated the alarm which is often felt at the high blood pressure which is an accompaniment of Bright's disease. He regarded this in the light of compensatory action and did not look upon it as a serious symptom in the case of the young, whose arteries were elastic and could bear a remarkable amount of pressure. In the elderly, in those over fifty or more, it was undoubtedly a cause for much alarm, as in these cases the arteries were brittle and frail. For the relief of edema the safest way, if possible, was to drain the skin by means of canulas. Sometimes venesection might be advisable. It was reasonable to suppose that when the poison in the blood overstepped the bounds of tolerance that bleeding might reduce the poison to just below the lethal dose and prolong life for a time. The life of a person suffering from severe Bright's disease was always hanging by a thread, and the wonderful thing was that such an individual lived as long as he often did live. Dr. Herringham thought that the presence of the poison in the system for a considerable period might establish a certain degree of immunity of its own and thus enable the patient to continue to exist in a highly diseased condition.

Among general business of interest transacted after the reading of the above paper was a recommendation by the executive council of the association that an association journal should be brought out forthwith, with Dr. Andrew McPhail of Montreal as editor, and the further recommendation was made that this journal should absorb the *Montreal Medical Journal*. The report was adopted after some discussion. Dr. T. G. Roddick then produced an amended bill on Dominion registration. The clauses in which it differed from the one formerly presented by Dr. Roddick were read and accepted, with slight emendations. The principal change was that the Canadian Medical Association council should not determine the qualifications necessary for matriculation in the study of medicine and for obtaining the provincial license, this, as heretofore, being regulated by the provincial authorities.

Polyneuritis.—Portilla defines the disease as the simultaneous alteration of many nerves owing to an infectious, toxic, or diathetic origin. He differentiates it from tabes and from anterior poliomyelitis, and describes the course of the disease which is favorable in peripheral cases. Prognosis is unfavorable if there are contractures and in alcoholic cases; reincidence is common.—*Crónica Médico-Quirurgica de la Habana.*

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE LATE KING—GLAUCOMA—WORD BLINDNESS—TREATMENT OF LUNACY—SOLID CARBON DIOXIDE—PELLAGRA—OBITUARY.

London, May 20, 1910.

One subject has dominated the thoughts and the conversation of the public throughout the week. The late King, his death, his funeral, his activities, his character, his objects, his hopes, seem to have absorbed attention wherever men met. Even the profession has been as much occupied with these things as every other group of citizens and as zealous to display its loyalty. Some have naturally talked over the nature of his illness. Not a few have asked one another in the presence of the official report whether a hint should not have been conveyed that his constitution might fail sooner than was expected. But the difficulty of so doing has been generally recognized and the course taken by the physicians approved. We have dwelt on his interest in the progress of medical science and practice as evinced by his patronage and support of cancer research, of the sanatorium treatment of tuberculosis, and of his long work on behalf of hospitals. One of the London hospital funds, you will remember, is called after him as its founder. These are examples, but it may be said, as it has been often enough, they are not to be regarded, showing merely his interest in medical matters—an interest shown in many other ways—but as affecting all his subjects, and, indeed, all humanity, and especially the poor and suffering. In fact, among the many characteristics ascribed to him one of the most striking is that he was in everything human—a man—and therefore interested in all pertaining to man. So as occasion offered he was at home with the scientist, the theorist, the artist, the sportsman, and every other group of citizens, as he was, of course, with the medical profession, to which he always acknowledged his indebtedness, and which he delighted to honor. Of the national honor accorded him and the national sense of loss and regret for him you have every information on your side, even as we have on this.

The Ophthalmological Society had an interesting meeting on the 5th inst. Mr. H. Herbert of Nottingham described his small flap incision for glaucoma, which has been described as a form of "subconjunctival paracentesis." With a narrow Graefe knife a small rectangular sclerocorneal flap is cut subconjunctivally, its base at the limbus. This flap can be forced forward a little under the conjunctiva by the intraocular pressure. Probably it tends to shrink slightly in volume from temporary deprivation of its direct blood supply. He gave the results of eight cases operated on two years ago. One failed, two so far are unknown. In the others the tension has been reduced to normal by linear filtering cicatrices. For some months he has made a rather broader flap. Combined iridectomy, peripheral or complete, according to the state of the iris, seemed advisable if the pupil did not contract well under eserine. The object of the operation is to secure the linear filtering cicatrix, which is sometimes a chance result of ordinary iridectomy and to which Mr. Herbert thinks the success of iridectomy is due.

Mr. Priestley Smith had been struck by the success and by the slight disfigurement caused. Mr. Allport reported eleven cases of success under Mr. Smith's control. Mr. F. R. Cross agreed that the fistulous opening favored a more permanent result. Mr. Laws had performed the operation fourteen times without a failure. Mr. Allport had done twenty cases with satisfactory results.

Mr. H. Fisher then read a paper on congenital word blindness, or inability to learn to read, of which he had met with four cases (three boys, one girl). He thought as more cases were reported there might be a group in which heredity might be traced from failure of development of the visual memory centre for words which he supposed resided in the left angular gyrus. A second group he ascribed to limited hemorrhage over the same gyrus. This might occur as a birth injury, and if so the larger head of the male child would account for the greater frequency of word blindness in boys. For children with this defect he urged that private, special tuition was desirable. He considered that an endeavor should be made to train a vicarious visual memory center in the right hemisphere. This seemed to him more likely to succeed than the ordinary method of learning to read. He approved the "look and say" method. The child must take the word as its unit of study—not

the separate letters. The method had been perfected in the "delightful reading box system" of Miss Mason, which he had used with great satisfaction in one of the cases he had related.

Mr. Batten could not agree that a word blindness was due to defect in the angular or marginal gyrus. Bastian attributed it to a commisural defect. These cases as a rule could read figures well. He knew a butcher's boy who could take orders on his round and deliver them correctly. He was impressed with the plan of teaching Mr. Fisher had described.

Mr. Treacher Collins said such cases were frequent, but too often overlooked or attributed to stupidity on the part of the child. Some were atrocious spellers. He suggested that they had visual memory for words, but did not recognize them when a letter was misplaced.

Mr. Doyne objected to the term "word blindness." There was defect, but it was not pathological. It was more common in boys than in girls. Those affected would read their lessons aloud in order to learn them.

At the Medico-Psychological Society Mr. Street opened a discussion on the question as to whether we are doing as much in the way of treatment of mental disorder as might be done. Though much had been written about treatment there were not many encouraging results to report, and the recovery rate had not improved during the last thirty years. He thought a higher form of moral treatment than occupation and recreation might be of use. He believed in discussing with a patient his mental symptoms, whether they were delusions or suicidal inclinations. He had found the plan beneficial, especially in melancholic and alcoholic cases.

Mr. E. P. S. Gane read a paper on the serum treatment of general paralysis proposed by Dr. Ford Robertson which he had tried in six cases, using diphtheria antitoxin which had the advantage of being standardized. Further, Dr. Anderson's researches suggested that the cause of the disease was an organism allied to the bacillus of diphtheria. In four of the cases he had no change to report. So in the fifth, but that was so advanced that nothing could have been expected. There was, therefore, only one which he could think somewhat improved during the treatment. The grandiose ideas and delusions left the patient and his mental power seemed somewhat improved.

Solid carbon dioxide is coming into use. It is not exactly a caustic, inasmuch as it does not act chemically, but kills the tissue by freezing. Yet the action of the brief application made is not such as we see in an ordinary frost bite. It seems more to resemble radium, over which it has the advantage of not being costly. It is practically as easy to use as a chemical caustic. The momentary application is painless and the reaction almost so. Anesthesia is, therefore, unnecessary. Those who have employed it are usually well satisfied. Some who have not seen it used are a little distrustful, as they think of frost bite, but all who have tried it assure us that such reaction never occurs, perhaps because the intense cold is only applied for a few seconds. After treatment resolves itself into protection from sepsis.

The "Prana" apparatus for producing "carbon dioxide snow," made by "Aerators Limited," has been fitted at several hospitals. A portable model is now supplied by the same makers, enabling the practitioner to produce the snow quickly and economically. The snow can be cut by a knife, manipulated by a spatula, and formed into pencils by forcing it into tubes or moulds. This requires a little care at first and may be a disadvantage to the very busy. But I hear that "Aerators Limited" are about to put at the disposal of operators small tubes enclosing a pencil ready for use.

Dr. Sambon, chief of the Pellagra Commission, reports that the *Simulium reptons* is the carrier of the contagium. Captain Siler, U. S. Army, who went out with the commission, has returned and he has expressed to the committee on pellagra the importance of continuing the campaign under Dr. Sambon.

The death is announced of Mr. Astley Cooper, Deputy Inspector-General of Fleets and Hospitals, who entered the Royal Navy as surgeon in 1857 and retired in 1889. He served in the Chinese expedition of 1857-1859, which included the blockade of the Canton River and capture of the city. He was also in the North China expedition in 1860. As P. M. O. he was at Shanghai during the repulse of two attacks; was landed from the "Perseus" in 1869 and present at the capture of three walled villages near Swatow. In the Egyptian war of 1882 he was fleet surgeon of the flagship ("*Minotaur*"). He was awarded the China medal and Canton clasp, the Egyptian medal, and the Khedive's star.

Mr. Creswell Baber, surgeon to the Royal Ear Hospital, died on the 14th inst., aged 59. He was a St. George's Hospital student and later served the resident appointments and the demonstratorship of anatomy. He took the two college qualifications in 1871-1872 and the M.B. Lond. in 1873. He became surgeon to the Throat and Ear Hospital at Brighton, where he practised for some years, but later he had also consulting rooms in London. He had been president of the Laryngological Society and was honorable secretary to the International Otological Congress. He contributed papers to the *Phil. Trans.*, the *Journ. Anot. and Phys.*, the *Micros. Journ.*, the *Archives of Otol.* etc., generally on subjects connected with his specialty.

OUR PARIS LETTER.

(From Our Regular Correspondent.)

DIAGNOSIS AND TREATMENT OF NASOPHARYNGEAL POLYPI—PROVISIONAL HEMOSTASIS BY MOMBOURG'S METHOD—TREATMENT BY DISINTOXICATION.

PARIS, May 10, 1910.

MICHAUX has studied the history of periosteal and central fibromata of the superior maxillary bone. Rouvillois recalls that the observations published of nasopharyngeal polypi are rare. He reports the case of a patient whose death made a strong impression upon him, for at the autopsy there was found in the sphenoidal sinus a prolongation of the nasopharyngeal polypus, of which there had been no sign at the time of the operation, and whose existence had been unperceived, and had been the cause of death by hemorrhage. These cases of penetration of the sphenoidal sinus by nasopharyngeal polypi are so much more interesting because the invasion of the sinus is only the first stage of intracranial penetration, and it seems that this last is not very exceptional. The insertion of fibrous nasopharyngeal polypi is often ethmosphenoidal. From the point of view of operation the author prefers the method of tearing away rather than curetting, for the last leaves fatally in place the concealed prolongations of the tumor, while the tearing process often extirpates them at the same time with the principal tumor. As a preliminary operation the ligation of the two external carotids is especially to be recommended as a method of hemostasis, immediate and secondary, in case of prolongations unperceived. Kirmisson states that nasopharyngeal polypi have their implantation at the base of the skull, and not on the anterior face of the vertebral column, contrary to that which has been formerly believed. But this insertion at the base of the skull may be much more extensive than has been thought. He condemns the operations by the natural passages, which, according to him, may result in disasters. He believes that hemorrhages are always occasioned by portions of the polypus left behind. Quénu is a partisan of the double ligature of the external carotid as a preliminary to the operation on nasopharyngeal polypi. He is a partisan of the ideas of Kirmisson and counsels us not to operate by the natural passages. Sébileau thinks that nasopharyngeal fibromata have not in general extended insertions, but usually have an implantation that is narrow and circumscribed. He believes that their implantation does not take place at the base of the skull, but more often on the wall of the upper nasal fossæ, on the vomer, and the palatine bone. According to him, these polypi have always an implantation that is single and never a multiple one. Sébileau thinks that the best method of access to the nasopharyngeal polypi is by the natural retropalatine way. When one is obliged to create a way of access for himself, and to give light one should never employ resection of the superior maxillary bone, which is an operation that is uselessly mutilating and condemnable. As a method of treatment Sébileau prefers tearing away, which makes the removal of the prolongations more sure. It is important in these operations not to delay; when we have wounded the tumor it begins at once to bleed and continues to bleed until it is entirely removed. When we cannot be content with the natural passages, Sébileau prefers the palatine method, which gives light, but less than we might think. He condemns the resection of the superior maxilla, which, according to him, should never enter into the discussion. Possi, *apropos* of the gravity of the hemorrhage in the course of ablation of the naso-

pharyngeal polypi, recalls that the severe syncope has been attributed by him to hemorrhage of the bulbocerebral. He believes that the syncope is due not only to the amount of blood lost, but to the rapid subtraction of the blood from the neighboring encephalic organs. Potherat thinks that nasopharyngeal polypi should be operated on by the buccopharyngeal method. It is not necessary to have recourse either to section of the palatal curtain, nor of the palatine bone, nor to laryngotomy. He believes that it is necessary, first of all, to detach the tumor by appropriate instrumentation from its insertion, and from the entire extent of its insertion. The natural passages will in the immense majority of cases be sufficient by themselves to permit a successful operation.

Auvrey recalls the methor of Mombourg for obtaining hemostasis in the lower portion of the body by compressing the waist with a rubber tube. Mombourg applies the tube slowly between the lower border of the thorax and the crest of the ilium; he passes it two or three times around the waist, making forcible pressure until the pulsations cease in the femoral artery. Auvrey has studied the results furnished by this new method of hemostasis; it constitutes a method of obtaining perfect hemostasis in the regions situated below the umbilicus. The accidents that may result from this application result from the action of the pressure of the elastic band on the circulation and secondarily on the heart. Very important modifications have been observed which must be considered as due to blood tension, at the moment of the putting in place of the elastic tube and of the removal of the elastic compression. There have been noted also passing nervous phenomena and passing paralysis of the bladder and rectum. The method of Mombourg should be applied with extreme caution; should be an exceptional procedure and not a matter of choice; it should be applied only in young subjects in whom the cardiovascular and respiratory apparatus are absolutely healthy. Morestin said he had employed this procedure once, and although hemostasis was perfect, cardiovascular troubles showed themselves at once which placed life in peril.

Guelpa made an interesting communication before the Medical Society of Paris on the treatment of the organism by general disintoxication. According to him the organism is constantly subject to intoxications due to the food, and to combat these toxins he proposes the following treatment: for two to four consecutive days he orders the patient a complete fast, permitting him to drink water at will. At the same time he takes care to order during the fast a free saline purgation. Under its influence and contrary to what would have been expected, the sensation of hunger disappears, there is no malaise, and the fast is perfectly well borne. Guelpa believes that food plays a double rôle: it brings both nutritive materials necessary to life, and also, and above all, it has a mechanical action in the intestine, in virtue of which it stirs up the intestinal contents and brings with it all the toxic elements. He believes that the sensation of hunger does not result from the necessity which the organism is under of renewing its forces, but much more from the necessity of disinfection experienced by the organism, which is brought about by the passage of the alimentary materials into the intestine. By the treatment which he proposes he succeeds in eliminating completely the waste of the organism and in clearing out the intestine, and the results that he obtains are very interesting. In diabetes, for example, he completely suppresses the sugar, and as a result of several periods of such treatment he cures the patient. In gout he has obtained remarkable results—the deformities of the articulations have disappeared, pains have gone, and tophi have been absorbed. Finally, in the general treatment of obesity or arthritism, Guelpa has obtained results worthy of attention; the body becomes more alert, the mind more clear, for it is to be remarked that under the influence of the disintoxication treatment the nervous system is relieved of toxins rapidly, and an intelligence more active and more markedly potent can be easily exercised and cerebral labor is well sustained and continued.

Hysterical Angina Pectoris.—Forchheimer says that in hysterical angina pectoris we find rudimentary and normal attacks. He has seen a house epidemic of hysterical angina, following the death of the father of the family; every one of the hysterical children had angina. As it is six years since the occurrence took place, and all of them have had no recurrence, it must have been of psychogenous origin.—*Illinois Medical Journal.*

Boston Medical and Surgical Journal, May 26, 1910.

The Cause of Gastroptosia and Enteroptosia, With Their Possible Importance as Causative Factors in the Rheumatoid Diseases.—J. E. Goldthwait and Lloyd T. Brown present an elaborate illustrated paper on this subject. They discuss the normal position of the stomach, normal position and character of the duodenum, effect of faulty posture on the position of the stomach, effect upon the duodenum of the downward displacement of the stomach, gastromesenteric ileus, effects of gastroptosia and enteroptosia upon the normal secretions of these organs with the systemic effects, the position of the pancreas and reasons for interference with its function, general results from all these conditions, congenital features in the etiology of gastroptosia and enteroptosia, type of the child with the visceral ptosis, general infections and treatment. They also refer to the importance of the cervical fascia in the visceral support. Of course, the various poses men tioned interfere with the normal course of the contents through the gastroenteric tract and as well with the proper discharge of secretions at the various points. It is in the ileum and the colon that the bacterial contents are chiefly found, and it is probable that under the conditions named they may develop in such quantities or reach such a degree of virulence that the individual becomes unable to resist and undesirable absorption takes place. Probably many cases of infectious arthritis occur in this way, and whether the bacterial element is in excess simply as the result of retention of fecal matter in the colon or whether as the result of interference with the functions of the viscera, the proper amount of digestive fluids, upon which the control of the development of the bacteria must to a considerable extent depend, is not present in the bowel, it is impossible to state. When such disturbances of normal chemical or bacteriological balance do exist it is apparently a matter of accident whether the systemic disturbance takes the form or arthritis, or some of the other structures become involved, and the frequency with which other lesions are met with in connection with the arthritis in the same individual becomes at once understandable. Of the arthritic conditions, the type in which there is the true peripheral inflammation, the infectious arthritis, and the type in which the peripheral inflammation is one of degeneration or atrophy, the atrophic arthritis, the infectious element probably acting centrally, are probably both to be explained in this way, and none of the cases seen since these visceral changes have been appreciated has failed to show its presence. The same is true of the hypertrophic form, in which for a long time the expression "disturbance of metabolism" has been used to suggest that some systemic disturbance other than bacterial is the causative factor. It seems probable that such a condition as here described may be the cause of the disturbance of the metabolism.

New York Medical Journal, May 28, 1910.

Animal Parasites Found in the Intestines of Native Children in the Philippine Islands.—Of fifty-one persons examined by I. W. Brewer, 47, or 92.2 per cent. were infected as follows: *Ascaris lumbricoides*, 38, or 76.4 per cent.; *Trichuris trichiura*, 26, or 51 per cent.; hookworm, 18, or 35.3 per cent.; cestodes, 3, or 5.9 per cent., and amebæ, 3, or 5.9 per cent. Of the children, 28 were males and 26 females. Physicians in the United States rarely consider animal parasites when treating children. Most of the test books on diseases of children, which are largely based upon hospital statistics derived from institutions in large cities, speak lightly of the animal parasites. However, during the past decade we have learned that the hookworm is of the greatest importance in the pathology of the Southern States, and it is very probable that if the feces of children in small towns and the rural communities are examined we will find that other parasites are much more common than is generally believed.

The Influence of Alcohol on Trauma.—F. S. Dennis says that there are three cardinal symptoms which should be considered in every case of alcoholism associated with trauma. These are tremor, insomnia, and delirium, with no fever disturbance, and he calls special attention to delirium tremens occurring as a sequel to trauma. This treatment calls for elimination of the toxemia, enforcement of sleep, administration of cardiac stimulants, maintenance of nutrition, alleviation of gastritis, necessity of restraint, attention to atony of the bladder, and cleansing of the oral and nasal cavities. For insomnia, the potassium bromide in 20-grain doses, with 1/100 grain of hyocine repeated hypodermically p.r.n. seems to give the best

results. Paraldehyde is a most important adjuvant. Strychnine is one of the best remedies to counteract the cardiac depression. It may not be advisable to cut off whiskey immediately. During the onset and attack of delirium tremens is not the time to reform the patient. Alleviation of gastritis may be effected by washing out the stomach with a 3 per cent. solution of boric acid in hot water, to which a dram of sodium bicarbonate is added. If this is not practicable, ten-grain doses of pancreatin combined with twenty of bicarbonate of soda or cerium with soda are beneficial. Finally, the prophylactic treatment is recommended in all cases of trauma in patients addicted to drink to avert the distressing and long continued sequelæ of alcoholism, to prevent an outbreak of delirium tremens, to ward off the condition known as wet brain, to reduce the tendency to insanity, and to lessen the mortality. The removal of any and of all of these conditions is a reason for urging the prophylactic treatment in these cases of trauma in which there is associated an alcoholic history. The necessity of these prophylactic measures becomes apparent when it is considered that more than 50 per cent. of the patients with trauma recently admitted to my hospital service have been shown to be addicted to alcohol, and that delirium tremens, with all the unpleasant sequelæ, is likely to develop in these cases, and in some cases with a fatal result.

Modern Methods in Pancreatic Diagnosis.—W. G. Lyle gives his experience in the clinical laboratory of one of the New York hospitals. He mentions a set of cases in which undoubted pancreatic disease has been marked by no loss of fat. The foods may have contained abnormally small amounts of fat, this substance having become distasteful to the patient or the fat ingested may have been of a kind readily absorbed as milk, or possible there has been an increase in the activity of the stomach lipase, in all which cases this condition occurred early in the disease. Friedman has lately demonstrated the presence of a strongly active autohemolysin in the pancreatic juice, which is analagous to serum hemolysin. When this enters the circulation through tissue destruction it brings about the same results as other hemolytic substances. This body is activated by human blood serum. The author recommends in all cases of suspected pancreatic disease that oil be given and trypsin tested for in the stomach contents with the casein method of Cross. Regarding the Cammidge reaction, the author says that at present a great difference of opinion exists among clinicians regarding the value of this test. Schum has investigated it from the chemical side and reports unfavorably. The reaction is found positive in other diseases, such as tuberculosis, etc., where the pancreas is not involved. It is possible that this may be due to a functional disturbance in the pancreatic secretion, effecting sugar metabolism, without any definite, anatomical lesions in the gland itself. Brugsch states that a small carcinoma will produce a greater interference in the activities of this gland than a much larger nonmalignant growth. This was demonstrated in one of our recent cases, in which there was a very small carcinoma, but a large loss of fat in the stools. If it can be proved that the Cammidge reaction may be produced by a disturbance of the internal secretion of the pancreas, without corresponding anatomical changes, then its value as a diagnostic help in determining diseased conditions is very much lessened, especially from a surgical standpoint. Moreover, as long as it is uncertain what substance causes the reaction too much reliance cannot be put on a positive result, unless confirmed by other tests. However, it should be tried in all suspected cases.

Journal of the American Medical Association, May 28, 1910.

Pancreatitis.—A. J. Ochsner insists on the importance of this condition. The infection undoubtedly passes into the gall bladder, also through the common duct, and then there is a chance for it to be diverted into the pancreatic duct, especially if there is obstruction from gallstones or edema below the point at which the duct of Wirsung enters the common duct. In his cases, the irritation of the common duct has been due quite as often to the passage of infected sandy bile as to the presence of gallstones. The difference in the statistics as to the frequence of pancreatitis accompanying gallstones is probably due, he thinks, to the observers basing the diagnosis on their judgment of the enlargement of the gland. What might seem pathological to one, might seem normal to another. All surgeons with large experience in this line seem to agree that pancreatitis patients almost always suffer from gallstone disease, especially if the gallstones lodge in the common duct. The colon bacillus is the most common cause of the infection, though frequently associated with the streptococcus and staphylococcus according to Egdahl and others. The pancreas once infected, a vicious circle is developed by the swollen organ obstructing the common duct passing through it, thus favoring the development of microorganisms above this point and also backing them up into the pancreas. This is the cause of the benefit derived from free drainage by cholecystostomy. All these facts seem to show that the accepted theory that, barring the rare occurrence of metastatic infection, pancreatitis is due to infection from the alimentary tract through the biliary passages or, according to Maugaret, through the lymphatics of these passages. In violent acute cases destroying the gland parenchyma, the cause is the retrograde injection of virulently infected bile and pancreatic juice. In the chronic forms, on the other hand, the secreting cells of the acini are more readily destroyed than the islands of Langerhans. The diagnosis has until recently been made only incidentally during operation, but latterly more attention has been given to this point and the diagnosis is made before and confirmed by the operation. The Cammidge reaction seems to Ochsner, from his own researches, to require too much of the observer to be useful except in expert hands, but he believes it to be of value. If we add to the symptoms of cholecystitis an area of tenderness, from 5 to 10 cm. long, to the right of the umbilicus over the middle of the right rectus abdominus muscle and can exclude duodenal ulcer we have the typical symtoms on which to base the diagnosis. There are cases, of course, in which both these conditions are present, but in these it is possible to determine the necessity of an exploratory incision and, if the indications for this are not clear, then it is usually safe to keep the patient under dietetic treatment for further studies. In advanced cases there is usually marked emaciation and anemia, frequently with peculiar roll-like areas of fat on the front and sides of the chest and abdomen. In chronic pancreatitis the treatment consists primarily in establishing free drainage and removing concretions, keeping the bowels and stomach normal by proper diet and hygiene. Early operation greatly improves the prognosis, though in mild cases of acute pancreatitis surgical treatment is not indicated. If the local irritation is removed by gastric lavage and exclusive rectal alimentation the obstruction to drainage through the common duct will generally soon subside, and the conditions will be favorable for recovery. Simple drainage of the gall bladder has in his experience always relieved the condition during the attack, except in cases in which a severe cholangitis coexisted, in which case there has been a mortality of about 20 per cent. The operation should be as simple as possible and without rough or unnecessary handling of the tissues. Even in violent acute cases a proportion of patients will recover if the abdomen is quickly opened and simple drainage introduced. Patients in whom the extravasation of pancreatic juice has caused fat necrosis are least likely to recover. Jaundice lacking, it is best to limit the operation to localized areas of infection or necrosis, controlling hemorrhage by fine catgut sutures and having free drainage of the entire area. With jaundice, simple drainage of the gall-bladder, removing loose gallstones is indicated. Stones impacted in the duct are best left alone.

Treponema Pallidum.—F. B. Gurd advocates the "India ink method" as the most valuable method of finding the spirochete for the general practitioner. The technic is simplicity itself. Scrapings from the superficial necrotic layer of an ulcerating surface, or the superficial epithelium of an abdominal lesion are taken and the serum which exudes is placed on a slide and an equal amount of ink added. The ordinary commercial India inks are usable. The serum and ink are then thoroughly mixed and smeared over the slide so that a pale brown color results. The material dries in a minute or slightly more and is ready for examination on placing the oil for immersion directly on the smear. The spirochetes, if present, show as clear white spirals, the red blood cells as clear circular areas, and bacteria and debris as clear white rods and dots. It is important that serum with a minimum amount of mucous material or fibrin is used, as otherwise the mucus, etc., would take up too much of the color material of the ink. If too much serum is used the albuminous matter seems to precipitate the stain and a granular appearance is produced which is worthless for diagnosis. If too much ink is used the smear is too large and more time is required to examine it. It is perhaps not possible yet to speak definitely of the reliability of this method, but in every case it seems to have demonstrated the organisms when present with a minimum expenditure of labor and time. Practically only two or perhaps four organisms need considering in the differential diagnosis, and only the *Spirochæta refringens* in lesions elsewhere than in the mouth and intestines. This organism is especially easy to identify by

this method, from its coarse body and broad curves. In the mouth the *Spirochæta dentium*, the *Sp. buccalis* and the spirillum of Vincent may be found. The presence of the latter with the fusiform bacillus and the larger size and smaller number of its curves renders confusion almost impossible. The *Sp. buccalis* is also easily distinguished from the treponema with its short deep curves. The *Sp. dentium* is more likely to lead to error. Its body is finer than the other forms and the curves shorter and more close together. Its body is, however, always definitely thicker than the treponema and one never finds more than five turns in the diameter of a red blood cell, nor are the extremities drawn out like those of the treponema. A useful point in diagnosis is noticed by Coles, *i. e.* that if the number of turns in a spiral of a syphilitic spirochete in the diameter of a red blood cell are counted these will be found to be six or seven. The motion of the live organism as shown in the dark field is also important for the absolute diagnosis. Instead of moving actively like the saprophytic spirilla, the treponema sways one way and another, with also a rotary motion, never moving much from one place.

Poliomyelitis.—S. Flexner and P. A. Lewis publish their seventh note on experimental poliomyelitis in monkeys. Using a virus which by repeated cultures had obtained its maximum potency they have endeavored to produce active immunity in monkeys and in some cases have succeeded. They failed, however, to produce a neutralizing serum in the horse by repeated injections of the filtrate, but the blood serum of children who had recovered from poliomyelitis has at least delayed, if not altogether prevented the development of poliomyelitis in inoculated monkeys. The serum of recovered monkeys also neutralized the virus *in vitro*. The indications from their experiments are stated as follows: (1) If the quantity of virus injected into the brain eighteen to twenty-four hours before the serum treatment is begun is not in excess of a given dose, the action of the virus can be prevented; (2) the infection of meninges from the nasal mucosa can also be prevented by the serum injections; (3) normal monkey serum has no such effect; (4) the horse serum is entirely without preventive action and tends rather to hasten the onset of paralysis. In the case of the intranasal inoculations, the injections of serum were made immediately after infection and at three days' intervals for three injections. The control animal treated with horse serum succumbed, and the animal treated with immune serum survived. Experiments are in progress to determine whether the paralysis, after intracerebral inoculation, can be prevented by immune human serum and what the limits of the experimental disease by such sera are. In considering the significance of these results for human pathology, account should be taken of the fact that experimental poliomyelitis in monkeys is a far more severe and fatal disease than epidemic poliomyelitis in human beings. Since the virus of poliomyelitis can reach the nervous system through the abraded mucous membrane of the nose, the authors have tested the effects on the virus of hydrogen peroxid and some other disinfectants. The virus is quickly destroyed by a solution of perhydrol containing 1 per cent. of hydrogen peroxid. It should be stated, the authors say, that the immune serum, obtained from the monkeys that had recovered from the paralysis, had in every instance been subjected to reinforcement by subsequent inoculations, often of large doses of active virus. Whether any actual reinforcement was accomplished is still undecided, but from analogy it should have taken place. This point is under examination.

The Lancet, May 21, 1910.

Injections of Solutions of Radium.—L. Wickham and M. Degrais allude to a paper presented at the Lisbon Congress by several French authors, the conclusions of which are as follows: "When introduced into the animal body the emanation diffuses itself through the structures and may in this manner reach deep-seated parts. It has a predilection for the glands which form an internal secretion and especially for the suprarenal capsules. It is eliminated by the lungs and the skin, and to a small extent by the kidneys." The authors then pass on to relate their own experience with this mode of therapy. In a case of lupus vulgaris of the neck, a curative change was produced by injections of (1) water rendered radioactive in the proportion of one milligram of pure sulphate of radium per liter, or (2) water impregnated with radium in the proportion of one milligram of pure bromide of radium per liter. In this case 40 injections of each kind and of from 1 to 2 c.c. were given in the course of two months. They have also presented a case of lupus erythematosus treating for comparison, the lesions on the left side by the application of the radium apparatus and those on the right side by injections. On the left side there was a sharp reaction with destruction of the lupus and a subsequent process of repair. Later there seemed to be a strong cicatrix, but still later there was recurrence of the lesion at the margin of the tissues of repair. On the right side there was no visible inflammatory reaction, but there was first a diminution and then a disappearance of the erythema of the lupus, the part assuming a whitish cicatricial aspect. At the time the recurrence was found on the left side, the recovery on the right side was maintained and there has been no reappearance of lupus there since that time. In these two cases the doses of radium were extremely small, but they contained the emanation, an element which is not present in the rays emitted by the radium apparatus. The injection of certain insoluble salts of radium suspended in an emulsion, into structures of small absorbent power prolongs the contact of the salt with the diseased tissues and intensifies the action of the radiations and of the emanation. This plan was followed in treating a large cancerous nodule of the breast, an emulsion of radium being made in a mixture of paraffin and vaseline. The object was to inject this preparation beneath the nodule, so as to prepare a stratum underlying the whole of the diseased part. Thus the nodule was exposed to a cross fire, as it were, diminished in size and rapidly disappeared. There was no ulceration and there has been no recurrence. Injections of gray oil with mercury and a radium salt have been made in syphilitics, and in three or four days the urine was radioactive, after which time it gradually decreased in this respect. It must be understood that soluble radium when injected is in a free state in the animal body and carries with it gaseous emanations which give rise to the phenomenon of radioactivity. The salt in a radium apparatus does not supply emanation for therapeutic purposes, for this gas does not pass through any solid body, being in this respect unlike the extremely penetrating radium rays. When, after some days the mercury begins to show itself in the urine, the latter no longer shows radioactivity. The authors believe that these experiments offer much hope for the future.

Treatment of Spasmodic Asthma by Hypodermic Injection of Adrenalin.—Three cases are given by B. Melland. He says that when we reflect it is easy to see why the blood vessels and circular fibers of the bronchial tubes and intestines should be supplied by opposing nerves. Take the gut for instance, when full of food and active in peristalsis. The motor nerve for this peristalsis is the vagus, which works reflexly. When digestion is taking place it will be an advantage to have all the blood vessels relaxed to promote local blood supply. Therefore, while the vagus is stimulated the vasomotor sympathetic is inhibited and thus the small vessels dilate. If an irritant gas accumulates in the bronchial tubes or some irritant substance, the irritation of the vagus sensory fibers causes the motor reflex spasm of the circular bronchiole muscles tending to keep out further irritants. This vigorous action of the vagus inhibits the sympathetic vosaconstrictor nerves and the bronchial mucosa becomes congested through dilatation of its blood vessels. This free blood supply will both help the production of mucus by the mucous glands and assist the closing of the smaller bronchi and thus protect the alveoli from entrance of the irritant. The effect of violent emotion in removing an attack of asthma is well known, and the author has no doubt it is due simply to sudden violent stimulation of the sympathetic overcoming the vagus. If one suddenly meets a lion in the path the heart gives a bound and is immediately vastly accelerated: the skin blanches, a cold sweat breaks out, and "each individual hair stands on end"; the pupils dilate, eyes widen and stand out, and the blood pressure rises rapidly, as a good high blood pressure is useful to the organs of locomotion in these circumstances. All these signs, which are historical as those of fear, are exactly the same as those produced by stimulation of the sympathetic or injection of adrenalin. As we know also, in extreme fear the vagus and sciatic outflow are inhibited, peristalsis ceases, and the anal and vesical sphincters relax, as well as the cardiac sphincter of the stomach. Undoubtedly the whole vagus outflow is inhibited, including the bronchial muscles. The nervous system is far too busy to pay any motor attention to the efferent gut system when the efferent skin system and voluntary muscles and heart require so much more attention if life is to be saved from the lion. He has thought sometimes that a bad paroxysm of asthma might tend to cure itself by the downward pressure of the diaphragm actually pressing mechanically on the adrenal gland and stimulating it to get rid of adrenalin through the adrenal vein into the general blood stream.

British Medical Journal, May 21, 1910.

High Tension and Cavitation.—S. Tidey says that the idea that arthritic diathesis is antagonistic to the incidence of tuberculosis is more or less present in the minds of the profession. The term arthritic diathesis includes both gout, a disease of high tension and rheumatism, a disease of low tension. As opposing the theory mentioned he relates a case of high tension and pulmonary cavitation. His patient is a man of 53 years, with considerable cavities at both apices and with hemorrhages occurring very frequently. He has a somewhat high tension and the author presumes that the hemorrhages result from aneurysmal dilatation of arterioles in the walls of an old tuberculous cavity. Strapping of the chest has not helped, the nervous system has been kept quiet, the tension diminished with calomel and the coagulability of the blood increased with calcium chloride, yet the hemorrhages continue. The general condition has kept up surprisingly well. What, asks the author, is the rational treatment? Is it to plug the cavity with some non-irritant coagulable injection or to compress it by means of an artificially induced pneumothorax?

Achondroplasia.—O. Eichholz has recently seen seven cases of this rare disease. The diagnosis is easy in typical cases and most authors lay stress on the pug nose, but in three cases which the author has studied, this peculiarity was not present nor was there anything in the appearance of the head or face to suggest any abnormality. Nevertheless the great disproportion between the length of the four limbs as compared with the body (which was certainly small, as would be expected from imperfect ossification of the ribs and pelvic bones) the small stature, the characteristic appearance of the hands described as *main-en-trident,* the absence of rachitic changes, such as contracted chest, bow legs, curved spine, deformed ribs, etc., leave (the author thinks) no doubt of the nature of the disease in his cases. Dentition did not appear to have been delayed. This absence of depression at the root of the nose has been observed by other authorities. The skin is described as smooth and pliable, although it may be redundant over the extremities. In the author's cases the skin of the trunk and head was normal, but over the limbs it was unusually soft and doughy to the touch. The pelvis of one of the women patients was contracted, the conjugate diameter at the brim being (external) 6.5 cm., and there was a sharp angle between the lumbar and sacral vertebræ, giving the impression of a spondylolisthetic pelvis, though the author does not think this was the case. Lordosis is described as one of the characteristics of achondroplasia, but he says this is only apparent, the acetabula being displaced backward from shortening of the ileopectineal lines so that the femora are attached in a plane posterior to that of the normal individual.

Cultural Characteristics of the Microbacillus of Acne.—E. H. Molesworth reviews the literature published along this line, and then passes on to describe his own work on the subject, a series of primary cultures from over 30 cases. The materials used for inoculation were generally comedones, sometimes seborrheic filaments and pus. He believes that the organisms heretofore described by Fleming and Sabouraud are not identical. The author discredits Fleming's findings, as his organism does not reproduce the comedones. This and not suppuration is the essential lesion of acne vulgaris. Treatment with vaccines of Fleming's organism apparently caused increase of the amount of pustulation, but no mention is made by Fleming of the disappearance of comedones. As to the cause of the pustulation, Molesworth says that in only one instance did he fail to find staphylococci in culture from pus, although Sabouraud occasionally found them absent. Macrobacilli can be easily cultivated from pus, but there is always a great amount of comedone debris in this material. The secret of success in cultivating the macrobacillus is in the use of anaerobic methods. He is inclined to give this microorganism credit for being the real cause of the disease. Many interesting details of his experiments cannot be related here.

Does Gastrostaxis Exist as an Independent Disease?—C. Bolton does not believe that the affirmative answer to this question has as yet been indisputably proven. In this malady there is said to be an oozing of the blood in the mucous membrane of the stomach, not only in the absence of any ulceration of that organ, but also in the absence of any other disease in which bleeding is likely to occur. The evidence that it exists is threefold: first, that at certain post-mortem examinations of patients who have died of hematemesis no lesion has been found in the stomach wall to account for the bleeding; second, that at certain operations performed upon such patients no ulcer has been found; and, third, that gastrostaxis possesses a definite clinical history. Hemorrhage from the gastric mucosa is due to one of two conditions. First, if it is profuse enough to kill the patient it is quite common to find at the autopsy multiple erosions of the mucosa. Second, if it be not profuse enough to cause death, at post-mortem following the death from the primary disease, the condition is one of multiple small or large interstitial hemorrhages into the mucosa, with perhaps a little coffee-ground fluid in the cavity of the organ. These bleedings during life cause no symptoms. In both forms there is a constant lesion in the walls of the vessels. In a second group of cases the hemorrhage is a secondary event from ulceration, opening up a large blood vessel. The terms "ulcer" and "erosion" express quantitative and not qualitative differences. The author says that he thinks it will be granted that serious hemorrhage will not occur from an erosion, so that if a patient dies from gastric hemorrhage any lesions which may be subsequently found in the mucosa and which are microscopically proved to be erosions, must be a result of the hemorrhage, which is therefore the primary condition. The author reports a number of illustrative cases.

Berliner klinische Wochenschrift, May 9, 1910.

Large Nongranular Mononuclear Cells in Myelogenous Leukemia.—N. v. Jagic and P. Neukirch report the finding in a case of chronic myelogenous leukemia which had received *x*-ray treatment, besides the typical inveloblasts of large nongranular mononuclear leucocytes which do not correspond to myeloblasts. In these cases there occurred in the blood after increased radiation, increased numbers not only of nongranulated cells, but a great number of cells which, by the triacid and Romanowsky stains, showed distinct granules, and still showed a negative or very weak oxydase reaction. They consider the loss of the oxydase reaction to be a functional injury to the granular cells. As the injury increases a complete loss of granules occurs. The observation of their cases makes it appear that there is a definite relationship between *x*-ray treatment and the granulation. A control of the blood picture and oxydase reaction is to be recommended during the course of the *x*-ray treatment in order to prevent over treatment.

The Destruction of Tubercle Bacilli in a Flowing Stream.—F. Jessen and Lydia Rabinowitsch have analyzed the water from the stream flowing through Davos as to the presence of tubercle bacilli. The main sewer of the city contains the excreta from many thousands of cases of tuberculosis, these, except among the few in the sanatoria being as a rule not disinfected. Water taken at the mouth of the sewer showed acid-fast bacilli, as did that taken 100 yards below. Water, on the other hand, from Frauenkirch, about two miles down stream, showed no organisms. Inoculation of guinea-pigs with the centrifugated sediment from water from the mouth of the sewer produced tuberculosis in the animals. Inoculation with the sediment from water at Frauenkirch and towns lower down did not affect the animals. The authors conclude that two miles of a flowing stream is sufficient to kill the tubercle bacillus.

Deutsche medizinische Wochenschrift, May 5, 1910.

The Polymorphism of Visceral Syphilis.—J. Kretschmer reports a number of cases of syphilitic lesions of the abdominal viscera showing widely different symptoms. He says that in indefinite and atypical diseases of the abdominal organs, especially when there are signs of involvement of several organs at one time, one should always consider syphilis as a possible etiological factor. The diagnosis of visceral lues is, however, to be made when not only the history of the case and the Wassermann reaction point toward this condition, but also when the clinical symptoms on careful and painstaking study can be explained on no other theory.

A Case of Traumatic Insufficiency of the Kidneys.—Wilhelm Beuster reports a case of a man, aged thirty, who was injured in a collision. That night he was restless and groaned in his sleep, but the next day seemed well and returned to work. Two days later he developed convulsions. On the fifth day he was unconscious and had chronic convulsions. There was suppression of urine with granular and hyaline casts in the little obtained. The patient died in uremia seven days after the accident. The history gave no clue to any previous nephritis or to an acute infection, and the author thinks it probable therefore that the acute nephritis was due to a subcutaneous injury to the kidneys.

Book Reviews.

International Clinics. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles by Leading Members of the Medical Profession Throughout the World. Edited by Henry L. Cattell, A. M., M. D., Philadelphia, U. S. A. Vol. I., Twentieth Series, 1910. Philadelphia and London: J. B. Lippincott Company, 1910.

The latest volume of this well-known quarterly contains three special articles on the serum diagnosis of syphilis by Homer F. Swift, Hideyo Noguchi, and B. Sachs, the latter dealing with the parasyphilitic affections of the nervous system. Two articles on pellagra by Drs. Watson and King follow. Dr. Gideon Wells contributes a most instructive review of our knowledge of purin metabolism and its relation to gout. Emil Beck writes on the use of bismuth paste in chronic suppuration. Halstead reports a case of tuberculosis of the thyroid gland. Numerous other articles with a review of the progress of medicine in the year 1909 enhance the value of this volume.

Lehrbuch der spezifischen Diagnostik und Therapie der Tuberkulose. Für Aerzte und Studierende. Von Dr. Bandelier, Oberarzt der Weicker'schen Lungenheilanstalten in Gorbersdorf, und Dr. Roepke, Dirigierendem Arzte der Eisenbahnheilstätte in Melsungen. 4. Erweiterte und verbesserte Auflage. Mit einem Vorwort von Wirkl, Geh. Rat Prof. Dr. R. Koch, Exzellenz. Mit 19 Temperaturkurven auf 5 Lithographischen Tafeln, 1 farb. lith. Tafel und 4 Textabbildungen. Würzburg: Curt Kabitsch, 1910.

Little need be said in praise of a book which has gone through four editions within two years, though its subject matter is of a very special nature. This is what has happened to the treatise of Bandelier and Roepke; in addition it has been translated into seven foreign languages. The book contains all that can now be said in regard to the diagnostic and therapeutic use of tuberculin. Every preparation of this nature from old tuberculin of Koch to the latest serum is fully described. Full details of treatment with many illustrative charts are given. A sober judgment of the value of the cutaneous and conjunctival tests for tuberculosis is pronounced by the authors. The book is the most complete in its field, and the new edition is recommended to all interested in the subject.

A Quiz Book of Nursing. For Teachers and Students. By Amy Elizabeth Pope, Superintendent Insular School of Nursing, San Juan, Porto Rico, Joint-Author of "Practical Nursing" and "Essentials of Dietetics" and Thirza A. Pope, Supervisor of Visiting Nurses of the New York A. I. C. P. Together with Chapters on Visiting Nursing by Margaret A. Bewley, R. N., Instructor in Visiting and District Nursing in the Presbyterian Hospital, New York City. Hospital Planning, Construction, and Equipment. By Bertrand E. Taylor, A. A. I. A., and Hospital Book-keeping and Statistics. By Frederic B. Morlok, Chief Clerk in the Presbyterian Hospital, New York City. With Diagrams. New York and London: G. P. Putnam's Sons, 1909.

This book is arranged in the form of a catechism, consisting of short questions each of which is followed by an answer which is supposed to be satisfactory. There are said to be some thousand questions on nursing in general, including the ward, general care of the patients, symptoms, temperature, pulse and respiration, treatments, medicines, surgical nursing, emergencies, obstetrics, care of children, diseases, and special senior quizzes. About fifty questions are given to hygiene, and the same number to bacteriology; three hundred and fifty to anatomy and physiology; two hundred and fifty to dietetics; and one hundred and fifty to materia medica. There are also special chapters on visiting nursing, hospital planning, construction, and equipment, and hospital book-keeping and statistics. It is difficult to see what purpose these last two chapters are intended to serve. Certainly no one would want to add these subjects to the nurses' curriculum, which already contains a fair share of non-essentials. The answers are, as a whole, satisfactory, the best being those on nursing in general. Some of the answers to the anatomy questions are inadequate: In answer to the question, "Name the muscles of the tongue," two only are given; on the same page, to "State the origin and insertion of the pectoral muscles," the answer is "They have their origin in the sternum and are inserted in the humerus." Both of these questions might be omitted. On page 242 it is inferred that the brachial artery is the continuation of the subclavian; the kidneys are said to be located between the first and fifth lumbar vertebræ. "Entroclysis" occurs four times; amyl "nitrate," four or five times. The book is intended for nurses who teach and those who are studying under them; judiciously used, it should be of service to some members of these two classes.

Outlines of Bacteriology. (Technical and Agricultural.) By David Ellis, Ph.D. (Marburg), D.Sc. (London), F.R.S.E., Lecturer in Bacteriology and Botany to the Glasgow and West of Scotland Technical College, Glasgow. London, New York, Bombay and Calcutta: Longmans, Green & Co., 1909.

This work will serve very well as an introduction to bacteriology in general. It differs in several respects from the majority of books on the subject. First, it is quite elementary; next, it omits almost all technical details; its reference to pathogenic bacteria is of the very briefest; and it contains much matter which the ordinary works on bacteriology either omit, or treat in a perfunctory way. Thus, there are valuable chapters on: bacteria and the preservation of food-products; The nitrogen bacteria; nitrification and dentrification; fermentation; industrial applications of fermentative processes; and sewage and sewage disposal. As a first book, or as a companion to any text-book this volume will serve a useful purpose; and there are few physicians who will not enjoy reading the volume. There is a very well arranged table of contents which makes reference easy and satisfactory.

Clinical Obstetrics. By Robert Jardine, M. D., Edin., M.R.C.S. Eng., F.F.P. & S. Glas., F.R.S. Edin., Professor of Midwifery in St. Mungo's College; Physician to the Glasgow Maternity and Women's Hospital; Examiner in Midwifery to the Scotch Conjoint Board; Examiner in Midwifery to Victoria University, Manchester; Chairman of the Central Division of the Glasgow and West of Scotland Branch of the British Medical Association; Formerly Examiner in Midwifery to the University of Glasgow; Late President of the Glasgow Obstetrical and Gynecological Society, etc. With 108 Illustrations and four colored plates. Third Edition. New York: William Wood and Company, 1910.

As the title implies, this is a book on clinical obstetrics, and is somewhat of a departure from the ordinary text-book in that there is cited a very large number of interesting histories of cases, all of which are of great interest and teach something. The author reports a case of neuritis complicating pregnancy, the only one he has ever seen. What he states about pyelitis, acute yellow atrophy of the liver, eclampsia, epilepsy, status epilepticus, pubiotomy, etc., is all very interesting, instructive, and well worth reading. The fact that this book has reached its third edition shows its popularity. There are few books of this kind published, and it is a pleasure to be able to recommend this to the general practitioner, since it is so full of good points and very interesting case histories.

Examination of the Urine. A Manual for Students and Practitioners. By G. A. De Santas Saxe, M.D., Instructor in Genitourinary Surgery, New York Postgraduate Medical School and Hospital; Assistant Genitourinary Surgeon Bellevue Hospital, Out-patient Department; formerly Assistant Pathologist to the Columbus Hospital; Member of the American Urological Association; Fellow of the New York Academy of Medicine., etc. Second Edition, Revised. Philadelphia and London: W. B. Saunders Company, 1909.

The second edition of the book has been required by the advance in the science of urinary diagnosis during the past five years, and to meet this requirement, many chapters have been entirely rewritten. The book as it stands today is a full and concise exposition of uranalysis in its relationship to clinical medicine. Part I. includes the general consideration of the urine in health, selection of specimens, etc. Parts II. and III. cover the chemical and microscopical examination of the urine, including the various tests, and especially emphasized, the clinical significance. Part IV. takes up urinary diagnosis. Here the classification is by disease, and the abnormal findings of each are discussed. Part V. under the heading of functional renal diagnosis describes the estimation of the freezing point, electrical conductivity and the methylene blue, indigo carmine, phloridzin tests, and the toxicity of the urine. The book is well illustrated and well printed.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Sixty-first Annual Meeting, Held in St. Louis, Mo., June 6, 7, 8, 9 and 10, 1910.

(Special Report by Telegraph to the Medical Record.)

House of Delegates.

Monday, June 6—First Day.

Col. William C. Gorgas, President, in the Chair.

President's Address.—Col Wm C. Gorgas, U. S. A., after calling the meeting to order, delivered a brief address, in which he said that the work of the Association had gone on so well during the year, and so much more had been accomplished than was expected that there was little he could say. There was a question regarding the authority of the president to fill vacancies in the standing committees which the House of Delegates should settle. Everyone was greatly impressed with the executive side of the work of the American Medical Association, but there was danger of diffusing efforts too much, and they should consider the matter most carefully before taking up any new subjects. Most members were more interested in the scientific side of the work and this should be forced as much as possible. Antagonism aroused by the action of officials of the Association should not discourage them. The Association had great power in legislative committees and there was no more compact organization in the United States than the American Medical Association, and for that very reason they should be cautious and confine themselves to the advocacy of measures useful to the people and to the profession.

Report of the General Secretary.—Dr. George H. Simmons reported that the membership in the Association was 33,935, on May 1, 1909, on May 1, 1910, it was 34,176, an increase of 241. Membership in the State Societies was 70,146. Less than half of those entitled to membership in the Association, therefore, availed themselves of the privilege. The Medical Association of the Isthmian Canal Zone had applied to the American Medical Association for recognition and affiliation and the secretary recommended that it be recognized as one of the constituent societies of the Association. He also recommended uniform regulation of details regarding individual membership. Dr. Simmons asked that at the present meeting of the Association he be relieved of responsibilities of the office of General Secretary. This report was referred to the committee for action.

Report of the Board of Trustees.—Dr. M. L. Harris of Chicago reviewed various lines of work of the Association calling special attention to that of the Council on Pharmacy and Chemistry, which reported directly to the trustees and not to the entire House of Delegates, the amount of work done greatly exceeded that of any other year. The speaker outlined the work done in examination of meat extracts which had shown that they were practically devoid nutritive value. They had obtained reliable information in regard to various serums and vaccines. This work was receiving just recognition beyond the confines of this country, a number of European firms having taken active measures to have their products listed by the Council. They had examined practically all non-official articles on the market and those unlisted were deemed unworthy of consideration by profession. This work should have been done by Federal, State and Municipal authorities. The amount of work done in the chemical laboratory had increased so that it was impossible even to mention the products and compounds investigated. There had been appointed a multiplicity of committees whose duties overlapped, with consequent duplication of work and expense. Committees with similar duties should be centralized in a single bureau with a paid secretary. The new building authorized at the last meeting was under process of construction and would have been completed by October 1, had not certain complications prevented its completion. The medical profession was becoming more firmly united in a universal desire for the dissemination of a knowledge of scientific medicine, but in their endeavors they should guard most carefully against a tendency to dip into politics and pollute the honorable traditions of the profession. The weekly issue of the *Journal of the American Medical Association* averaged 55,361, an increase of 1,382 copies over that of 1908. Examination of the finances of the Association had been conducted along the lines of previous audits by chartered accountants who stated that the work of the office was conducted in an intelligent and accurate manner. There was an increase of surplus assets for the year of $41,867.

Report of Judicial Council.—Dr. C. E. Camtrell of Texas said this committee met, but had no report to make, as after a thorough study and discussion of the subject they had decided that ethical matters were more satisfactorily settled by the State and County societies.

Report of the Committee on Medical Legislation.—Dr. Charles A. L. Reed of Cincinnati said the energies of this committee had been devoted to national legislation. A bill for establishing a department of public health and for other purposes had been presented to the Senate by Robert L. Owens of Oklahoma. This bill was so in consonance with the traditional attitude of the Association that the committee had recommended no alternative measure. Since that time another bill had been introduced, differing from the Owen bill in that it did not provide for a representation in Cabinet, but placed the proposed department in charge of a commissioner of public health. Another bill had been brought forward which provided for dropping the words "and marine-hospital service" from "the public health and marine-hospital service", but without otherwise modifying the bureau under that name. Advanced legislation along public health lines had been urged by President Taft, and the people were aroused to the importance of the subject. The character of the opposition to the bill had impressed the public with the conviction that they must support the movement for their own protection against the rapacity of ignorant venal interests. He called attention to the principal laws that had been enacted in the Legislatures of the different States. The work of the Bureau of Medical Legislation had been continued and increased use was being made of the bureau by State Boards of Health, medical examining boards, officers of State societies, and the profession in general. The committee had secured copies of the health laws of various States which were collected with a view to publication in a special handbook. The classification of the Supreme Court decisions regarding medical practice acts had been practically completed, and the committee had now on hand about two hundred Supreme Court decisions classified and indexed, as well as references to various court reports. This would soon be issued in book form. The same work was going on regarding decisions of the Supreme Court interpreting public health laws. He presented a report of the Conference which the Committee on Medical Legislation had held with the Council on Medical Education in Chicago on March 2, 1910. The proceedings showed that they had by no means secured unanimity among their members as to fundamental principles underlying the regulation of the practice of medicine, and much study and careful discussion would be necessary before uniformity could be secured even on essential points. A committee had been appointed to draw up a bill to protect the public health and regulate the practice of medicine, and this was submitted to the House of Delegates for consideration and criticism. The committee had rep-

resented the American Medical Association in a conference on uniform State laws called by the National Civic Federation. The Civic Federation had undertaken to establish branches in each of the States as State Councils on uniformity in laws, and it was hoped that the efficiency of the work of this State commission on uniform laws would be increased. It was expected that cooperation of the Civic Federation and its branches would help in securing the passage of uniform laws on vital statistics, pure food and drugs, medical practice, and various other subjects in which the medical profession was interested. The committee had learned from experience that in National and State Legislative campaigns any effort to secure the adoption of desirable laws for protecting the public health must be preceded by a sampaign of publicity, of public education both of the people and of their representatives in the legislative assemblies. The committee urged that it be authorized to establish a press bureau for the education of public opinion on health topics and as a precedent measure for any legislative campaign. The time had passed when any fears that such a course would be regarded as undignified and unprofessional should deter. If the public was not enlightened by the medical profession it would be biased by quacks, and the manufacturers of adulterated food and drugs. Dr. Reed recommended that the bureau of legislation at Chicago be strengthened and its scope widened. The bureau ought to be in position to furnish State legislative committees with literature for information and guidance. The National Organization should not take any hand in the promotion of defeat of proposed legislation in any State, even if the State committees requested such cooperation. Uniformity in State legislation had been urged with respect to reciprocity in State licensure. Most States extended reciprocity only in the case of those who had obtained license by examination and declined to extend the same privilege in the case of those who had secured a license by registration at time the examination law went into effect. This was an injustice and an insult to reputable physicians. He objected to many of the State laws that excluded medical teachers from membership in State examining boards. Existing State medical laws were responsible for the propagation of sectarianism in medicine in that they failed to protect people against dangerous cults. Sects were recognized by separate boards or by mixed boards, thus recognizing various systems or methods of cure. If one sect was recognized why not another. The most that the law could do was to establish a common safe rational foundation for all persons or plans of cure. This foundation must consist in human anatomy, physiology, bacteriology, pathology, diagnosis, hygiene, sanitation, obstetrics, surgery, and such allied branches as might be essential to the comprehension of these subjects. Questions of remedies and cure might be left to the intelligence of one thus otherwise equipped. All cults standing on such a foundation might be considered safe. To defer the adoption of this rational basis was to defeat the object in view and to multiply cults and isms. A model practice act should take this into consideration. They must not only attain legislative victory but must guard it against reprisals.

Report of the Council on Medical Education.—Dr. Arthur Dean Bevan of Chicago reported that a second tour of inspection of medical colleges of the United States and Canada had been made during the year and additional data collected. After a careful study of this information and other data regarding the needs of medical education the committee had prepared an outline of "essentials of an acceptable medical college", which they presented. The data in regard to each college were grouped under ten headings and ratings were made according to Civil Service methods. They divided colleges into three classes: those which were acceptable, those which with certain definite improvements could be made acceptable, and those which were not acceptable. About one-half the medical schools were teaching medicine in an acceptable way. It was important that each State should have but one licensing board and that there should be but one portal of entry to the practice of medicine. The council believed that the coming American standard would be a four-year high school education, a year or two in a university laboratory of chemistry, physics, and biology, four years in a medical school, and a clinical year as interne in a hospital. The American standard would soon compare favorably with that of any country in the world. The total number of medical colleges in all other countries was 172, while in this country there were 138, of which 68 were acceptable, 37 needing certain improvements, and 33 not acceptable. As standards of colleges were raised those of State boards also improved. The standards in Illinois, Missouri, Tennessee, and Maryland were still far too low.

Report of Post-Graduate Work.—Dr. John H. Blackburn of Kentucky said that some of the societies had given up the post-graduate course of lectures because of the difficulty of getting regular attendance, but many others had taken up the course. In many societies they reported much larger attendance, due to interest in post-graduate work. One of the topics for discussion was "Pharmacology and Therapeutics." One society planned a meeting with the Pharmaceutical Society for discussion of the U. S. Pharmacopeian. A large number of letters received from secretaries of societies which had been following the coarse bore witness to the interest and enthusiasm of members in the course and its practical application to the needs of a large number of societies. In addition to the knowledge gained they were of service in bringing doctors together and in helping adjust small personal differences.

Committee on Ophthalmia Neonatorum.—Dr. F. Park Lewis of New York presented a digest of all legislation on this subject enacted in the various States. They had found that to succeed it was necessary to have the support of the public. They had secured the cooperation of the New York Association for the Blind, and the financial support of the Russell Sage Foundation. Most efficient agencies for promulgation of this propaganda had been the Federation of Women's Clubs, and the public health education committee. The National educational association would soon take up the work. The committee recommended that the work be continued and the scope widened to comprehend in the largest sense the prevention of blindness.

Committee on Davis Memorial.—Dr. Henry O. Marcy of Massachusetts stated that he had been unable to arouse interest in this deserving work of commemorating the services that Dr. Davis had rendered the profession and the people. The committee had as yet received only $2,771, although at the last meeting of the Association it had been voted to furnish $5,000 of a total of $25,000,

Council on Defense of Medical Research.—Dr. Walter B. Cannon of Massachusetts reported that during the year they had carried out the program suggested by their work of the first year, which consisted in furthering the adoption of rules in medical laboratories, the publication of papers, and the distribution of information regarding the work of the Council of data collected by it. Regulations concerning the care of animals in laboratories had been adopted by fifty-two schools, including all large institutions. They would probably soon be adopted in laboratories wherever animal experimentation was carried on. The collection of papers showing the relation between animal experimentation and practical medicine and surgery would form a unique collection of data never so thoroughly gathered together before. These papers were of permanent value. Much of the work of this council had

been given to the daily press for the education of the people.

Committee on Uniform Regulation of Membership.—Dr. Thomas McDavitt of Minnesota presented recommendations for amendments to the constitution and by-laws, among them one that provided that a proposed amendment be not acted upon until the annual session next following that at which the amendment was introduced, and providing three-fourths of the members of the house favored such amendment. Recommendations for uniform regulation of membership were offered, and it was suggested that the employment of paid county secretaries would result in better business methods and in a financial saving in the long run. The payment of secretaries would, of course, be optional with the individual societies.

Report of Committee on Anesthesia.—Dr. James G. Mumford of Massachusetts said they had investigated along four lines as to which anesthetic to use. G. W. Crile had studied nitrous oxide combined and not combined with morphine and found less nausea when it was not preceded by morphine. They had found that ethyl compounds were associated with a high death rate and that they were not serviceable for prolonged anesthesia. The results attained by experiments with nitrous oxide were essentially those set forth by Dr. Crile. As to the best anesthetic to use in military surgery and other extensive operations they could not report for at least two years. A definite distinction should be made between two classes of anesthetists. Ether by the drop method was best for general practitioner. The use of chloroform should be discouraged, and that of nitrous oxide should be confided only to experts.

Reports of the Committees on Nomenclature and Classification of Disease, Patents and Trademarks, Elaboration of Principles of Ethics, Revision of the Pharmacopeia, Selection of Insignia for the American Medical Association, and the Establishment of a Physicians' Sanatorium were also presented.

All reports were referred to special committees before acceptance.

Tuesday, June 7—Second Day.

Dr. Welch, President-elect, in the chair.

Report of Committee on Scientific Exhibits.—Dr. Frank B. Wynn of Indiana stated that the range of instructive exhibits had been widened beyond the museum type. It gave emphasis and illumination to following subjects: Clinical application of research work; practical value of thorough scientific work whether in laboratory or hospital; methods of newer medical teaching, progress of clinical work in hospitals and dispensaries; newer methods of dealing with tuberculosis and other hygienic and sanitary problems; the role of parks and playgrounds in conserving health; advantages of competent food and dairy inspection; desirability of local medical societies giving more attention to medical history. Twenty-five institutons were represented in the exhibit. It was recommended that $500 be appropriated for expenses and $300 for medals. These exhibits had proved their usefulness as an educational influence. They stimulated the growth of museums in colleges and hospitals and advanced standards in teaching. It was practical for the Association to inaugurate an educational force throughout country which would prepare this soil for public health work. The Association might undertake a standardization of public health methods. As to the best method to pursue, should the Association undertake a publicity campaign, public lectures accompanied by stereopticon views seemed to be most popular at present. Forensic presentations were open to the objection that they might not be judiciously conducted and might be sporadic; also many looked upon them as a scheme for the advertisement and personal advancement of certain physicians and this aroused jealousy. The utility of public health exhibits as a means of instructing the people had been demonstrated; they approved this plan, but the study of such exhibits showed that they were apt to be heterogeneous and wanting in systematic arrangement. Often data were unwarrantably sensational, terrifying, or misleading. They were cumbersome, the initial cost was great and the cost of maintenance was too heavy. They were practicable only for State health boards and for large cities. If the exhibits were of the traveling kind, their influence was only temporary; hygiene and sanitary reform should be religion of daily life. The Association should develop cheap, compact, yet complete exhibits relating to all problems of public health and comfort. They could thus standardize methods throughout the country. They could guard against erraticism and could seek to cooperate with existing forces working for public health. This committee was impressed with the feasibility of such a publicity campaign and asked for the appointment of a representative special committee to meet with this committee for a detailed consideration of such plan.

Report of Committee on Organization of Council on Public Health, Publicity, and Legislation.—This committee recommended the organization of such a council and asked that a committee be appointed to arrange for such council and to formulate rules of government.

Report of Committee on Sections and Section Work.—The committee approved the establishment of section on Genitourinary and Venereal diseases. The officers appointed for this section were: *President,* W. T. Belfield, Chicago; *Vice-President,* James Pedersen, New York; *Secretary,* Hugh H. Young, Baltimore.

Report of Reference Committee on Medical Education.—This committee congratulated the Council on Education on their work, but thought its ratings of colleges had been very lenient and that schools rated as first class should not be satisfied with their standard or think themselves perfect. They agreed with the council that these ratings should be made public and were willing to assume the responsibility of such action. They would continue to cooperate with other bodies interested in education but would insist upon the right of American Medical Association to establish its own standard in accordance with existing conditions in various localities.

Report of Reference Committee on Reports of Officers.—Dr. George W. Guthrie of Pennsylvania said that this committee approved the reports, and it offered an amendment to the by-laws giving the president authority to make appointments to vacancies that occurred in committees during the year. They concurred in opinion that the Medical Association of Isthmian Canal Zone be recognized as a constituent association. They expressed regret that general secretary wished to be relieved of his duties but thought that his request should be granted.

Report of Committee on Organization.—Dr. J. N. McCormack of Kentucky said that in his campaign he had been greately aided by the American Health League, especially by Mr. Irving Fischer, whose unselfish labors had been so effective. He referred to the Owen bill and said that few measures were so ably supported as this had been. It should be made plain to the public that this bill was for prevention and not for cure, and that it did not menace personal freedom. He recommended that the president appoint seven members as a committee to frame a bill for the next congress and that this committee invite the cooperation of other organizations having the same end in view.

GENERAL SESSIONS.

Tuesday, June 7—First Day.

The opening meeting was called to order by the president, Col. William C. Gorgas, U. S. A. The Rev. Charles S. Mills of St. Louis made the opening prayer.

Addresses of Welcome.—Dr. Henry Schwartz, president of the St. Louis Medical Society, after extending greetings, said that the physicians of St. Louis appreciated the help and encouragement that this meeting would give to the profession of the city and of the State of Missouri. They would derive great benefit from learning that they were an integral part of the American Medical Association, and that this organization was a mighty factor in enlightening the public, encouraging the pursuit of scientific medicine, and promoting legislative reform. They would be aroused to assume their share of work and to live up to that part of the constitution which gave as one of the objects of the Association "promotion of friendly intercourse among American physicians."

Dr. Herman E. Pearse of Kansas City, President of the Missouri State Medical Society, said he welcomed the American Medical Association for what it could do. It had promoted pure food laws, driven out quacks, abortionists, drug adulterators, and others who preyed on the misfortunes of humanity, and he welcomed them to a five days' fight in St. Louis and assured them that they would find elegant fighting all along the line.

Dr. W. G. Moore of St. Louis said the Association had in its outgoing and incoming presidents two of the greatest men in America and that the organization, judged by the standards of philanthropy and of the greatest good to the greatest number, was the greatest organization in the country. Somebody had said that the medical profession was a trust and had asked, "Do you want government by medical politicians?" The speaker answered, "We do by all means," and to the question, "Do you want health and hygiene under a medical bureau?" he had answered, "This is a consummation devoutly to be wished." If it was a trust it furnished proof that there was such a thing as a good trust. It was a trust 30 or 40 per cent. of whose earned increment went to charity. The results of its scientific work went to prince and pauper alike. It limited its own income constantly by diminishing ills to which flesh was heir. If it was a sin to belong to such a trust he gloried in the company of such sinners. They might differ on all other political questions but on questions of public health they should array themselves on side of righteousness and well doing. If in future political positions were held by medical men, the government should require that they were thoroughly qualified for the performance of their duties, but it should never make them pawns of political expediency. To remove them from office for political reasons would be unjust and unfair and the speaker gave warning that the American Medical Association would make a firm stand against such methods.

Hon. Herbert S. Hadley, Governor of Missouri, said that no other body of men could excite as great human interest as this. The usefulness of physicians was not limited to weakness and sickness but to existence itself. They had increased longevity as well as health and the enjoyment of life. If the practice of medicine was sometimes regarded by the laity as after all only a system of empiricism, then this was a most hopeful indication of progress. It showed that they were ever searching for something better. No one could ever witness the marvelous results of antitoxin in diphtheria without taking off his hat to the profession. A strange thing it was that great truths were, when understood, found to be so simple, and the only wonder was no one had known them sooner. He referred to work in preventive medicine as having raised the science of medicine in public esteem. He hoped government would soon awake to the error of spending millions on cattle and hogs and nothing on women and children. They had recently done much to raise the status of the Health Department in Missouri and now they had a bureau of vital statistics in operation. The State Board of Health should be more interested in raising the standard of medical education in the State. He had the privilege of making medical appointments and had made none without the recommendation of the State Board of Health. He had never received from any body such sane and practical help as he had from State Board of Health; this was especially true in the work of reforming prisons. The legal profession would do well to follow the example of the medical profession in ridding their ranks of unworthy men. The militant spirit shown in disposing of charlatans was most commendable.

Hon. Frederic H. Kreismann, Mayor of St. Louis, also welcomed the association.

Col. Gorgas then introduced the president-elect, Dr. Wm. H. Welch of Baltimore, who, he said, was already well known, known throughout Europe as well as this country for his scientific attainments, and known by profession for his sound advice on lines pertaining to their welfare as well as for attainments.

Address of President.—Dr. William H. Welch thanked the Association for the honor conferred upon him, an honor to which no one could be indifferent, and he assured his hearers that he held the office as both a privilege and an opportunity. In the recent death of Koch, humanity had sustained the loss of one of the greatest benefactors of the race, one who shared with Pasteur the honor of establishing the science of bacteriology. The world owed to him, not only the methods of investigation, but a most fruitful exploration of fields whose gates had been unlocked. He paid a tribute to the memory of the late president, Dr. Herbert Leslie Burrell of Boston and of Dr. W. B. Atkinson, who had been secretary of the American Medical Association for many years, and he lamented the loss of Dr. Howard T. Ricketts, who had won a place in the front rank of pathologists. In his death science had suffered a great loss. Dr. Welch welcomed the action of Senator Owen in presenting a bill for the establishment of a National Department of Health, and also the action of Congress in appropriating $50,000 with which to honor the men who had overcome yellow fever. A commission had been appointed to select a suitable location for the erection of this memorial and he hoped the effort would receive the grateful acknowledgement and endorsement of the Association. The move toward the erection of a monument in memory of the medical officers on both sides during the civil war should appeal to the profession throughout the country. He said his purpose was to outline the work of the Association in recent years.

Dr. Welch thought the earlier workers had been wise in selecting a representative form of government for the Association; it was well suited to the needs of the organization at the time of its adoption. The Association had grown and accomplished so much in recent years that they were in danger of forgetting what had been done before that time. The Association had been the great unifying force in this country, and had had the loyalty and services of the leaders of the profession. The fact that it had not accomplished more in earlier years was largely due to defect in the machinery of government. The improvement in government did not mark a break, but only an evolution toward better things. The plan adopted in 1901 had been proposed in 1887, but owing to defects in the system they had never been able to effect the changes. Dr. Davis, for whose memorial they were trying to raise $5,000, had originated the plan. They had been fortunate in securing the best men in the profession and allied fields for the working out of these plans. The Council of Chemistry and Pharmacy, supported by the Association, had done good work, and legitimate pharmacists appreciated its benefits. The work of the Council on Medical Education should be commended. Their conferences had been attended by leading educators of the country. The

object of their work was constructive, not critical. The results were of enormous consequence to the profession and to the community, for they were alike dependent upon the quality of the training in medical schools. They had secured a reduction in the number of unacceptable medical schools, an elevation of standard in others, better laboratories, and had impressed all with necessity of having hospitals under the control of the schools. There were four or five times as many physicians in proportion to the population as were necessary, and influences now tended to lessen the number somewhat. The speaker congratulated the city of St. Louis on the reorganization of Washington University.

The speaker said that the defense of medical research was a duty, not only to present, but to following generations. There was little hope of progress in scientific medicine without animal experimentation, it was the lever of advancement. Animal experimentation differed from other laboratory work and should never be undertaken without a serious purpose and a sense of responsibility. Antivivisectionists had an utterly hopeless undertaking in trying to convince the public that experimentation was valueless. Agitation should be welcomed as giving an opportunity for presenting conclusive evidence of its value to the public. The charges of wanton cruelty showed recklessness of statement and disregard of truth, and of the interests of science and humanity. He was convinced that animal experimentation, as practised, needed no legislative restrictions, and all that had been proposed subjected the experimenter to intolerable restrictions and annoyance. Such restriction had been detrimental in England, and they should exercise all vigilance in preventing it here. The question as to how far the American Medical Association should interest itself in legislation was one of considerable difficulty and was not yet solved. They should keep clear of politics in the ordinary conception of that term, and should undertake nothing except for the public welfare. As a rule, the Association should not interfere with State legislation. All legislation that it had thus far supported seemed right. He referred with approbation of the labors of Col. Gorgas, who had, with the help of the Army, achieved the greatest sanitary triumph of the age.

The bill of vital statistics had improved conditions in the registration area, and this work should move on as rapidly as possible. There was a most gratifying public sentiment in favor of a National Department of Health. Arguments in its favor were better than those which had been advanced for the establishment of a Department of Agriculture. The attack on the bill and on the Association was the work of patent medicine manufacturers, and was of such preposterous nature that there was no reason for taking concern about it. There should be no such thing as sectarianism in medicine. All good work was based on scientific knowledge and experience, and these should be required of those who wished to practise a knowledge of the human body and its diseases without which it would be unsafe and unfair to the public to permit men to practise. There was nothing in the principles of the Association to interfere with any method of healing, so long as the interests of the public health were not interfered with. A National Department of Health would have nothing to do with medical-practice acts; its purposes would be preventive, not curative. Thus far cults had concerned themselves only with curative functions, never with prevention. Dr. Welch emphasized the importance of keeping the scientific and educational functions of the Association always in the foreground. Thus it would be a force for advancing the well-being, happiness, and progress of the country, and would contribute a beneficent share to the working out of our national destiny.

SECTION IN MEDICINE.

Tuesday, June 7—First Day.

DR. GEORGE BLUMER OF NEW HAVEN, CONN., CHAIRMAN.

Experiences with the Duodenal Contents in Man.—Dr. MAX EINHORN of New York reported the results of some investigations which he had made by means of the duodenal pump. Among seven cases of achylia gastrica trypsin were absent twice, whereas steapsin and amylopsin were present. The disturbance of the pancreatic function in this affection explained why they frequently found intestinal troubles associated with it. Admixture of mucus to duodental contents occurred in two ways. It might be evenly and intimately mixed with the contents or it might appear at intervals in relatively clear contents of the duodenum. The latter pointed to the origin of the mucus from the duodenum, whereas its intimate mixture would point to an origin in either the pancreas or the bile passages. Occasionally one obtained on aspiration of the duodenal contents at first a clear or slightly amber-colored fluid, of alkaline reaction, and containing the pancreatic ferments. Usually after waiting a short time and after repeated aspirations a golden-yellow fluid appeared. This had no diagnostic significance. If, after waiting and repeated aspirating, only pancreatic juice, with no trace of bile, appeared, this might be of importance, particularly in cases of chronic jaundice. If bile was present in the duodenal contents a complete closure of the common bile duct could be excluded. If bile was entirely missing and pancreatic juice was present it pointed to a seat of obstruction above the common duct. Further work in this field would be productive of results of great value, not only for diagnosis, but for therapy.

Case of Diffuse Purulent Ventricle. Septal Myocarditis with Adams-Stokes Syndrome.—Drs. HARVEY G. BECK and WM. ROYAL STOKES of Baltimore said that purulent myocarditis had been described by various writers, but the medical literature contained few, if any, cases of this condition associated with the Adams-Stokes syndrome. Heart block occurring in infectious diseases had recently been described. After reviewing the pathology of purulent myocarditis, the clinical history of a case showing syncopal attacks with heart block was given. At autopsy the heart was enlarged and the coronary arteries showed extreme endarteritis, with thrombosis of the right coronary artery. Microscopical sections revealed diffuse purulent myocarditis practically limited to the interventricular septum. Serial sections of the bundle of His showed hemorrhages in the main bundle in the auriculoventricular groove, and branches in the right and left ventricles showed a fragmentation of the nuclei of muscle fibers and diffuse purulent infiltration.

Case of Heart Block with Alternation of Systolic and Diastolic Jugular Waves.—Dr. ISAAC IVAN LEMANN of New Orleans said that just as in ventricular weakness there was often an alternating arterial pulse, so in auricular weakness there might be alternation of strong and weak contractions. The case presented showed alteration of the *a*-wave in the jugular tracing. The influence of the auricular weakness was shown by an alternation of the systolic wave, due probably to alternation of tonicity of the auricular wall.

The Radical Cure of Malaria; Its Importance, and How It Is Attained.—Dr. SEARLE HARRIS of Mobile, Ala., said that malaria, though decreasing in severity and frequency, continued as one of the most prevalent diseases in many localities of the United States; in some places its mortality rate amounted to 25 per cent. of the total number of deaths. In this country in 1900 the number of deaths from malaria was 14,909. It should be remembered that malaria, as a complication of pregnancy and a number of diseases, and as a cause of arteriosclero-

sis and nephritis, was responsible for many deaths which were ascribed to other causes. It seemed, therefore, that these statistics did not overestimate the number of lives sacrificd to this easily preventable and curable disease. It had been estimated that malaria cost the nation from $80,000,000 to $100,000,000 annually. The unnecessary burden of malaria could be relieved simply by radically curing those suffering from the disease. Malaria could be entirely eradicated in one year in any community, without regard to the number of anophelines present, if every person having the disease would take quinine long enough to be completely cured. It was the man and not the mosquito that carried malaria through the winter, thus perpetuating the disease. The average physician did not regard malaria as a serious disease. He relieved the acute symptoms in a few days, and when the patient died of malaria he felt that the patient had neglected himself. It was in the most malarial regions that the disease was most lightly regarded. The seriousness of the disease and the importance of radical cure should be more emphasized. The complications which resulted from failure to cure were responsible for more deaths than the acute and pernicious forms. The most marked effect of malaria was seen upon the renal organs and vascular structures; consequently, in malarial regions the death rate was high, and the mortality from nephritis and various forms of paralysis was inordinately increased. There would be little chronic malaria if acute cases were cured, but there were to-dav probably two or three million persons in the United States who were harboring malarial parasites. All authorities agreed that quinine was almost a specific when treatment was begun early and continued long enough to eradicate the parasite from the system. The microscope was not always a criterion as to chronic malaria; undoubtedly the disease did exist without the presence of the parasites in the peripheral circulation. A campaign should be instituted at once against malaria. There should be a campaign of education begun with the medical profession, because physicians as a class did not appreciate the seriousness of malaria, or the ease with which it could be eliminated. The public should be educated by means of popular addresses, and literature on the subject should be placed in the hands of all living in malarial districts. Being infectious and contagious, this disease should be classed among the reportable diseases, and State and county boards of health should lead in the fight. Money spent in eradicating malaria would yield greater returns than that expended in any other form of philanthropy.

A Possible Differential Sign Between Cardiac Dilatation and Pericarditis with Effusion.—Dr. W. J. Calvert of Dallas, Texas, said that extreme dilatation of heart was often difficult or impossible to differentiate from large pericardial effusions. He described a possible differential sign. In large hearts the sternum was depressed, the entire liver was depressed, the right lobe of the liver was relatively elevated, the right lung was elevated and pushed outward and backward, thus giving a high position of the liver with a narrow band of lung-liver relative dullness. In pericarditis with effusion the liver was depressed, the right lung was pushed outward and backward more than upward, thus giving a low position of liver with a narrow band of lung-liver relative dullness. The size of the liver was of no material importance.

Wednesday, June 8—Second Day.

The morning session was devoted to a symposium on circulatory disorders in acute infections.

Oration in Medicine.—Dr. Richard C. Cabot of Boston delivered this address, which was entitled "A Study of Mistaken Diagnoses Based upon the Analysis of 1,000 Autopsies and a Comparison with the Clinical Findings." The speaker presented the following statistics:

Cardiovoscular System.—Mitral Stenosis: Total, 71 cases; correct diagnosis in 49 cases, or 69 per cent.; error of omission in 16 cases, or 22 per cent.; error of commission in 9 cases, or 9 per cent.

Aortic Stenosis.—Total, 31 cases; correct diagnosis in 19 cases, or 61 per cent.; error of omission in 11 cases, or 36 per cent.; error of commission in 1 case, or 3 per cent.

Aortic Regurgitation.—Total, 68 cases; correct diagnosis in 57 cases, or 84 per cent.; error of omission in 5 cases, or 7 per cent.; error of commission in 6 cases, or 9 per cent.

Chronic Myocarditis.—Total, 59 cases; correct diagnosis in 13 cases, or 22 per cent.; error of omission in 15 cases, or 26 per cent.; error of commission in 31 cases, or 52 per cent.

Arteriosclerosis.—Total, 220 cases; correct diagnosis in 131 cases, or 60 per cent.; error of omission in 77 cases, or 35 per cent.; error of commission in 12 cases, or 5 per cent.

Aneurysm.—Total, 23 cases; correct diagnosis in 12 cases, or 52 per cent.; error of omission in 10 cases, or 43 per cent.; error of commission in 1 case, or 5 per cent.

Cardiac Hypertrophy and Dilatation.—Total, 339 cases; correct diagnosis in 223 cases, or 66 per cent.; error of omission in 113 cases, or 33 per cent; error of commission in 3 cases, or 1 per cent.

Acute Endocarditis and Ulcerative Endocarditis.—Total, 59 cases; correct diagnosis in 23 cases, or 39 per cent.; error of omission in 32 cases, or 54 per cent.; error of commission in 4 cases, or 7 per cent.

Acute Pericarditis.—Total, 54 cases; correct diagnosis in 11 cases, or 20 per cent.; error of omission in 38 cases, or 70 per cent.; error of commission in 5 cases, or 10 per cent.

II. *Respiratory System.*—Lobar Pneumonia: Total, 157 cases; correct diagnosis in 116 cases, or 74 per cent.; error of omission in 23 cases, or 15 per cent.; error of commission in 18 cases, or 11 per cent.

Bronchopneumonia.—Total, 94 cases; correct diagnosis in 31 cases, or 33 per cent.; error of omission in 60 cases, or 64 per cent.; error of commission in 3 cases, or 3 per cent.

Phthisis (Active).—Total, 54 cases; correct diagnosis in 32 cases, or 59 per cent.; error of omission in 16 cases, or 30 per cent.; error of commission in 6 cases, or 11 per cent.

Miliary Tuberculosis.—Total, 54 cases; correct diagnosis in 28 cases, or 52 per cent.; error of omission in 20 cases, or 37 per cent.; error of commission in 6 cases, or 11 per cent.

III. *Urinary System.*—Acute Nephritis: total, 32 cases; correct diagnosis in 50 cases, or 16 per cent.; error of omission in 200 cases, or 62 per cent.; error of commission in 7 cases, or 22 per cent.

Chronic Glomerulonephritis.—Total, 72 cases; correct diagnosis in 53 cases, or 74 per cent.; error of omission in 9 cases, or 12 per cent.; error of commission in 10 cases, or 14 per cent.

Chronic Interstitial Nephritis.—Total, 50 cases; correct diagnosis in 25 cases or 50 per cent.; error of omission in 19 cases, or 38 per cent.; error of commission in 6 cases, or 12 per cent.

Amyloid Nephritis.—Total, 4 cases; correct diagnosis in 0 cases, or 0 per cent.; error of omission in 4 cases, or 100 per cent.; error of commission in 0 cases, or 0 per cent.

Renal Tuberculosis.—Total, 3 cases; correct diagnosis in 1 case; error of omission in 2 cases; error of commission in 0 cases.

Renal Neoplasm.—Total, 6 cases; correct diagnosis in 1 case; error of omission in 5 cases; error of commission in 0 cases.

IV. *Nervous System.*—Cerebral Hemorrhage: total, 51 cases; correct diagnosis in 34 cases, or 67 per cent.; error

of omission in 4 cases, or 7 per cent.; error of commission in 13 cases, or 26 per cent.

Cerebral Tumor.—Total 11 cases; correct diagnosis in 8 cases; error of omission in 2 cases; error of commission in 1 case.

Septic Meningitis.—Total 36 cases; correct diagnosis in 23 cases or 64 per cent.; error of omission in 8 cases, or 22 per cent.; error of commission in 5 cases, or 14 per cent.

Tuberculous Meningitis.—Total, 36 cases; correct diagnosis in 26 cases or 72 per cent.; error of omission in 5 cases, or 14 per cent.; error of commission in 5 cases, or 14 per cent.

V. *Digestive System.*—Gastric Cancer: total, 42 cases; correct diagnosis in 30 cases, or 72 per cent.; error of omission in 7 cases, or 17 per cent.; error of commission in 5 cases, or 11 per cent.

Peptic Ulcer (Gastric or Duodenal).—Total, 26 cases; correct diagnosis in 9 cases, or 35 per cent.; error of omission in 14 cases, or 54 per cent; error of commission in 3 cases, of 11 per cent.

Hepatic Cirrhosis.—Total, 31 cases; correct diagnosis in 19 cases, or 61 per cent.; error of omission in 9 cases, or 30 per cent.; error of commission in 3 cases, or 9 per cent.

VI. *Miscellaneous.*—Typhoid Fever: total, 60 cases; correct diagnosis in 53 cases, or 90 per cent.; error of omission in 2 cases, or 2 per cent.; error of commission in 5 cases, or 8 per cent.

Diabetes Mellitus.—Total, 20 cases; correct diagnosis in 18 cases, or 90 per cent.; error of omission in 0 cases, or 0 per cent.; error of commission in 2 cases, or 10 per cent.

General Septicemia.—Total, 157 cases; correct diagnosis in 20 cases, or 12 per cent.; error of omission in 134 cases, or 85 per cent.; error of commission in 3 cases, or 3 per cent.

The following were the speaker's summary and conclusions, based upon this extensive and painstaking investigation: (1) Never make a diagnosis of uremia in patient seen for the first time in acute illness characterized by coma or convulsions. Such diagnosis rarely turn out right. (2) Never make a diagnosis of ptomaine poisoning without definite chemical evidence; general peritonitis or tabetic crises is usually the correct diagnosis in such cases. (3) Make no diagnosis of hysteria, neurasthenia, or psychoneurosis in a patient whose symptoms began after the forty-fifth year; the correct diagnosis in such a case is likely to be arteriosclerosis, hyperthyroidism, dementia paralytica, or pernicious anemia. (4) Diagnoses of tertian malaria in patients whose symptoms have resisted quinine more than three days are almost invariably wrong. (5) Bronchial asthma beginning after the age of forty is usually spelled heart or kidney disease. (6) Epilepsy beginning after the age of forty is usually spelled dementia paralytica or cerebral arteriosclerosis. (7) Typical migraine is often a symptom of unrecognized brain tumor of chronic nephritis. (8) Most cases of bronchitis are tuberculosis, bronchopneumonia, or multiple bronchiectatic cavities. (9) Aside from the immediate results of acute infections, such as scarlet fever, diphtheria, tonsilitis, and pneumonia; acute nephritis usually turns out to be chronic. (10) Acute gastritis and gastralgia usually mean appendicitis, gallstones, or peptic ulcer. (11) Pus in or near the liver is often mistaken for a serous or purulent pleurisy, for it produces identical signs in the chest posteriorly. (12) An *x*-ray picture of the shin-bones may give the first hint of an active syphilitic process in the joints or internal viscera. (13) Systolic or presystolic murmurs heard best at the apex of a markedly enlarged heart rarely mean valve lesions. (14) Diastolic murmurs at the base of the heart afford very uncertain evidence of aortic disease unless there are characteristic jerkings in the peripheral arteries. (15) Myocarditis is a diagnosis which can never be made with any certainty. (16) Besides the direct evidence afforded by the history and physical and chemical examination, diagnosis profits much by taking account of certain familiar pathological chains or groups of items; given one or two members of a group it is often wise to act as if the others were present, provided, of course, that direct evidence in no way contradicts this assumption. (17) Cerebral localization applied to tumors, hemorrhages, and the like is still in its infancy. (18) The clinical diagnosis of so-called diseases of the blood is still the easiest and surest in medicine.

Magnesium Poisoning.—Dr. William F. Boos of Boston read a paper with this title, based upon a study of ten cases. He said that magnesium poisoning was probably more frequent than was generally supposed, the true cause of a given toxic condition remaining unknown in most cases. Two of his three personal cases were brought to notice merely through the discovery of a very high specific gravity of the urine (1070 and 1080 respectively). These two cases ended with recovery, the third with death. The speaker then discussed the seven cases found in the literature. In his three cases intoxication was undoubtedly caused by absorption of considerable quantities of magnesium sulphate from the gastrointestinal tract. He outlined his experimental work on the conditions governing absorption of Epsom salts from solution.

Certain Popular but Erroneous Notions Concerning Angina Pectoris.—Dr. James B. Herrick of Chicago said that several rather prevalent notions concerning true cardiovascular angina pectoris were erroneous. Among these were: that peripheral arteriosclerosis, cardiac hypertrophy and high blood pressure were always to be made out; that the symptom-complex in one who had an aneurysm or an aortic valvular lesion was not to be classed as a true angina; that the attacks were always few, brief, and occurred only after exertion; that death soon after the first attack was inevitable; that the disease was practically unknown in women; that pain radiating to the neck or arms was always present; that the patient during an attack was never unconscious; that he was always immobile and erect, sitting or standing; that eructations or vomiting during an attack argued conclusively against its cardiovascular origin; that nitrites were seldom if ever of benefit in relieving symptoms, or per contra that a case in which nitrites gave no relief was not true angina.

Orthodiagraphy.—Drs. Thomas A. Claytor and Walter H. Merrill of Washington gave a lantern slide demonstration of a series of diagrams of the heart and aorta, with explanatory remarks.

The Diagnostic Value of Orthodiagrams.—Dr. James G. Van Zwaluwenburg of Ann Arbor read this paper. It was discussed by Dr. Sidney Lange of Cincinnati.

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

Tuesday, June 7—First Day.

Dr. John G. Clark of Philadelphia, Chairman.

Infectious Endometrium.—Dr. William S. Gardner of Baltimore described the changes of the endometrium following infection in a series of cases studied pathologically. These showed definite cell changes, gland changes, and changes in structure of the blood-vessels. In the late stages, while the epithelium might be normal, there was frequent fibrosis in the stroma, and the glands were dilated, but a differentiation could not be made between a primary fibrosis and secondary effect of infection. In very late cases the glands were frequently largely destroyed.

Dr. Novak of Baltimore called attention to the similarity between acute infections of the endometrium and those of other tissues.

The Plastic Surgery of the Pelvic Structures.—Dr.

Henry O. Marcy of Boston was disappointed with the result of plastic surgery of many other men, but he would criticise the methods rather than the operators. He described a method of perineorrhaphy, which he used, giving a complete restoration of the anatomical relations after skillful dissection on a rather extensive scale, the use of buried absorbable sutures, and aseptic healing under iodoform-collodion dressing. He reported less than two per cent. of failures in 15 years.

Dr. Gilliam of Columbus did not get as good results from absorbable suture as from nonabsorbable.

Dr. Gilbert of Ohio spoke well of the after-treatment described in the paper, but he saw no need of post-operative douches.

Dr. Hall of Kansas City used a paste made from subiodide of bismuth with water in place of iodoform-collodion as an after-dressing.

Dr. Shoemaker of Philadelphia called attention to the value of an apron of mucosa to cover the deep tissues and prevent infection

Arteriosclerosis of the Uterine Vessels.—Dr. S. H. Chalfont of Pittsburg called attention to cases of bleeding, all of which were formerly called endometritis, that are now considered to be due to metritis. He said it had been shown that in the uterus after pregnancy a new set of arteries with three new coats was developed inside of the old vessels. The old vessels normally were reabsorbed, but in many cases the muscular coat of the old vessels remained and was replaced by elastic tissue, or in less favorable cases by fibrous tissue. He showed pictures from twelve cases of bleeding in which hysterectomy had been done, showing many large vessels, all with an increase of connective tissue, but not in proportion to the amount of the bleeding. It was impossible, therefore, to associate accurately the pathology with the history. He excluded the cases of endometritis and varicose veins of the uterine wall. In a certain number of the cases muscular relaxation of the vessel walls, which were normally always contracted, must account for the bleeding. Four factors which seemed to account for these hemorrhages were increased size and thickness of the blood-vessels, general arteriosclerosis, local acute congestion, and local loss of tone in the blood-vessels. For the treatment of this condition, the speaker suggested hystereceomy.

Dr. Novak of Baltimore said that uterine bleeding was present in a certain number of cases in the absence of any pathological lesion. Here the physiological cause seemed probable, and a hormone secreted by the ovary was, without doubt, the factor that was at fault.

Dr. Foulkrod of Philadelphia considered either that the muscles of the blood-vessels were too weak to control sclerotic vessels or that an endometritis was present in practically every case.

Ideal Operation for the Cure of Total Prolapse of Uterus.—Dr. S. W. Bandler of New York described this operation. He made a thorough and complete separation of the bladder from the vagina through a longitudinal incision from the cervix almost to the urethra. Sutures were then placed in the anterior wall of the uterus, but instead of being passed immediately through the anterior vaginal wall, they were left unfastened temporarily. Then a very high amputation of the cervix was done, sewing the mucosa to the uterine canal, beginning posteriorly and using up all the surplus mucosa until the anterior median line was reached. Then the excess of mucosa was trimmed off, and fixation sutures of the uterus were passed through flaps and tied. Then posterior colporrhaphy was done through a transverse and median T-incision, pulling the levator ani muscle together up to within one-half inch of the amputated cervix. By combining a special high perineorrhaphy, the operation occupied about an hour and a half. The after-treatment included immediate dilatation of the splincter ani, which prevented all interference with the sutures when the bowels moved. The patient was catheterized for two days, and sterile boric-acid solution was poured over the wound from four to six times a day.

Dr. Carstens of Detroit said Bandler in this operation tried to save a useless uterus. Personally he preferred hysterectomy, which could be done in fifteen minutes.

Dr. Goffe of New York said that Bandler cut the cardinal ligaments of support of the uterus, which were essential, and so spoiled his operation. Personally the speaker did a hysterectomy, suturing the broad ligaments together and uniting them to the round ligaments and the anterior vaginal wall. Then did a rectocele operation, plicating the rectum with from one to three lines of buried sutures and then united the levator ani muscles.

Dr. Lawrence of Columbus called attention to a cause of prolapse in the lack of support through the broad ligaments which resulted from this operation. Moreover, a large amount of scarred tissue was produced.

Dr. Baldy of Philadelphia criticized the operation as not removing the cause of the prolapse, which lay in the laxity of the upper end of the vagina.

Dr. Bandler, in closing, responded to the adverse criticism, calling attention to the type of operation as simply modified from the established operations now in use throughout Europe. The operations described by his critics were inadequate in that they were followed by recurrences. Hysterectomy was merely doing something as an excuse, while his operation was backed up by the results in seventy cases in which there had been no recurrence.

Papillary Cystadenoma of Kidney with Myoma Uteri and Spinal Caries.—Dr. Shoemaker of Philadelphia described a case in which he had done hysterectomy for a bleeding fibroid and then found a previously unnoted hematuria which showed its origin to be the left kidney. After washing out the bladder through a vaginal incision to avoid any later possible infection (it was filled with blood clots), indigo carmine solution was injected in the buttocks and the right kidney was proven sound. Nephrectomy was then done, and the kidney was shown to be a large solid tumor made up of minute papillary ademomatous cysts without definite signs of malignancy. Eighteen days later the vesicovaginal fistula was closed under cocaine. Before the patient left the hospital symptoms of pressure on the spinal cord from a previous spinal caries appeared, but for those the patient refused treatment.

Uselessness of Local Treatment in Puerperal Sepsis.—Dr. J. H. Carstens of Detroit read this paper. He said that he did not believe in douches, irrigations, or iodoform suppositories, but in asepsis. As a preventive measure he gave quinine and opium and flushed out the system with water. He encouraged the formation of antibodies in the system, and used antitoxins after determining which germs were the cause of the trouble.

Dr. Zinke of Cincinnati considered local treatment of great value in cases of sapremia. He cleaned out the uterus once with about twenty quarts of sterile solution, and then left the patient alone. In septic cases there was usually early profound systemic infection. In these he cleaned out the uterus and then gave about twenty c.c. antistreptococcus serum; no more local treatment.

Dr. Wetherill of Denver advocated drainage and irrigation continuously through a double-tube irrigator, preferably with 30 per cent. alcohol.

Dr. Boldt of New York said that bacteriemia could not be treated locally, and that the main objection to local treatment was that the traumatism hereby caused opened up channels for infection.

Dr. Glasgow of St. Louis thought that local treatment could remove the deeper germs in the deeper layers. To do this he gave injections with pure glycerin, producing a profuse exosmosis.

Dr. Schwartz of St. Louis said that in the cases in which streptococci were found in the blood it was too late to use an antitoxin.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held May 5, 1910.

The President, Dr. John A. Wyeth, in the Chair.

This meeting was held under the auspices of the Section on Public Health.

The Prevention of Alcoholism.—Dr. Frederick Peterson in considering this phase of the subject referred to the change that had taken place in recent years in the attitude of the medical profession toward the problem of alcoholism. Thirty years ago physicians were rather promoters of the use of alcohol both as a stimulant and as a remedial agent. No master mind in the whole profession had raised his voice against alcohol. Now, everywhere on both sides of the Atlantic medical men were foremost opposers of the use of spirituous liquors as a beverage or even as an agent in the treatment of disease. They had been living rather securely in the tradition that alcohol had always been with them and that most peoples who had reached the crest of development had been free users of wines and beers and that if alcohol carried with it any peril to the race, mankind would have degenerated long ago. Close historical study showed that drinking was not so widespread in ancient days as now. The liquors contained less alcohol and having no ice-machines they could not brew beers all the year around. The strong drinks, whiskeys, brandies, cocktails, bitters, and absinthe had not been invented. Without railroads and without bottles there was less distribution. With the wider diffusion of the idea that alcohol was a food, drinking became more general and alcoholism more noticeable. With the tremendous awakening of science in the latter part of the nineteenth century, and with the extraordinary progress of the science of medicine it was natural that alcohol should have its share of investigation. The facts which had been borne in upon medical men by such studies were overwhelming, and physicians were just beginning to understand how much responsibility rested upon them for the abatement of this evil. All physicians were familiar with a large catalogue of physical disorders directly due to alcohol, such as cirrhosis of the liver, dropsy, multiple neuritis, heart disease, Bright's disease, inflammation of the stomach, arteriosclerosis, delerium tremens, wet brain, and the like. The number of these cases was constantly increasing. Between 20 and 25 per cent. of all the insane owed their insanity to alcohol. Of the 4,000,000 paupers in the United States, 2,000,000 owed their dependence to alcohol. It was estimated that 25 per cent. of all crime committed was due to intemperance, and that there were 365,000 arrests for drunkeness annually in the United States. Physicians were somewhat divided as to the effect of alcoholism, an acquired characteristic, upon the offspring, but the evidence of experiments of Hodge on animals and the comparative study of Demme of the children of ten temperate and ten intemperate families led to the conclusion that parents thus poisoned affected their descendants disastrously. Alcohol was often the direct cause of epilepsy in a drinker, while between 20 and 40 per cent. of all epileptics had alcoholic parents. From the monetary standpoint it had been figured that the loss to society induced by the ravages of alcohol in the United States alone represented an economic waste of not far from a billion dollars per year. Alcohol was now regarded by most physicians as a drug whose action was to depress the heart, pervert the digestion, decrease muscular capacity, diminish intellectual function and when regularly used to bring about slow, far-reaching anatomical changes throughout the system. It had been said that the most alcohol had been consumed by the leading nations of the world, as if civilization and intemperance were necessary partners. In Japan they had a country which ranked well as a center of culture and efficiency where neither alcohol nor narcotic had been required. In answer to the question as to what was best to be done for the prevention of alcoholism he thought that a campaign of education such as was being carried on in the fight against tuberculosis was the only efficient method of warding off the evils of drink. Prohibition was helpful in so far as it educated the public. It did not, however, seem to be deterrent to the degree hoped for, since in prohibition States all sorts of evasions were practised. Substitutes in the way of medicines, bitters, and cordials containing alcohol were used. In one prohibition State an enormous appetite for aromatic spirit of ammonia had developed. The doses taken were often far in excess of what a physician would dare to prescribe. Aromatic spirit of ammonia contained 70 per cent. alcohol. Education would help these people where prohibition laws had been ineffectual. He advised having printed in brief form all the facts bearing on this question which the medical profession now had at hand. In Paris they had statements regarding the dangers of drinking to excess, printed on posters and put up in every ward and waiting room of every public hospital and printed on every prescription blank of the Paris hospitals and dispensaries. Dr. Peterson asked why our public spirited citizens should not join in such a crusade. Children should be taught these facts in the schools. Every hospital and dispensary in our country should begin a similar method of disseminating them. Our asylums for the insane and institutions for epileptics ought to print the statistics of alcohol as a cause of insanity and epilepsy on every letter sent out. There were doubtless many shop-keepers, owners of department stores, druggists, and so on, that would be willing to have such instructions printed on their wrapping-paper. Indeed such facts should be kept as a standing advertisement in many of our newspapers with large circulation. He had himself tried the experiment of printing them in briefer form on his own prescription blanks and wished that the 132,000 other physicians in the United States might be induced to aid the movement to this extent, for they know better than anyone else the fearful ravages of alcohol. Several of our States, notably Massachusetts, Iowa, and Minnesota, had established institutions for the treatment of public intoxication and inebriety, and there was now before the Legislature a bill prepared by the State Charities Aid Association to organize an efficient method in New York City for combating this growing evil. It had been sought to embody in this scheme all the best features of experiments in this line conducted in America and England. There was to be a Board of Inebriety consisting of five members appointed by the Mayor, field officers to act as investigators and probation officers, and an industrial and agricultural colony with a hospital within easy access of the city. It was planned to release all first offenders, to abolish the short sentence and fine, to place second offenders on probation for an indeterminate period, and to commit more frequent offenders to the Colony for from one to three years. The futile workhouse method would be displaced. Alcoholic repeaters who burdened the police courts and public hospitals would be eliminated. Medical care and treatment would be the main features of the new system in contrast to the present purely legal and penal methods. This emphasis of the medical side of the subject should bring to the support of the measure the endorsement of every physician in the city, and if the experiment succeeded

here, the New York City plan should be copied all over the country.

Alcohol in Its Economic Aspects.—Dr. Irving Fisher of Yale University spoke on this phase of the question. He said that Dr. Peterson's paper was the basis for his remarks. The present temperance movement had a sound physiological basis and that Dr. Peterson had shown. The question no longer was whether a small amount of alcohol was harmful or not, it was not a question of dose. The fact was that as alcohol actually was used it was doing a vast amount of harm. One observer had made an investigation of one thousand families who used alcohol and of the same number who did not and the results demonstrated beyond a peradventure that those families that abstained from the use of alcoholic drinks were better off in every respect. Some English statistics on the comparative death rate of abstainers and non-abstainers among the insured showed that between the ages of 30 and 40 the mortality among the abstainers was 56½ per cent. of that among the non-abstainers. Between the ages of 40 and 44, 57 per cent.; 50 and 54, 62 per cent.; 60 and 64, 78½ per cent.; 70 and 74, 86½ per cent.; 80 and 84, 94 per cent. Of course, statistics as to the injurious effect of alcohol might be somewhat vitiated by the well known element of selection. Professor Farnam of Yale, writing a report for the Committee of Fifty, concluded that among the cases of poverty investigated by charity organizations societies, 25 per cent. were due to alcohol and among the cases of poverty in almshouses 37 per cent. were so due; 31 per cent. of the crime was due to alcohol as a first cause and 50 per cent. to alcohol as a partial cause. The Bureau of Labor for Massachusetts in 1895 reported that alcohol was the cause of 84 per cent. of the crime and 48 per cent. of the pauperism and 35 per cent. of the insanity. Carroll D. Wright, who was at the time of his death America's leading statistician, stated that he had looked into the homes of a thousand families in England and many thousands in the United States and in almost every case misery was due, not to industrial conditions, but to alcohol.

The Use of Alcohol in Its Moral Aspects.—Dr. George H. Avery said that he had been asked to speak because he was engaged with the drunkard face to face; he was a witness, as it were. The New York Christian Home had been founded in 1876 for the purpose of caring for inebriates, not only those from New York City but from all parts of the country. A building had been erected at the corner of Eighty-sixth Street and Madison Avenue at a cost of $100,000. In 1886 it was decided to move this home into the country and twelve acres of land and buildings were purchased at Mount Vernon and he had been manager of this farm for twelve years. The drinking man was in great need; he needed medical attention and rest, but above all he neded a friend. It had been their object to be simply human and to help the drunkard as a friend would do. The victim of drink was not treated as a criminal but as an unfortunate; he was in an atmosphere of sympathy and courtesy. He was not talked to on the subject of religion as men of all different faiths and of no faith were alike welcome. The drinking man was treated as a man, talked to in regard to his business and his future and given work to occupy his time. After being with them for a few days the men usually braced up, ate well, and began to build up rapidly. They had chapel every night. In dealing with moral questions they had no hesitation in showing the men that they had lost standing physically and had also lost their moral standing in the community. It was very difficult to show these men that they were moral bankrupts. During the time he had been in charge of the home he had seen inmates who were from the best families and best colleges in the country; there had been bankers, lawyers, mechanics, druggists, and even clergymen. Many New York philanthropists had been interested in this institution. From a physical, mental, and religious standpoint it was as unconventional and happy as any community could be, not withstanding the fact that all had been drunkards. The physicians had been their best friends, but he could not say the same of the clergy. They did not seem to have much patience with the drunkard; they regarded him as foolish and bothersome.

Dr. John A. Wyeth announced that a committee of fifty members had been appointed with Dr. Ditman as chairman who would take certain steps to initiate the educational movement so well emphasized by Dr. Peterson and Dr. Fisher.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held April 25, 1910.

The President, Dr. John E. Weeks, in the Chair.

Report of the Public Health Education Committee.—Dr. Rosalie S. Morton, chairman of this committee, reported that a series of lectures had been given by fifty-two physicians. There had been from 360 to 550 people at each meeting, and this educational movement had reached to at least 5,000 people. The attitude of the public toward this movement was greatly appreciated; a great public interest had been awakened because of these lectures. The course of lectures for next winter was outlined.

The Owen Bill, Establishing a Department of Public Health, was endorsed by the society and it was resolved that the congressmen and senators from New York State be notified of such action.

Metrorrhagia and Uterine Fibrosis.—Dr. Arnold Sturmdorf read this paper. He said that the complacency of the physician might be seriously disturbed by an infrequent type of metrorrhagia, occurring about the preclimateric period, almost exanguinating in severity, for which no palpable routine cause was in evidence and nothing in their therapeutic equipment proved effective short of hysterectomy. The gross appearance of such an extirpated uterus revealed pale tissue of slightly augmented bulk and consistency. Microscopically, the small subendometrial vessels would be found increased in number and deformed in outline by a deposition of concentric fibrous layers, with well staining nuclei. Similar vascular changes existed in the myometrium, the muscular elements of which were encroached upon and replaced by fibrous bundles and round cell infiltration. Clinically, the uterus was converted into a rigid, engorged organ incapable of contraction, owing to a degeneration of its muscular and elastic elements, which were largely replaced by fibrous tissue traversed by stiff tortuous vessels, which were deformed and dilated. The question as to the relative significance and natural sequence of these vascular and myometrical degenerations in the causation of the uncontrollable bleeding was at present a theme of interesting debate. Dr. Sturmdorf outlined the present status of this controversy, but left the decision to academic discussion, and gave his attention to the clinical elements of the condition which was recognized under the various terms "uterine fibrosis," "uterine apoplexy," "senile hemorrhagic endometritis," "essential metrorrhagia," "metrorrhagia myopathica," etc. Reinecke and Martin reported thirteen cases in which hysterectomy was performed, the extirpated uterus in every case revealing sclerosis of vessels and musculature, but these authors failed to exclude the possibility of obstruction to the return circulation from thrombosis, cardiac, pulmonic, and hepatic disease, such as were found at autopsy in each of the eight cases reported by Von Kahlden. Popoff reported a case where kidney and heart

lesions were present with pleural effusion; Herxheimer reported one where cardiac and renal lesions were present with aortic atheroma. Palmer Findlay reports a case in which the immediate cause of uterine hemorrhage proved to be an embolus of the uterine artery, engrafted upon a generally disturbed circulation. These facts prompted him to the conclusion that sclerosis of the uterine vessels alone, and without coexisting general circulatory disturbance was insufficient to cause uterine hemorrhage. This, however, did not go far enough, for it ought to be added that the various hematogenic, toxemic, and metabolic disorders, as well as perverted ovarian functions, all and any of which, singly or combined, recognizedly exercised an etiological influence in the production of metrorrhagia. The terms usually applied to this condition were clinically misleading, as they tended to circumscribe the diagnostic horizon and limit therapeutic aim by focusing the attention on local manifestations, to the exclusion of general underlying factors. In the present state of their knowledge the diagnosis of uterine fibrosis could be established only upon the microscopic evidence of its existence in the extirpated uterus and upon their ability to exclude every other possible cause for—and their inability to control—the existing hemorrhage. They met many persistent, profuse, and apparently uncontrollable metrorrhagias, but they found an extremely small number that would not ultimately reveal causes other than uterine fibrosis to account for the bleeding, and it was essential to realize that they were treating not merely a bleeding uterus, but a bleeding woman. Uterine contraction alone would not control bleeding. Normal coagulation was an essential concomitant to such control, and this demanded normal blood, under normal pressure. Their operative records in a long series of metrorrhagic conditions revealed a significant group of cases in which gross abnormalities within the uterus by their nature and location completely eluded tactile recognition prior to surgical intervention. Among these unrecognized local causes were: first, fundal polypi; second, submucous or short pediculate myomata springing from the cornual area of the uterine cavity, and, last, maglignant disease. In all of these cases the unrecognized factor was located in and limited to the upper lateral angles of the uterine cavity. Pernicious anemia had proven to be the primary etiological factor in two cases. Jaundice, scorbutus, and other toxemias would recall conditions capable of inducing various degrees of hemorrhagic tendency. Functional disorders of the thyroid might influence menstruation and the development of metrorrhagia in exophthalmic goiter. A retinal hemorrhage was frequently the initial symptom, pointing to renal or vardiac disease, yet these conditions were rarely sought in explanation of uterine hemorrhage. The veins of the uterus, like those of the intestinal tract, might be varicosed by cirrhotic processes in the liver and other portal obstructions. They recognized this varicosity as productive of hemorrhages from mouth or anus, but failed to connect the same cause and effect in metrorrhagia. The recognition of any of the systematic conditions outlined as the cause of the metrorrhagia excluded uterine fibrosis and established imperative therapeutic indications. The control of local hemorrhage demanded prompt consideration. It could not be sufficiently emphasized that failure of ergot, the tampon, and the curette to control such hemorrhage did not demonstrate its uncontrollability, nor establish the diagnosis of uterine fibrosis. To check bleeding they must induce coagulation; to induce coagulation the blood current must be retarded and reduced. In these metrorrhagias the same tendency to incoagulability seemed to exist as in the normal menstrual fluid. The effort must, therefore, be to endeavor to induce coagulation before the blood was extravated into the uterine cavity. Such a result might be accomplished by a combination of medicinal and mechanical means. The so-called vasodilators, especially atropine and nitroglycerin, which retarded the general blood current by lowering vascular tension, should be pushed to their full physiological limit or point of toleration. The local uterine circulation could be reduced by snug, full, intrauterine packing, so applied as to substitute mechanical compression for the normal contractions of the vascular area. This packing should be applied under anesthesia if possible, through a cervical speculum after thorough dilatation, and should fill every portion of the uterine cavity. This packing should be supported by a comfortable vaginal tampon of cotton wool, and should not be removed without special indication for at least four days. During this period postural adjuvants were of great utility. In very urgent cases impeding the venous reflux from the extremities by intermittent annular constriction, as suggested by Dawbarn some years ago for inaccessible hemorrhages in other parts, had yielded the happiest results. This was no place for the curette; it should never be used without an obvious indication. The author very emphatically condemned the use of ergot in these cases. His objections to ergot also applied to cotton-root bark and hydrastis, while all the later synthetic oxytocics were quite inert. If the treatment outlined showed a tendency to control the bleeding, the packing should be removed every four days and renewed. If, on the other hand, no such tendency was manifested, their next step was digital exploration of the uterine cavity. To do this thoroughly the cervix should be exposed and drawn to the vaginal outlet through a transverse incision about 2½ cm. above the external os; it was freed from the bladder by blunt dissection as far as the peritoneal reflection. A median longitudinal section of the exposed anterior uterine wall would now permit of the introduction of the rubber covered exploring finger into the uterine cavity.

Dr. J. Riddle Goffe said that the best treatment in these cases was to pack the uterus with gauze. While it was necessary to investigate the uterus with the curette, one did not find it necessary to scrape away the mucous membrane. It was wise, however, to explore the endometrium and find out if there were any degenerated mucous membrane, polypi, or other pathological condition requiring attention present. In case of intractible hemorrhage, it should be controlled by dilating the cervix and then firmly packing the uterus with gauze. The outcome in these conditions, however, was hysterectomy. Adenocarcinoma occasionally found at the fundus uteri and associated with intractible hemorrhage was an important condition, had points of much interest, and Dr. Goffe recited a typical case that came under his observation years ago. She had nearly reached the menopause and suffered from severe hemorrhages. She had her uterus packed once or twice, and had been advised to be curetted. This was done, and the pathological report of the scrapings showed that there was a chronic inflammation present. The hemorrhage was controlled for two or three months, but it then returned with great severity. It was believed that she would bleed to death. Finally hysterectomy was performed and the pathologist reported an adenocarcinoma at the fundus uteri. Dr. Goffe believed that there were many such cases.

Dr. Herman J. Boldt agreed that the condition under discussion was one which could not be diagnosed clinically; it was only under the microscope that a positive diagnosis could be made. The uterus would be found to be enlarged, and in most instances there were evidences of hemorrhage, but this was not always the case. They must look for some pathological element that caused the hemorrhage further than simply an increase in the connective tissue. There seemed to be some change in the

blood-vessels which accounted for the bleeding. Finley was correct when he maintained that there was an arteriosclerosis present. In a number of instances, moreover, there was no increase in the size of the uterus. With regard to the use of the curette for making a diagnosis when in doubt, he believed in it; the curette would do no harm. If one failed to learn the cause of the bleeding by the use of this instrument, there would probably be no thickening of the endometrium, but in all probabilities there would be little endometrium present at all. He believed the uterus should be split open and its interior explored by the finger. Were these cases amenable to other forms of treatment than hysterectomy? He believed they were, and the form of medication depended largely upon the physician and his experience with certain agents. Personally, Dr. Boldt thought carbolic acid was of value; also chloride of zinc as used in the treatment of inoperable carcinoma. He believed this problem would be solved in the laboratory.

Dr. Samuel W. Bandler said he had had abundant opportunity to examine these cases under the microscope, and arteriosclerosis was a condition rarely found to be sufficiently marked to explain the large number of cases encountered. What might be found was: (1) a diminished number of muscle fibers; (2) muscle fibers of diminished contractile power; and (3) substitution of muscle fibers by fibrous tissue. The structure of the uterus in uterine fibrosis resembled the structure of fibrous tumors more than anything else; therefore, this term had been applied to this condition. Dr. Bandler said he was struck by another factor: the frequency with which he met with this condition in women who were broad-chested, broad shouldered, strong, vigorous women; women who could stand hemorrhages fairly well. In operating upon these cases, the ovaries would be found to be large, and under the microscope they would appear to have the ability to secrete. In women thirty-nine, forty or forty-seven years of age, when the ovaries were supposed to secrete less and when the uterus was supposed to undergo atrophy, the ovaries would be producing as if the woman was twenty-five or thirty years old. No response was found in the use of large doses of ergot or allied agents in the treatment of these cases. There seemed to be a hypoplasia, and not a hyperplasia of the mucous membrane. The curette made the diagnosis; its use was also important in therapy. He believed in performing hysterectomy in these cases, especially by the vaginal route, leaving behind the ovaries to prevent the early occurrence of the menopause.

Operations for the Correction of Deformities Following Pott's Fracture.—Dr. W. O. Plimpton read this paper. He first discussed the fracture, with its varying degrees of injury and dislocation, the complications and the length of time elapsing after the fracture occurred and the various operations to be done when each particular case had been summed up. No particular operation applied to all cases, but a general plan of procedure was to be pursued. The principle to be followed was to reduce the parts to the condition in which they were at the time of the fracture, then reduce the dislocation, and put up the leg and foot as in a recent injury. In doing this no one operation could apply to all cases. The object to be obtained was to bring the astragalus squarely under the perpendicular axis of the tibia, so that all the bones might be in their normal positions. To retain them there, wire sutures might be used if needed. Plaster-of-Paris was suitable as an outer dressing. Dr. Plimpton included in his paper the report of twelve cases, eight belonging to other surgeons and four of his own, with the description of the operation performed in each case. Good results, with useful limbs and excellent motion, resulted in all instances.

PLACENTA PRÆVIA.*

BY EDWARD P. DAVIS, M.D.,

PHILADELPHIA.

PLACENTA PRÆVIA may be defined as such an attachment of the placenta that the placenta must inevitably be separated during dilatation of the uterus in spontaneous labor.

It may broadly be divided into two classes: Central placenta prævia, where the placenta is over the internal os and covers the internal os, and marginal, lateral and partial, where the placenta covers a portion of the internal os, or extends to the margin of the internal os, or is attached to the wall of the lower uterine segment.

The causes of this abnormality are a relaxed condition of the uterine muscle, often seen in ill-developed, badly nourished primiparæ. Multiple pregnancy also predisposes to placenta prævia, especially if the uterus be distended by multiple pregnancy, and if in addition, polyhydramnios be present.

Placenta prævia may develop early in pregnancy so soon as the placenta forms. Its dangers in early pregnancy are indicated by a reported case in which a primipara while intoxicated bled to death from central placenta prævia. The case was investigated by the coroner of the city in which it occurred, and at autopsy central placenta prævia at ten weeks gestation, was found.

The diagnosis of placenta prævia may be made by auscultation in many cases. In others vaginal examination enables the physician to touch the placenta and to recognize its presence directly. In many cases vaginal examination is negative and only an hyperemic condition of the cervix and surrounding tissues can be felt. Where the abdominal walls are thin the placental bruit may be detected at the pelvic brim, and a low attachment of the placenta may be diagnosticated.

The condition may also be diagnosticated by hemorrhage without pain. The hemorrhage is bright, occurring at irregular intervals, sometimes following exertion or violence, and often persisting when the patient resumes the recumbent position. It frequently occurs during micturition or defecation.

The hemorrhage of placenta prævia is to be distinguished from the bleeding from fibroid tumor, bruised varicose veins in the vagina, menstruation persisting during pregnancy, and oozing from a degenerated and hypertrophied cervix. Ruptured tubal gestation is often accompanied by slight vaginal hemorrhage which might be mistaken for placenta prævia.

Placenta prævia can be distinguished from accidental separation in a normally implanted placenta by the external discharge of blood, the fact that in placenta prævia the uterus does not become hard and painful, and the history of accidental separation which often points to straining or external violence as the cause of the accident.

The treatment of partial, marginal, and lateral placenta prævia is comparatively simple. The effort of the practitioner should be to evacuate as much as possible of the amniotic liquid, bringing the presenting part to the pelvic brim, and stimulating the uterus to force it into the pelvic cavity. The placenta will thus be compressed between the presenting part and the wall of the pelvis, and hemorrhage will be checked or greatly lessened. In some cases the introduction of an elastic bag and its distention with sterile fluid, will make efficient pressure, stimulate dilatation, and check bleeding. The life of the fetus may often be preserved in these cases if the cervix dilates with sufficient rapidity to permit the birth of the child within a reasonable time.

The maternal mortality and morbidity of partial, marginal and lateral placenta prævia are not excessive, and the condition is one which can usually be dealt with successfully in private houses. Central placenta prævia has long been recognized as one of the most serious complications of pregnancy. Hemorrhage cannot be controlled until the womb is empty, and efficient pressure is made upon the enlarged sinuses of the lower uterine segment and the hypertrophied vessels of the cervix. If the case be treated by the vagina the uterus cannot be emptied until the cervix is dilated, and such dilatation is inevitably accompanied by hemorrhage; and the condition is quite as serious as ruptured tubal pregnancy, and must be dealt with with equal care. Too much importance cannot be laid upon the fact that so soon as a diagnosis of central placenta prævia can be made the attending physician assumes great responsibility. He can no more delay safely in his treatment of the case than he could if a diagnosis of ruptured tubal gestation had been made.

In the presence of this complication, the treatment must be largely influenced by the resources of the practitioner, and the circumstances of the case. It is of primary importance to ascertain and recognize clearly the condition of mother and child. If there has been but one considerable hemorrhage, and the mother is in good condition, and the child viable and vigorous, the question must be raised as to whether or not an effort shall be made to save the lives of both mother and child. If the mother is exhausted by bleeding, and the child dead or dying, obviously only the interests of the mother must be considered.

With mother and child in good condition, if the patient is to receive treatment which does not require the major operation, the following method

*Read before the Atlantic County Medical Society, April 8, 1910.

has proved of value: In many cases of central placenta prævia the cervix is partly dilated or dilatable if the child has reached viability when the practitioner sees the case.

The plan of treatment consists in piercing the placenta, evacuating as much of the amniotic liquid as possible, and introducing through the placenta and within the fetal envelop an elastic bag. This bag is distended with sterile salt solution, and moderate traction made upon the bag through its tube. The urinary bladder is frequently emptied by catheter, and if the uterus is relaxed a tonic dose of strychnia may be given hypodermatically. The pressure of the bag against the placenta controls or lessens hemorrhage and excites dilatation. If the bag has been but partly distended, additional fluid may be introduced by a piston syringe until the bag is completely distended. So long as hemorrhage is controlled, the practitioner should wait for thorough dilatation before removing the bag. Should the bag be spontaneously expelled, so long as dilatation is secured no harm has been done.

So soon as dilatation has been accomplished the practitioner must proceed to empty the uterus. In exceptional cases spontaneous labor develops and strong uterine contractions expel the child. Usually the bag must be removed, dilating the vagina during its removal, and the child extracted as promptly as possible by the use of forceps. This will require anesthesia, preferably by ether, given by a competent person. Care must be taken in these forceps deliveries that the head is not drawn quickly through the cervix, as serious lacerations of the cervix may result. Soon as the child is delivered the placenta must be removed, the uterus thoroughly irrigated with hot salt solution and thoroughly packed with 10 per cent. iodoform gauze. If cervical lacerations sufficiently deep to cause bleeding have occurred, they must immediately be closed by catgut sutures. If the patient's condition permits, lacerations in the anterior and posterior segments of the pelvic floor and perineum should also be closed. The vagina should be firmly packed with bichloride gauze, and a firm pad placed over the vulva with a tight binder upon the abdomen. Such stimulation as the patient needs, including, if necessary, intravenous transfusion with salt solution, should then be given.

In central placenta prævia, if the life of the child is not to be considered, and the major operation cannot be undertaken, the child's body should be used as a tampon or plug to control bleeding and accomplish dilatation. Under anesthesia the cervix must be dilated sufficiently to permit the introduction of several fingers, the placenta perforated, version performed, and one or both legs of the child brought down, and by traction upon them, the breech pulled down upon the pelvic floor, thus exerting firm pressure against the placenta. The extraction of the child should not be done, and this point is one of great importance.

Experience shows that the rapid extraction of the child after version in central placenta prævia produces such lacerations of the cervix as to cause fresh hemorrhage from torn vessels, and adds greatly to the mother's danger. Nothing more should be done than to perform version. Hemorrhage will cease or become very slight, and no effort should be made to remove the child. The mother should then be given tonic doses of strychnine, and if the hemorrhage has been severe, saline solution should be introduced into a vein, into the bowel, or into the connective tissue. Practitioners should wait for spontaneous expulsion of the fetus, taking the opportunity to stimulate the mother during this time. When the child has been expelled the placenta must be removed, and the case treated as has already been described in the preceding paragraph.

The classic treatment of central placenta prævia has long consisted of the use of the tampon by iodoform gauze to secure dilatation, to permit manual dilatation, version, and extraction. The dangers of this procedure are, infection following repeated tamponing, and serious lacerations of the cervix and surrounding tissues caused by the extraction of the child through a partly dilated cervix. This method of treatment will sometimes result in the birth of a living child, but frequently the child's life is lost, and the mother's as well.

Ruptured tubal gestation is considered a condition calling for surgical treatment. On equal grounds central placenta prævia merits the same consideration. Two methods of delivery by operation have been tried in the treatment of this condition.

The first consists in rapid dilatation, or section of the cervix and lower uterine segment, followed by the immediate delivery of the fetus. When Bossi's dilator was introduced and extensively used in eclampsia it was further applied to the treatment of central placenta prævia. The results were disastrous. The powerful blades of the instrument tore the cervix extensively, sometimes rupturing the urethra and causing lacerations which extended into the peritoneal tissues. Its use in central placenta prævia is so dangerous that it has practically been abandoned.

Vaginal cesarean section by Dühressen's method has also been applied to the treatment of placenta prævia. In this condition the tissues are so vascular that the field of operation is obscured by blood, and hemorrhage is so severe that the operation has not been successful for this condition. The extraction of the fetus sometimes produced severe lacerations which increased the hemorrhage.

Abdominal cesarean section has been applied to the treatment of central placenta prævia with a considerable degree of success. As in other cases, much depends upon the condition of the patient at the time of operation. Experience has shown that the removal of a central placenta prævia from above, after the uterus has been opened, is the most efficient, safe, and speedy method of controlling hemorrhage. Furthermore, if the opened uterus be tamponed with iodoform gauze, the end of which is carried into the vagina, the secondary hemorrhage which follows vaginal delivery in central placenta prævia is avoided. The child is subjected to no injurious pressure, the operation is quickly done, and with a minimum of injury to the mother.

Abdominal section for central placenta prævia is best performed in well appointed hospitals. In clean dwellings, where the obstetrician can transport the essential apparatus for asepsis, and with competent assistants, the operation may be successfully undertaken.

It is the consensus of opinion at present that cases of central placenta prævia rarely come to the notice of the obstetrician in a condition suitable for section. They do not report to the attending physician before several hemorrhages have weakened mother and child. If the general practitioner

undertakes to treat the case by the tampon the patient is often infected before the obstetrician sees her.

In the discussion upon this subject before the American Gynecological Society in its meeting at New York, May, 1909, it was thought that about 5 per cent. of cases of central placenta prævia would be found in a suitable condition for section.

The Results of Various Methods of Treatment in Central Placenta Prævia.—In estimating the results of various methods of treatment in central placenta prævia, one must remember that marked advances have been made in obstetric surgery during the last five years. The use of the elastic bag introduced through the placenta is comparatively modern, and a clear understanding of the indications for abdominal section in placenta prævia has but recently been obtained.

In the discussion before the American Gynecological Society in May last, to which allusion has been made, Jewett had collected 2,010 cases of placenta prævia, with the birth of 2,020 children, treated by vaginal delivery by the use of the gauze tampon, forceps, manual dilatation, version, and extraction. In some of these the elastic bag had been employed. In most of them other methods were used. The maternal mortality of this series was 10.9 per cent.; the fetal mortality 57.3 per cent.

In various hospitals better results were sometimes obtained than this. Novak (*Monatsschrift f. Geburtshülfe und Gynäkologie,* Band 30, Heft 4, 1909) reports 237 cases of placenta prævia treated by vaginal delivery, with a maternal mortality of 5.9 per cent., and a fetal mortality of 79 per cent.

Krönig (*Zentralblatt f. Gynäkologie,* No. 34, 1909) reports 6,569 cases of placenta prævia treated by vaginal delivery, with a maternal mortality of 9.3 per cent., and a fetal mortality of 58.7 per cent. Among these 1,602 cases were treated by version with a maternal mortality of 6.26 per cent., and a fetal mortality of 58.9 per cent.

Schauta (*Monatsschrift f. Geburtshülfe und Gynäkologie,* Band 30, Heft 3, 1909) in 18 years' experience in 54,000 cases of labor had seen 438 cases of placenta prævia treated by vaginal delivery, with a maternal mortality of 7 per cent., and a fetal mortality of 57 per cent.

Under the most favorable circumstances in private houses, Thies (*Monatsschrift f. Geburtshülfe und Gynäkologie,* Band 29, Heft 3, 1909) collected 179 cases, with a maternal mortality as low as 3 per cent., and a fetal mortality of 60 per cent.

In a small series of cases the maternal mortality in placenta prævia may be low, provided the cases are treated in a well equipped hospital. Thus, Richter (*Zentralblatt f. Gynäkologie,* No. 22, 1909) in 4,624 labors collected 83 cases of placenta previa of all varieties, with one maternal death; 12 per cent. of these mothers had post-partum hemorrhage. The fetal mortality was 53 per cent.

If we turn now to cases of central placenta prævia treated by the introduction of an elastic bag through the placenta, we find that Hannes (*Zentralblatt f. Gynäkologie,* No. 3, 1909) reports 246 cases of placenta prævia, of which 143 were treated by the elastic bag. The maternal mortality was 5.5 per cent.; the fetal mortality 30 per cent.

Krönig (*Zentralblatt f. Gynäkologie,* No. 34, 1909) in 380 cases of placenta prævia treated by the elastic bag had a maternal mortality of 6 per cent., and a fetal mortality of 33 per cent.

A short series of favorable cases treated by the elastic bag is reported by Zimmerman (*Zentralblatt f. Gynäkologie,* No. 10, 1909) who had 28 cases so treated, with no mortality. Krönig also in 19 cases treated by the use of bags had 21 per cent. maternal mortality, thus showing that even in a short series of cases the mortality may vary enormously, probably depending upon the condition of the patient at the time of admission to hospital.

Turning now to delivery by abdominal section in placenta prævia, Jewett collected 95 cases of section with the birth of 97 children, and with a maternal mortality of 11.5 per cent., and a fetal mortality of 34 per cent.

Pankow (*Zeitschrift f. Geburtshülfe und Gynäkologie,* Band 64, Heft 2, 1909) in 8 consecutive cases of placenta prævia performed extraperitoneal section under lumbar anesthesia, with a record of no mortality.

Summary.—One may summarize our present knowledge as regards the treatment of central placenta prævia as follows: Under the use of the gauze tampon and version, or version and extraction, the average result, under favorable conditions, gives a maternal mortality of 11 per cent., and a fetal mortality of 57 per cent.

If the practitioner performs version, and is careful not to proceed to extraction, but to wait for uterine action and spontaneous delivery, the fetal mortality becomes 100 per cent., although the maternal mortality may be reduced to between 6 and 7 per cent.

If central placenta prævia be treated by the introduction of the elastic bag, the maternal mortality in favorable cases may be reduced to 5.5 per cent., and the fetal mortality to 30 per cent. This is an evident gain for mother and child.

If a case of central placenta prævia be seen early, and hemorrhage has been slight, and the mother and child are in good condition, and the child well developed, aseptic delivery by abdominal section will give a maternal mortality not exceeding 5 per cent., and a fetal mortality of nil. This favorable result may be obtained when cases are brought under competent treatment at the earliest possible moment before infection and hemorrhage have developed. These statements may be illustrated by a case occurring in the practice of a general surgeon—a friend of the writer.

He was summoned to go ten miles to a healthy young primipara, under the care of a general practitioner. The attending physician had correctly diagnosticated central placenta prævia and had instituted no treatment. There had been one considerable hemorrhage, but as the mother was robust, she and the child were in good condition. The cervix was but little obliterated and not dilated. There were no active labor pains. Taking with him the necessary appliances and assistants, the surgeon went immediately to the case, and operated in a clean dwelling. Mother and child recovered without complications. As the cervix was somewhat softened by the presence of the placenta, it was easily dilated from above sufficiently to secure drainage for the lochia.

In 71 cases of delivery by abdominal section for various conditions, the writer has twice performed abdominal section for central placenta prævia. The first case was that of a primipara, who was seen in her dwelling by one of the staff of the Jefferson Maternity. The patient was in fairly good condition, having suffered considerable hemorrhage from central placenta prævia. The child's heart sounds

were good. The patient was immediately transferred to the hospital and was delivered by abdominal section.

The second case was that of a multipara who lost her first child from inanition shortly after its birth. She was seen by the out-patient staff at her home, and was suffering considerable hemorrhage. The vagina was carefully tamponed with gauze in the hope of checking the bleeding, and the patient immediately transferred to hospital and delivered by section.

At both these operations it was interesting to note that hemorrhage ceased so soon as the uterus was opened and the child extracted. The placenta could readily be studied, being exactly transverse and entirely covering the os. The abnormal situation of the placenta could be plainly demonstrated to the attending class. In one case the placenta was of abnormal size, not only covering the os, but occupying one side of the lower uterine segment. The plan of operation consisted in incising the abdomen, removing the uterus from the abdominal cavity, and placing a large soft pad, wrung out of hot sterile salt solution, over the intestines. The uterus was then opened longitudinally through the upper expulsive segment, the child removed, and the cord immediately clamped and severed. The situation of the placenta was then demonstrated to those witnessing the operation, and the placenta was loosened from its attachment and removed with the membranes. The fingers were then passed from above through the cervix to be sure that sufficient dilatation was present to permit drainage. The uterus was then packed with 10 per cent. iodoform gauze and the end carried through the cervix into the vagina. Especial care was taken to tampon the lower uterine segment firmly. Strychnine and ergot were given by hypodermatic injection as soon as the child was removed. The uterus was then closed in the usual manner.

During the operation the patient received intravenous saline transfusion. At the conclusion of the operation the vagina was thoroughly sponged out with cotton dipped in bichloride solution and tamponed with bichloride gauze.

In both of these cases the recoveries of mother and child were uneventful. Lactation was established with very slight delay.

In concluding, we may remark that three points have been brought out by our study of placenta prævia during the last few years:

1. Central placenta prævia, like ruptured tubal gestation, should, if possible, be transferred to hospital and treated by abdominal section. If this is impracticable, and aseptic technique can be carried out in the patient's dwelling, operation should there be done.

2. Where an effort is to be made to save the life of the child in the patient's dwelling, and abdominal section cannot be performed, the introduction of an elastic bag through the placenta, under aseptic technique, may be attempted. This should be followed by vaginal delivery, if possible, by forceps, and in many cases by version.

3. If the life of the child is not to be regarded the cervix should be sufficiently dilated to permit version and the bringing down of one or both thighs and the breech. Complete dilatation and uterine contractions should be waited for before delivery is undertaken. If possible, the spontaneous expulsion of the fetus should be secured.

DEEP PERINEURAL INJECTIONS FOR THE RELIEF OF TRIFACIAL NEURALGIA (SIXTY CASES) AND SCIATICA (THIRTY-THREE CASES).

By D'ORSAY HECHT, M.D.,

CHICAGO, ILL.

ASSISTANT PROFESSOR, NERVOUS AND MENTAL DISEASES, NORTHWESTERN UNIVERSITY MEDICAL SCHOOL; ATTENDING NEUROLOGIST, MICHAEL REESE AND ST. ELIZABETH'S HOSPITALS; CONSULTING NEUROLOGIST TO THE COOK CO. INSTITUTIONS FOR THE INSANE, DUNNING, ILLINOIS.

The experiences herein set forth are personal and relate to the treatment of some forms of neuralgia by deep intraneural or perineural injections after methods already referred to and advocated in earlier papers.*

As concerns their employment in trifacial neuralgia, Schlosser, in 1903, was the first to conceive the idea of the deep alcohol injections for this distressing condition. I have, however, not availed myself of his method, preferring that of Levy and Baudoin, which contemplates the injection by an extrabuccal route of the three large divisions of the fifth nerve at their foraminal exits from the skull. The observance of particular landmarks and the use of an especially designed needle are essentials to the success of these injections.

General anesthesia is neither necessary nor desirable, although two patients insisted upon its administration. The formulas with the alcohol in ascending strength of 70, 80, and 90 per cent. remain unchanged, but a slightly sharper cutting-edge needle is used. Analgesia in the area supplied by the branch injected is the best criterion of having successfully reached the nerve. In two instances, however, analgesia was prompt and marked and yet the paroxysms of pain continued unabated. Why this should be I am unable to say. In one patient, with hemophiliac tendencies, a hematoma of the size of a small apple formed in the cheek. Facial edema is often marked, but should not give rise to anxiety, since its subsidence may be slow. No ocular palsies resulted in my cases, although a few instances are reported in the series of other writers.

My first patient was injected November 20, 1906, and my last to date April 8, 1910. During this interval I have injected in all sixty cases of what I regard as genuine tic douloureux. Eight cases besides this number I have construed as atypical or impure forms of the disease, and as such unsuited for this treatment. In all the cases the chief diagnostic criterion was the existence of short, sharp paroxysms of intense pain, without referable cause, and characteristically refractory to treatment. To reduce error, due regard was shown for dental abnormalities and diseases of the jaws, mouth, nares, accessory nasal sinuses, any of which sources are frequently responsible for pains which may quite closely simulate those of the disease. It should be added that tumors involving the fifth nerve as well as syphilis and migraine can and do give rise to pains that may readily deceive as trifacial neuralgia. Hysterical pains, either primarily or secondarily superimposed upon those of tic douloureux, need not give rise to confusion, although they must be given due consideration in advising the treatment and thereupon basing the prognosis.

*(*a*) "The Methods and Technic of the Deep Alcohol Injections in the Treatment of Trifacial Neuralgia," *Jour. Am. Med. Assoc.*, November 9, 1907. (*b*) "The Treatment of Sciatica by Deep Perineal Infiltrating Injections of Salt Solution," *Jour. Am. Med. Assoc.*, February 6, 1909.

In most of the cases external skiagraphs were taken and where these were felt to be unsatisfactory or unreliable, *intrabuccal* films were supplemented for the purpose of eliciting better detail, thereby affording a still more accurate means of properly localizing foci of irritation.

To be more specific, I submit that: (*a*) In point of age the incidence in my cases conforms to that noted by others and bears out the contention held for so long that trifacial neuralgia is essentially a degenerative type of disorder, tending to increase in severity and frequency with advancing age.

Number of Cases	Age
1	20–30
2	30–40
8	40–50
14	50–60
24	60–70
9	70–80
2	80–90

(*b*) In point of duration:

Number of Cases	Duration
2 had existed	6 to 12 weeks
5 " "	4 " 12 months
18 " "	1 " 3 years
16 " "	3 " 5 "
7 " "	5 " 10 "
6 " "	10 " 15 "
4 " "	15 " 20 "
1 " "	26 years
1 " "	32 "

(*c*) In point of involvement:

Branch 1	4 cases
" 2	16 "
" 3	12 "
Branches 1 and 2	7 "
" 2 " 3	17 "
" 1, 2 and 3	4 "

(*d*) In point of clinical type:

Typical	41 cases
Atypical	19 "
Rejected and not included in the series	8 "

(*e*) In point of number of injections requisite to the initial control of pain:

Number of Cases	Injections Received
6	1
9	2
17	3
10	4
8	5
5	6
3	7
2	8

Total: 180 injections; an average of 3¾ injections to subdue the original pain.

(*f*) In point of theapeutic results: 37 cases were distinctly benefited (complete abeyance of pain for a longer or shorter period); 11 were improved (great reduction of pain); 8 were unimproved (pain uninfluenced); 4 were aggravated (pain increased, if anything).

Of the thirty-seven benefited, one patient was entirely free from pain for one year and eight months. The shortest free interval has been two weeks. Among the successful cases recurrences have been recorded; many, however, went without recurrences for about one year. A given number returned for reinjection upon the first reappearance of pain, some in four months, others in six, and others again in ten months. This variability in results does not admit of satisfactory explanation, but may in large part be due to the accuracy with which the alcohol was deposited in, at, or near the nerve.

As concerns the solution available for the injection treatment of *sciatica*, it should at the outset be emphatically stated that *alcohol is strictly contraindicated in this affection*, on the ground of its being harmful and even disastrous when injected into a mixed (sensorimotor) nerve.

The landmarks, as given in my previous paper, I have continued to use, because they are the most accurate and effective in reaching the sciatic nerve. My first series of cases injected numbered sixteen; my present series since then numbers thirty-three cases, and this number represents only about one-third of the total number of cases I have seen and rejected. Here, as in trifacial disease, the treatment is limited to those cases in which the diagnosis of sciatica is made only after a rigid exclusion of all those conditions which through some underlying pathology may give rise to sciatic pain as a symptom. Prolific sources of diagnostic error are the cases of arthritis of the rheumatoid or deformans variety, tuberculous spondylitis, tabes, spinal syphilis, diabetes, inflammatory pelvic exudates, intermittent claudication, and advanced generalized arteriosclerosis. All these have I seen mistaken for nonsymptomatic sciatica. In nearly all this method of treatment was contraindicated, and, therefore, denied. One condition, however, is deserving of mention, for its close resemblance to sciatica and the fact that it lends itself well to this treatment. I refer to myalgia. Exact information concerning this affection has been volunteered by several writers of late, among them Peritz.

Myalgias are characterized by areas of pain coextensive with muscles and have not the linear distribution of nerve pains. The muscles are hypersensitive to pinprick, and cause a hypersensitive burning response to faradism. The muscle masses feel sore in a patchy outline in contradistinction to the distribution of nerve pain taking the direction of the nerve trunk. Occurring so frequently in the buttocks, these myalgias are far too often construed as sciaticas. The pain is in the glutei and along the iliac crests. In a receding myalgia the thinnest part of the muscle yields the last remnant of pain. The condition may last for years. When myalgia is present and the muscle mass is injected, the needle gives rise to more intense pain in its passage through the muscle masses than is the case when the trouble is one of nerve origin. This I have noted in several instances, and it has served as a differential point in the diagnosis.

There is little or no advantage in detailing case reports: suffice it to say that the following conclusions may be drawn from my series:

By reducing diagnostic error to a minimum, the deep intraneural injections of salt solution stand approved in the acute, subacute, and early mildly chronic nonsymptomatic cases of sciatica, and also in the group that may be classed from the site and distribution of the pain as myalgias.

In most instances the relief after treatment was almost immediate and complete. Only in a few patients were more than three injections at intervals of forty-eight hours apart indicated. There were neither unpleasant effects nor untoward complications.

103 State Street.

The spontaneous nystagmus of infective labyrinthitis passes through three stages: (1) A short and transitory stage of irritation, with nystagmus to the affected side. (2) The stage of destruction with nystagmus to the sound side. (3) The stage of disappearance of spontaneous nystagmus.—Royce, in *The Canadian Practitioner and Review.*

IMMUNITY IN TUBERCULOSIS CONSIDERED FROM BOTH THE EXPERIMENTAL AND CLINICAL STANDPOINT.*

By F. M. POTTENGER, A.M., M.D., LL.D.,

MONROVIA, CALIFORNIA.

Immunity as we understand it to-day has a different significance from what it had a few years ago. Where it formerly was considered to be a more or less absolute resistance to some infection, we now understand it to mean any degree of specific resistance that may be developed against any foreign substance, whether it be a germ or its toxin or any ordinary substance which is foreign to the animal economy.

By gradually accustoming an organism to a foreign substance, even although it be highly toxic, a specific protection against that substance is formed. Following the inoculation of people or animals with germs as occurs in our ordinary infectious diseases, if a cure results, an immunity is present the completeness of which varies with the disease and the individual. This protection or immunity has long been recognized as a factor in certain diseases, such as smallpox and measles, but has not been recognized in connection with others in which it is also present, but not to so high a degree. With our present knowledge, recovery presupposes the presence of immunity.

Cure in all infections consists in the production of a specific immunity against the causative germ, its toxins or both, and this is the aim of therapy. In the therapy of tuberculosis we are just now beginning to realize that the establishment of immunity to the tubercle bacilli and their toxins is the thing for which we are striving. The main issue has been befogged by so many and such varied therapeutic suggestions that we have failed to grasp the true purport of our endeavors. Open air, hygienic living, rest, exercise, diet, various mechanical devices and tonic measures have been put forth as cures, and, while we must assign to them their due part in the cure of tuberculosis, yet we must not allow them to detract from the one necessity to cure—the establishment of immunity to the bacillus and its toxins.

In our discussions of bacterial immunity we must not forget that different individuals react differently to the same stimulus. The question of disposition and predisposition must not be so entirely ignored as it has been in the past. Inherited qualities, mental attitude and physical condition are important factors in determining the manner in which the individual is going to react in the presence of a given toxin. While I shall not refer to this point again, I desire to have it understood as recognized throughout the discussion.

The production of immunity in tuberculosis is surrounded by many difficulties, in fact, it may be doubted whether such a thing as an absolute immunity is attainable; nevertheless, careful clinical observation and animal experimentation reveal the fact that we have a much higher degree of immunity in this disease than is apparent at first thought.

A certain degree of immunity to tuberculosis is probably inherited by the child of civilized races where the disease is prevalent; but, no sooner is it born than the conflict between it and the bacilli begins. The acquiring of immunity to tuberculosis probably goes on very rapidly during the first few years of life, as is evidenced by the gradual decrease in the number of acute cases of tuberculosis as the child increases in age.

Careful students of the question are now coming to the conclusion that tuberculosis is a disease which lasts over a period of years, during much of which time it produces no well recognized symptoms. It is now quite generally believed that childhood is the time when most infection occurs. In a careful study of this subject made by the author several years ago[1,2] attention was called to the fact that the habits of the child in living so much of the time on the floor where bacilli are most apt to be found, its liability of being fondled by everyone on account of its helplessness, its unhealthy condition due to living in bad surroundings, errors in diet and consequent catarrhal conditions of the digestive tract, all point to this as a time favorable for infection to occur. To this must also be added the multitudinous opportunities for the contamination of the child's food. Recent studies of Hamburger,[3,4] von Behring,[5] von Pirquet[6] and others show us that a very large proportion of children (in Vienna a majority) are infected with tuberculosis during the first four or five years of their lives. The cutaneous and conjunctival tuberculin tests have added much to our knowledge of the time when tuberculous infection takes place. The proper conception of the conflict which takes place between the human organism and the tubercle bacillus requires a most careful inquiry into the conditions which surround the early months of life. Almost from the time the child is born, and in tuberculous families from the first few hours after birth, the child is placed in contact with the bacilli of tuberculosis. If the bacilli are taken into the body in small numbers the defensive forces of the infant's body are probably brought into action and the invaders repulsed. Resulting from this destruction of bacilli, toxins are set free which further stimulate the machinery of immunization and a certain degree of immunity is produced. From this the child is better able to cope with further inoculations of bacilli which take place. Doubtless in this manner many inoculations of tubercle bacilli are overcome during the early months of life. But the exposure of the child to tubercle bacilli in civilized life is more or less constant. Soon it is inoculated with more bacilli than it can destroy, its defensive forces are overcome and an infection results. In some cases, especially during the early months of life, this leads to immediate active clinical tuberculosis; but the great majority of children, especially those infected in the late years of childhood, attain a certain degree of immunity, recovering temporarily, at least, from their infection, the disease becoming quiescent for a longer or shorter time and producing no marked symptoms. In some instances the disease seems to interfere with the growth and development of the child, but in the great majority its presence is not suspected.

For some time it has appeared to me that patients suffering from tuberculosis must develop a certain degree of immunity to the bacilli producing their own infection at least; otherwise, they would have no chance for life against the countless myriads of bacilli which are thrown out into their air passages and which are swallowed by them daily during the period of a long illness. But in spite of this opportunity for inoculation, which is present even for

*Read before the Medical Association of the Greater City of New York, March 21, 1910.

years in many instances, patients recover. If the number of bacilli which are found more or less constantly in the air passages of patients with open tuberculosis of a moderately advanced degree were placed in the air passages of healthy individuals, or, if the number swallowed by such patients were injected into the alimentary canals of healthy individuals we certainly would expect infection to result.

Recent experiments of Calmette,[7] Hamburger,[8] Römer[9] and others show that through the first infection an immunity is developed, which affords protection against further infection from both the bacilli within the body and from those coming from outside sources. Guinea pigs, rabbits, sheep and cattle which have been once infected with tuberculosis show a resistance to a second infection that can only be accounted for by the presence of a considerable degree of immunity.

It is a self-evident fact that the greater the degree of immunity present the more chronic the disease. This is noted in the manner in which tuberculosis destroys people who have not been previously inoculated with the disease, such as the Africans and people of the Faroe Islands, as compared with the way it affects the inhabitants of Europe and America. It is also noted in children in the early months of life when compared with children in later years. During the first year of life tuberculosis is nearly always acute, assuming the form of meningeal or acute miliary. Hamburger[3] gives the following interesting statistics of tuberculosis in childhood as presented by postmortem evidence at the St. Ann Kinderspital, Vienna, from 1903 to 1906 inclusive:

TABLE I—MORTALITY OF TUBERCULOSIS BY AGE PERIOD

	I One Year			II	III	IV	V	VI
	From Birth to 3 Mos.	4–6 Mos.	7–12 Mos.	2 Years	3–4 Years	5–6 Years	7–10 Years	11–14 Years
Number of cases		49		74	102	38	41	31
	4	13	32					
Fatal cases		44		51	69	23	28	16
	4	13	27					
Per cent. of fatality		90%		70	67	60	68	50
	100	100	80					

TABLE II—FREQUENCY OF HEALED TUBERCULOSIS BY AGE PERIODS

	1 Year	2 Years	3–4 Years	5–6 Years	7–10 Years	11–14 Years
Total number of cases	49	74	102	38	41	31
Number with signs of healing	0	0	7	4	7	10
Per cent. of healed tuberculosis	0	0	7	10	17	33

and also cites the following table from Hamburger and Sluka[10]:

TABLE III—RELATIVE FREQUENCY OF ACUTE AND CHRONIC TUBERCULOSIS BY AGE PERIOD

Cause of Death	I	II	III	IV	V	VI
	1 Year	2 Years	3–4 Years	5–6 Years	7–10 Years	11–14 Years
Miliary or meningeal tuberculosis	13	19	28	10	8	2
Chronic general or pulmonary tuberculosis	7	6	6	1	4	6
Total fatal cases	20	25	34	11	12	8

These statistics show that tuberculosis is nearly always fatal in the first years of life; in 90 per cent. the first year, 70 per cent. the second, with a gradual decrease, so that by the time puberty is reached the mortality has fallen to 50 per cent. Another interesting fact is found in Table II. No tendency to healing was manifested during the first and second years and only in 7 per cent. in the third year. By the time puberty is reached signs of healing appears in 33 per cent. Table III shows that of 20 cases in the first year of life 13 were cases of acute miliary or meningeal tuberculosis; of 25 cases in the second year 19 were acute miliary or meningeal tuberculosis, and of 34 in the third year 28 were of this form, while between the eleventh and fourteenth years of 8 cases only 2 were of these acute forms.

If we undertake to explain why tuberculosis is so much more fatal, and why it takes the rapid form with little attempt at healing in these early years, we are led into a very interesting field of speculation; yet, one on which clinical observation and animal experimentation shed much light.

We can safely say that children have a certain inherited immunity to tuberculosis, the degree being variable, but, probably, in no case absolute. It is probably sufficient in most cases to ward off inoculation of small numbers of bacilli, but not sufficient to protect against large numbers of a virulent strain. We might assume, however, that it is sufficient to stimulate the machinery of immunization, and that by a repeated number of small inoculations the child develops a considerable degree of immunity. Unless the child associates intimately with tuberculous people or is brought intimately in contact with bacillus-bearing materials such as contaminated food, bedding, clothing or table utensils used by tuberculous patients in such a manner as to expose it to great numbers of bacilli, the time of infection is postponed until the child develops sufficient immunity to prevent the disease from assuming the rapid form; but, where the association is more intimate and the child is inoculated with greater numbers of bacilli or with bacilli which are more virulent, the rapid form is the rule. The younger the child under all circumstances the more apt is the disease to be acute, because there has not been the opportunity for developing an immunity. It is a common thing for children who associate with careless consumptives, especially those in the first years of life, to die of miliary and meningeal tuberculosis.

Acute miliary and meningeal tuberculosis are rarely, if ever, found in adults except as a result of a rapid dissemination of bacilli from some previous focus. It is probable that a degree of immunity far greater than we have believed protects patients suffering from tuberculous infection from an extension of their disease, and that the extensions which do occur are the result of those bacilli remaining after the defensive forces of the body had spent themselves in endeavoring to overcome enormous quantities of bacilli which had broken into the blood stream.

Regardless of the immunity which children develop, sooner or later they nearly all become infected with tuberculosis. This early infection, however, is not an altogether unmixed evil, for if it heals, as will be seen from animal experimentation, it leaves behind a considerable degree of immunity; and, even if it does not heal entirely, it still seems to protect the patient against further infection.

The degree of immunity developed in the experimental animals depends upon the numbers and

virulence of the bacilli with which they are primarily inoculated. We must assume that there is a dividing line somewhere, in virulence and numbers of bacilli for each animal, on one side of which there is the production of immunity without infection, or with a slight infection which results in healing, and on the other side an infection which does not heal but which nevertheless is accompanied by a degree of immunity.

The experiments of Trudeau,[11] von Behring,[12] Pearson and Gilliland,[13] Neufeld,[14] Römer,[9] and others show definitely that previous inoculation with bacilli of different strain or weakened virulence produces an immunity against a second inoculation with virulent cultures, which is able to lengthen the life of the animal far beyond that of the controls and also cause the disease to assume a chronic course.

No less significant is the experiment of Vallee,[15] who reports the case of a cow which reacted to tuberculin but later lost the power of reaction owing to a spontaneous healing. Vallee inoculated this animal, together with controls, with a large dose of virulent tubercle bacilli. While the controls developed virulent tuberculosis this animal remained well and when killed showed only calcified mesentery glands which Vallee considered as resulting from the primary disease. The spontaneous healing he interpreted as being the cause of the immunity.

These experimental facts when interpreted in accordance with clinical observations help us to understand tuberculosis better.

Until recent years, no one thought of mentioning immunity in connection with tuberculosis. Clinical diagnosis of tuberculosis was in such a demoralized state that eminent clinicians doubted that patients suffering from it ever got well. A feeling of hopelessness was attached to every phase of the subject. As we learn more of the disease, however, we are forced to conclude that it is a disease that has a tendency to self cure and that while nearly all people are infected some time during their lives only a comparatively small number die of the disease; that while the disease is active and even destroying the patient, there is a degree of immunity present which still protects him to a certain extent. Although the tendency to heal seems greatest in lesions which are not very extensive, yet any one who has closely observed advanced cases of tuberculosis has at times been astonished to see a very extensive lesion heal. In fact, we must look upon both cavity formation and fibrosis as being expressions of chronicity and results of the successful action of the protective forces of the body. They are proofs of the presence of a degree of immunity.

In experimental animals there is a wide difference between the primary and secondary inoculations with tubercle bacilli. A guinea pig, which is already infected with tuberculosis, shows upon reinoculation with moderate doses of bacilli a slight reddening at the point of inoculation on the following day. After a few days this disappears and the regional lymph glands do not show pathological swelling. In many cases no further symptoms result, the pig regaining full health. A pig, the subject of a primary inoculation, on the other hand, shows no reaction at the point of injection on the day following, but about ten days later an infiltration appears at the site of the inoculation and the regional lymph glands are swollen. If the dose of bacilli is very large the reinoculated pig may die within a few hours as a result of hypersensitiveness, while the control receiving the primary inoculation lives several weeks, to die of tuberculosis. If the dose of bacilli used in reinoculation be too large to be successfully thrown off by the reinoculated animal, yet not large enough to kill the pig by a hypersensitive reaction, it may produce an infection, but the influence of the previous inoculation will be in evidence in causing the infection to assume the type of chronic tuberculosis. While pigs inoculated with non-virulent cultures are rendered immune to bacilli from without, the bacilli within their own bodies may continue spreading the disease, because large quantities of bacilli are every now and then being thrown out into the tissues from the original focus, some of which the protective forces of the animal are not able to destroy.

It seems that we are justified in assuming that the primary infection in tuberculosis is a very important one from the standpoint of the future resistance of the patient to tuberculosis.

If this infection is produced by very virulent bacilli or great numbers of bacilli, the patient will likely succumb to acute tuberculosis. If it is produced by few bacilli or bacilli of low virulence, no infection may occur at all or one which may later result in healing, leaving the individual with a certain amount of immunity. If an infection results but is again prevented from spreading, although not healing, it may yet be able to modify future reinfections and, reasoning from animal experiment, prevent them from occurring. It seems probable that reinoculation from without with ordinary doses of bacilli in an individual who is already infected, or in one who has a healed lesion, could do no more than produce a chronic type of tuberculosis. Of course it remains to be determined how long this immunity will last.

The question which interests us as clinicians is how to utilize these facts for the benefit of mankind, how to make this immunity, the presence of which is demonstrated by both animal experiment and clinical observation, of greatest value to those who are afflicted with tuberculosis.

The following principles seem to have especial clinical significance:

1. A primary tuberculous infection affords immunity against reinoculation.
2. A healed lesion affords immunity against reinoculation.
3. A primary infection may afford protection against reinoculation from without and yet the animal die of reinoculation from the focus within its own body.

From this it can be seen that the patient who is cured of tuberculosis has an immunity against reinfection. When we speak of cure in tuberculosis, I realize that we are speaking of an uncertainty. It is a very difficult thing, except by control tuberculin tests, which are not resorted to as often as they should be, to tell when a patient who has had an infection is cured, in fact, it is probable that a very large proportion of patients who are treated for tuberculosis and in whom a satisfactory state of health has been attained are not cured. On the other hand, we have reason to believe that many are cured and spontaneous healing is common.

From the nature of the pathological picture in tuberculosis, it is evident that a cure is easiest of attainment when the lesion is small, because the cure comes about through the body fluids, which are shut off from the tubercule as it grows in size and undergoes degeneration.

Clinical results show that whereas about 75 per cent. of incipient cases are attaining an apparent cure as treated to-day only a very small percentage of far-advanced cases can obtain this result. The problem of curing or immunizing the patient, then, requires the employment of treatment while the involvement is still small, while the tissues are more easily penetrated by immunizing bodies and while the danger of the disease spreading is not so great.

Knowing that nearly all children are infected before the fourteenth year the question must be seriously considered whether it is not the duty of the medical profession to seek out by the tuberculin test those children who are infected and give them the benefit of treatment. It is probable that such a course would not be approved. It might be considered that patients are being treated, who, if left to themselves, would heal spontaneously. Such a course would, however, have the effect of letting the patient and the physician who makes the test know that the individual was infected and then place both on guard for the future. Then in case any suspicious signs presented themselves the patient could be treated at once.

Our method of treating tuberculosis, while effective, is far from satisfactory. The disease has a tendency to become quiescent, when the infection is small. But, unfortunately, it will often remain in this latent or quiescent state for a long time, producing no symptoms but yet not healing. Such lesions can sometimes be kept in ckeck for a long time by careful hygienic living, yet they are not entirely free from danger to the patient, and should be cured if possible.

During recent years the specific or immunizing treatment, as it is sometimes called, has been rapidly gaining friends, because it is well established that patients treated by the various tubercle bacillus vaccines come more nearly attaining a lasting cure than those treated without them, as is shown by the fact that they do not relapse so frequently. If patients, who have small lesions, corresponding to the incipient stage of clinical tuberculosis, are treated under the best hygienic conditions with close, intelligent medical supervision, and given the advantage of the intelligent employment of tuberculin, and treated not for a period of three months, but until the signs in the chest have disappeared, or until the best result attainable has been produced, I believe that we are justified in hoping that more than 80 per cent. can be permanently cured. It is unfortunate that the time required for treatment in this disease is so long, but we only defeat our purpose in shortening it. The average time for treating incipient cases of tuberculosis in my practice has been about five or six months, the result of treatment has been an apparent cure in 87 per cent. with a relapse of less than 10 per cent.

The way in which tuberculin acts is unknown, but that it has a specific effect in the production of immunity is accepted. Experiments on animals by Koch[16 17], C. Spengler[18], Calmette[7], Denys[19], and others show that tuberculin will protect animals sometimes wholly and sometimes partly from infection. It also produces the same hypersensibility to a reinfection that a primary inoculation of living bacilli does, as was shown by the experiment of Courmont[20], who treated a guinea pig with extracts of tubercle bacilli and produced such a hypersensibility that the animal died of the reaction following a dose of virulent bacilli. It may be stated as a general rule, however, that living bacilli produce the greatest immunity and that the more virulent the strain of the bacilli with which the animal is previously treated the greater the immunity. A substance like tuberculin, however, which will produce a specific hypersensibility on the part of an animal to living tubercle bacilli must be considered as an immunizing agent against the bacilli, for hypersensibility is intimately associated with immunity. To quote from Römer[21]: "I am now in the habit of looking upon this hypersensibility not only as an accompanying symptom of immunity, but to recognize in it the cause, or at least one of the causes, of artificial immunity." Wolff-Eisner[22 23] believes hypersensibility to tuberculin and to tubercle bacilli to be the same.

Animal experimentation shows:

1. That animals previously treated with tuberculin develop a certain degree of resistance to infection with virulent bacilli, and that even where infection is not prevented the course of the disease is somewhat retarded.

2. That animals treated with tuberculin develop hypersensibility to living bacilli, which indicates that it has the power of producing immunity against them.

During the past fifteen years I have employed tuberculin therapeutically and have used it cautiously, yet with more boldness than most clinicians. I have employed it in all stages and on patients showing all types and all complications of the disease. My experience leads me to conclude:

1. That a sufficiently long treatment with tuberculin (five or six months on the average) will immunize or cure a very large percentage of incipient cases of tuberculosis, nearly all prior to the open stage.

2. That when properly given in the more advanced cases tuberculin fortifies the patient by an increased immunity so that he is better able to prevent reinoculation from the bacilli which escape from the focus of his disease, as is proved by the fact that a larger percentage of patients so treated attain an apparent cure and by the further fact that they are not subject to so many or such severe tuberculous complications as are found when they are not so treated.

3. That tuberculin modifies the course of the disease by increasing the patient's immunity as is evidenced by the fact that the disease usually assumes a more chronic course during its administration, cases running a rapid course being often converted into the chronic type.

4. That further evidence of the specific immunizing action of tuberculin is shown in the fact that such complications as tuberculous laryngitis, genitourinary tuberculosis, fistula in ano, articular, osseous, and glandular lesions, in fact, tuberculous lesions of any kind, wherever found, may be healed by its employment.

5. That tuberculin establishes a degree of immunity much greater than that attained by ordinary hygienic measures as is further shown by the fact that patients so treated have less tendency to relapse than where it is not used.

While the intelligent use of tuberculin offers the patient suffering from tuberculosis the greatest opportunity for establishing immunity and improving or curing his infection, yet its proper administration is so difficult that comparatively few patients who are being treated with it are receiving the full advantage which can be gained from its use. My long experience teaches me that it is probably the

most difficult remedy that we have to employ. While many schema have been published showing the size and increase as well as intervals between doses, yet the proper administration knows no regular dose and no set interval. It cannot be given to the greatest advantage except by studying the capacity and reactive powers of each patient. In one patient it is possible to attain a dosage in one month that cannot be reached in another in two or three months. Tuberculin treatment is much more than the injection of tuberculin, the same as operations are much more than cutting through tissues. It implies most careful individualization and the application of all other rational measures which will fortify the patient and increase his power to produce specific immunizing bodies.

These statements are not made for the purpose of hindering the intelligent use of tuberculin, but, if possible, to use whatever influence I possess against the reckless, ignorant way in which it is often employed to-day. Believing as firmly in the power of tuberculin to produce a specific immunity in tuberculosis as the surgeon believes in the power of the knife to remedy operable conditions, I hope that the time will soon come when those suffering from tuberculosis may be given the benefit which its intelligent use offers, at a time when the lesion is still small and an apparent cure may safely be expected.

UNUSUAL COMPLICATIONS OCCURRING IN THREE CASES OF RHIZOMELIC SPONDYLOSIS.

By EDWARD MERCUR WILLIAMS, M.D.,

PHILADELPHIA, PA.

ASSISTANT IN CLINICAL NEUROLOGY AND NEUROPATHOLOGY AT THE UNIVERSITY OF PENNSYLVANIA.

The three cases of rhizomelic spondylosis herein reported, which were examined by me in Dr. Spiller's service at the University of Pennsylvania and the Philadelphia General Hospitals, present complicating conditions of considerable interest and importance, among which are great weakness of the muscles of both legs with permanent unilateral toe drop, sensory changes resembling those found in syringomyelia, and an unusual form of vertebral exostoses.

While stiffness and ankylosis of the spinal column have been described by some of the oldest writers, it was not until more recent years (1892-1893) that Von Bechterew first called attention to a particular and well-defined form of this disease. Von Bechterew's type is characterized by a predominance of nerve root symptoms with the absence of any joint involvement other than of the vertebral articulations and depending for its symptomatology upon a meningitis with involvement of the spinal roots and a deformity of the back secondary to paralyses of the muscles.

In a type of the disease later described more particularly by Marie and Strümpell, the so-called rhizomelic spondylosis, little, if any, involvement of the nerve roots occurs, or at least the symptoms of their involvement are not very pronounced in this form. The large or proximal joints are, however, involved in these cases together with the vertebral articulations, but the small or distal joints are not affected.

Neither of the above forms in typical cases is the same as arthritis deformans. In the latter affection there occur, not only deforming ankyloses of the vertebræ—the pathological change in the vertebræ in the other two forms consisting only of change in consistency of cartilages and flat overgrowth of bones of the vertebræ of a nondeforming character—but also typical joint changes elsewhere, particularly, of course, in the small joints, where the deformities of this disease are generally first found.

Besides the distinct types given above there are also gradations of the different forms, these being probably of more frequent occurrence than the classical cases.

Case I.—J. Y., a Russian laborer, age 30 years, was admitted to the University Hospital October 9, 1909. The patient came to the hospital complaining of pain and weakness in the legs and back. There is no history of tuberculosis or rheumatism in the family. The father died of cancer of the stomach and the mother of apoplexy. The patient always was well until the present illness, which began five years ago, as pain and weakness in back and in the legs, the patient being unable to lie down on account of the severity of the pains. The pain was particularly marked in the lumbar region and in the upper part and the back of the thighs. There were never any symptoms in the upper part of the body, the head, or the upper extremities.

The pain and weakness have increased to the extent that the patient is confined to his bed and can only move about with the greatest difficulty, and by aid of crutches. Paresthesias, tingling, and

burning sensations are present in the left leg below the knee, and sometimes in the right leg and the left thigh. Pain in the back and legs has become worse. There was never any disturbance of the bowels or the bladder.

The heart and lungs are normal. The head and the cranial nerves are normal. There is no ankylosis of the jaw, nor trophic disturbances of the upper part of the body, the head, or the extremities. There is no wasting or deformities. The upper extremities show no sensory or motor involvement, and no ankyloses. Active and passive movements are normal. The biceps tendon reflex is slightly increased on either side. The triceps jerk is about normal on both sides. There is considerable tenderness on pressure over the muscle bundles on either side of the spine, but this is particularly marked on the right side in an area extending from the tenth dorsal to the second lumbar vertebra, and for a few inches laterally along the last ribs. The spine is not completely fixed as there is some power of rotation with slight ability to flex and extend the spine, but these movements are only in the dorsal and cervical regions; any attempt to move the lower spinal vertebræ causes intense pain.

Sensory changes: The patient, while at first only complaining of paresthesias in the lower legs, now has these sensations in the thighs and a feeling of constriction around his waist. The nerve trunks in the calves of the legs and just above the knees on both sides are very tender upon pressure, a condition having appeared only in the last few days. Tactile sensation is not impaired in any part of the legs. Pain sensation by the pin point test is absent in an area over the anterior part of the right thigh, extending down to the knee. There is also a similar area in the left leg, extending from just above the knee to about three-fourths of the distance to the ankle and half way around the front of the leg. This area is continued still further to the ankle as an area of hypalgesia. Heat is not recognized as such (by test tube method) in an area on the right lower leg extending from just above the knee downwards over the lower leg, with the exception of a small area of retained sensation on the middle posterior part of the thigh (area about 3 inches by 2 inches). Changes in the left leg are about the same as the above except that here the area begins just below the level of the knee and there is no spot of normal perception posteriorly.

Cold is recognized as cold over all portions of the legs but in the areas mapped out above the quick responses are not elicited as in the other portions of the extremities. The muscles in both thighs are weak and movement is impaired, and in attempting to move his legs the patient complains of pain in the hip joints and back and in the muscles of the thighs. Movements in the hip joints are stiff and restricted and very painful. When first admitted movements were not so restricted and the impairment was due only to muscle spasm, but at present there appears to be a slight degree of ankylosis. Both lower legs are atrophied and cold and have a doughy appearance with glossy hairless skin. The feet are somewhat cyanosed and swollen, but do not pit on pressure. The power in the right lower leg muscles is diminished, especially in the extensor and peroneal groups and there is toe drop. This can, however, be overcome as patient has some slight remaining power in the extensors. The left lower leg shows great loss of power in the extensor and peroneal groups, and weakness in the flexors, and there is permanent toe drop. There is a very slight power of movement in the extensor brevis digitorum.

Electrical Examination: In the muscles of the right thigh and lower leg the response is slow but in normal series. Examination of left thigh and leg gives a reaction of degeneration (An Cl C> Ca Cl C) in the quadriceps group, hamstrings, and the anterior tibial and peroneal extensors of toes. The flexors of the toes and the muscles of the calf and the extensor brevis digitorum give normal but slow response.

Case II.—E. O., a teamster, age 33 years, was admitted to Philadelphia General Hospital Aug. 24, 1909, complaining of pains in the back and shoulders. There was nothing of importance in the family history. One year ago the patient had what probably was a chancroid, having had no secondary symptoms of any character, and no other venereal disease. At the age of eight he had pain in his knees, this, however, was not of acute rheumatic type, and as there are some of the other signs of rachitis present the pains in the knees were probably rachitic in origin.

The present illness began about four months ago (May) when the patient upon awakening had severe pains, sharp and stabbing in character, in the mid-dorsal region. This pain was not present when the patient lay quiet, but upon making any movement, such as turning or sitting up in bed, it became very severe, as it was also at times when the patient drew a deep breath. The pain always has the same sharp, stabbing character and extends along a line just to the left of the vertebræ, sometimes involving the neck and head. It does not radiate laterally or into the extremities. The patient has lost 17 pounds in four months.

Examination: The heart is normal. The lungs show consolidation of the right upper lobe. There are bony prominences at the left sternoclavicular articulation and at the costocartilaginous junctions probably rachitic in origin. The head and cranial nerves, with exception of disturbance in sensation, which will be mentioned later, are normal. There is no ankylosis of jaw.

The upper extremities: With the exception of impairment of motion in the left forearm, due to a previously fractured radius, the arms show no impairment or restriction of active or passive motion. Within the last month, however, the left shoulder joint has become to a certain degree ankylosed and interferes with the free movement of the arm. The reflexes are normal on the right, absent on the left for the above reasons.

Lower extremities: No impairment of active-passive movements is noted. The patellar tendon reflexes are somewhat exaggerated. The Achilles jerk is normal. There is no Babinski.

Sensation: Pin prick, over entire body, is only recognized as dull. Over an area including the face, anterior part of neck, and body down to the lower costal border, also both arms and shoulders with exception of the interscapular space and a small area on upper, outer, anterior, and posterior surface of the left upper arm. The patient recognizes cold as warm. On external upper surfaces of both thighs the patient distinguished cold and warm, but not so well as in the other normal areas. The palms of the hands are also normal. Cold is called warm in the right lower leg and this area extends up to about six inches above the knee, with a further extension upwards of a couple of

inches on the external (lateral) aspect of the thigh. The left lower leg has the same sensory changes but the area only extends above the knee in two narrow strips internally and externally situated, and extending to about four inches above the knee.

Vertebral column: There are stiffness and restricted movement of the vertebræ of the dorsal, the lumbar, and to a lesser degree of the cervical regions. Tenderness, upon pressure, is elicited in the muscles of the back to the left of the vertebræ and from the angle of the scapula to below the pelvic crests, and is most pronounced in the lumbar region.

Case III.—W. A., a painter, age 57 years, was admitted to Philadelphia Hospital Sept. 17, 1909. He complained of pain in the right shoulder and arm and limited motion and weakness of the right leg. The early medical and family histories contain nothing of clinical importance. He fell upon his back from a high ladder about a year ago and has had a stiff back ever since. He also fell from a trolley car in March, 1909, hurting the arm and shoulder and has at present a circumflex and musculospiral paralysis. About two months ago (July) the patient's right foot and ankle became swollen and painful and has remained so ever since. He cannot move the right leg and foot around in the bed. Two weeks ago he began to have dull pains in the hips, back, and back of the neck.

Examination: The heart and lungs are normal. The head and cranial nerves are normal. The left arm is normal in power and mobility, and the reflexes are normal. The right shows the characteristic changes of the peripheral palsies mentioned above. Upon electrical examination, besides reaction of degeneration in muscles supplied by musculospiral and circumflex nerves, there was diminished response to the faradic current in the infraspinatus and cervical part of the trapezius on the right side.

The left leg is normal. The right leg shows stiffness in the hip and knee joints with dull pain in the right hip and the bottom of the foot when patient tries to stand. Power is diminished though there are no paralyses of the muscles. The patellar tendon reflexes are exaggerated and crossed adductor contraction can be elicited. The Achilles jerk is also exaggerated, with at times a clonus. Flexion of the thigh and leg causes reflex rigidity and pain. The cremasteric, abdominal and plantar reflexes are normal.

Sensation: The temperature sense seems to be impaired except in the face and hands, as patient frequently mistakes hot for cold and *vice versa*. No tactile or pain disturbances occurs except in the right arm, where it is due to the peripheral palsy. The sternoclavicular joints are enlarged, as are also the costocartilaginous junctions of seventh and eighth ribs. The transverse processes of the cervical vertebræ, especially the sixth, are elongated and enlarged.

A few days after admission the patient developed a stiffness of the jaw, interfering with the movements in opening and shutting it. There is stiffness extending over the entire vertebral column and causing impairment of motion and stiffness in the patient's gait.

All three of these cases seem to conform to the type described by V. Bechterew, the root symptoms being the predominating and in the first case even causing a distinct muscular atrophy and double toe drop, this condition being permanent in the right leg. The possibility of palsies occurring in this condition has been mentioned by several writers, but I can find only one case in the literature, recorded by Heiligenthal,[1] in which reference was made to a peroneal palsy.

The trophic changes found in the lower extremities, in the first patient, brought to mind the possibility of the presence of a sclerodermal change; attention having been called to this possible complication or accompaniment of rheumatoid arthritis by Dercum,[2] the changes here present, however, though rather suggestive, were not sufficient to warrant such a diagnosis. That the above cases were not classical cases of the Von Bechterew's type can be seen when the involvement of the proximal joints is taken into consideration, such as was present in these cases and is characteristic of the Marie-Strümpell type. This brings up the question as to the probability of all forms, in time merging, more or less, into each other, and I do not believe a distinct type, as a rule, to exist throughout the entire course of the disease.

A fact of some importance, observed by Heiligenthal[1] and present in one of the above cases, is the intermittence or change in the condition of the ankylosed joints. This may go to such a degree that a joint apparently very stiff may later become practically free and then again become involved. This intermitting, if a patient were to be examined by different observers at different times, would no doubt lead to some confusion as to the type of the disease. Difficulty might occur in the differential diagnosis between this disease and syringomyelia, due to possibility of occurrence of dissociation of sensation together with spinal rigidity and kyphosis. This should, however, by careful study leady to no error in diagnosis as the signs, other than those mentioned, are in no ways similar.

The cervical exostoses in the third case, with the rheumatic diathesis and the rachitic enlargements, are interesting as having possibly some connection with a condition of body in which there is tendency toward this disease.

3326 Walnut Street.

ILEUS FOLLOWING LAPAROTOMY.

By A. H. LEVINGS, M.D.,

MILWAUKEE, WIS.

SURGEON TO ST. JOSEPH'S HOSPITAL.

During the past twelve months, six cases of obstruction of the bowels following operation have occurred in my practice, operative or consultant. It has seemed to me that the frequency and importance of this condition was not fully appreciated. I am also of the opinion that many cases of so-called peritonitis go to their death where one of the factors, perhaps the chief one, is obstruction.

Post-operative ileus may be divided into mechanical and nonmechanical. In the majority of cases, both factors are active. Obstruction of the bowels following laparotomy most frequently occurs in cases where there has been a localized or general peritonitis at the time of or following operation, and where drainage by some mechanical means has been employed. The mechanical form is frequently caused by the formation of adhesions between the adjacent coils of intestine; between a coil of intes-

1. Heiligenthal, H.: "Recognition of Spondylosis," etc., *Deutsch Zeitsch. für Nervenheilkunde*, 1900.

2. Dercum, F. X.: "Scleroderma and Chronic Rheumatoid Arthritis," *Journal of Nervous and Mental Diseases*, Vol. XXV, No. 10.

tine and the parietal peritoneum; between a coil of intestine and the gauze drainage, or by the formation of bands over or beneath which a coil may fall or pass and become constricted. The nonmechanical or dynamic form is usually due to infection which acts upon the neuromuscular intestinal mechanism and produces paralysis. In the bowel, ptomaines, toxines, and gases are formed as the result of fermentation, decomposition, and bacterial growth, and produce distention and often profound systemic intoxication. Following every laparotomy there is more or less of a dynamic intestinal paralysis. This may be due in part to the use of morphine just before operation, to the handling of the bowels, exposure to cold, and to the toxins and ptomaines which accumulate in the intestinal canal during this quiescent period. If infection is present at the time of or occurs following operation, it will be the chief factor in irritating the abdominal sympathetic and causing dynamic obstruction. In these cases, peristalsis may be held in abeyance or arrested as the result of irritation of Auerbach's or Meissner's system of nerves (Starling).

When obstruction occurs due to mechanical causes, peristalsis above the seat of obstruction is greatly increased. The peristaltic wave can often be seen as it starts near the stomach and travels downward to the seat of obstruction. It may be felt by placing the hand over the abdomen and the rush of gas and liquid through the bowel can be distinctly heard. These peristaltic waves, when coupled with obstruction are very painful. They frequently occur every few moments. Vomiting is frequent and large quantities of fluid are ejected from the stomach. With excessive pain, obstruction of the intestinal contents absorption of toxins and ptomaines, tympanitis, vomiting, and inability to take food, the patient becomes in a short time greatly exhausted and soon dies. In both forms, the bowels are constipated but not always obstructed in the sense that daily evacuations may not occur with aid.

While it would be ordinarily held that a diagnosis of obstruction is readily made, I am free to confess that I do not think it is always an easy matter to differentiate which is the prominent factor or what kind of obstruction one has to deal with, or whether peritonitis is active or not. It is seldom that one of these cases is wholly one of mechanical obstruction, because, as a rule, there is more or less of peritonitis with septic absorption and fever. This fever, pain, and abdominal distention following laparotomy, even if there be some increase of peristalsis, is very apt to fix the surgeon's attention and perhaps make him believe he is dealing with a case of peritonitis or septic poisoning, more than with a case of obstruction of the bowels, but the three conditions are often joined.

In cases of general peritonitis, there is little or almost no peristalsis, but pronounced fever, high pulse rate, excessive tenderness, and a boardlike hardness of the abdomen in a case of pure and simple obstruction from mechanical means these conditions would be absent.

The following are the histories of six cases:

Case I.—Male, age 44 years, suffered from appendicitis with abscess. Operation on third day at patient's home. Abdomen opened and appendiceal region packed off with gauze; abscess opened and drained. On the fifth day following operation, and before all of the gauze had been removed, the patient was taken with violent and painful peristalsis, which came on quite suddenly, with nausea, vomiting, and distention of the abdomen. The patient grew rapidly worse. Twenty-four hours after the inception of these symptoms, the gauze pack was removed, the area washed out with normal salt solution, a finger introduced into the wound without an anesthetic, and the surrounding adhesions broken up. Following this, a wick of gauze was introduced, for the purpose of drainage. The symptoms of obstruction were relieved at once and the patient made an uninterrupted recovery.

Case II.—Female, age 25 years, unmarried, was taken suddenly ill with pain in the right iliac region, nausea, and vomiting. Ten hours after onset, temperature was 102°, pulse 120, the abdomen was tense and very sensitive to pressure. Patient was taken to St. Joseph's Hospital and a gangrenous appendix removed, which was free of adhesions. There was a quantity of milky fluid in the abdomen, which showed a pneumococcic infection. Two tubes were carried down into Douglas' cul-de-sac, giving vent to a large quantity of milky fluid. Before the patient left the table and while the wound was being closed, two quarts of an acetozone solution 1 to 10,000 was run through the tubes. The temperature the following day was 99.4° and the pulse 110. All went well for four days, although the pulse remained about 110 and the temperature ranged between 99° and 100.4°. At this time, the patient's condition changed for the worse. She became very restless and the upper abdomen much distended. There was decided pain and uncontrollable vomiting, with an absence of peristalsis. After trying to overcome the condition by stomach lavage and colonic flushing with out success, the distention increasing and the patient growing rapidly worse, the tubes and two stitches were removed and the wound slightly enlarged. At once a large distended coil of intestine made its appearance. The finger introduced alongside of this detected a collapsed coil. These were brought into the wound and a lateral anastomosis done with silk. The paralysis, pain, vomiting, and distention readily subsided, and the patient made a slow but good recovery. In this connection, the following nonoperative case of dynamic obstruction may be of interest:

Mrs. W., aged 34 years, mother of five children, youngest six weeks old. Recovery from confinement, normal. Taken ill, April 10, 1909, with pain in the lower abdomen. Temperature 103°. Pain of a colicy nature came and went and was associated with marked peristalsis in the upper abdomen. Vomited occasionally. Uterus somewhat fixed and tender on pressure, pronounced leucorrhea. After three days, the fever disappeared, but the pain continued to recur at intervals requiring morphine. Slight movement of the bowels following purgatives and injections. Patient's condition after five days was such that she was taken to a hospital. I saw her on the sixth day, her face was pinched, pulse 130, rectal temperature 99, abdominal tympanitis. Some tenderness, no great amount of muscle tension. Patient had had fecal vomiting during the day and had explosive vomiting of about one and one-half quarts of very offensive material, while I sat at the bedside.

Diagnosis.—Obstruction of the bowels, cause unknown. The abdomen was opened in the medium line. Omentum spread over intestines and adherent, loops of small intestine distended very red and adhering by a fibroplastic exudate. Considerable bloody fluid in the abdomen. There were adhesions

near the gall-bladder and down in the pelvis. In pulling up the cecum, which was normal, the appendix was found covered with a plastic exudate and about three feet of the lower end of the small intestine collapsed. The small intestine above this was very red and very much distended. There were no adhesions which could account for the collapse of the intestine. The dilated portion of the small intestine was brought into the wound, fixed by a few catgut stitches and a drainage tube inserted. A second tube was placed in the pelvis. The patient reacted well from the operation and the obstruction was relieved, but she died ten days after from toxemia and general exhaustion. Several weeks following the operation it was learned that she had at the time an acute gonorrhea.

Case III.—Mrs. J., age 34 years, entered St. Joseph's Hospital some four hours following rupture of an etopic gestation. She had been pregnant three months. About 5½ hours after the rupture, the abdomen was opened and found filled with fluid, blood, and clots. There was a ruptured sac connecting with the right tube. The broad ligament was ligated and the sac removed. The clots were pretty well washed out, a tube placed in the pelvis, and a wick of gauze packed down to the former site of the ruptured tube. The patient was put to bed in a sitting posture and did well for three days. The bowels moved and during this time there was no special nausea or vomiting. On the fourth day, there were symptoms of obstruction, violent peristalsis with pain, marked distention and frequent vomiting. The patient was restless and anxious. The peristaltic waves were frequent and were associated with nausea and vomiting. The stomach was washed out and an attempt made to move the bowels with enemata, but this failed. On the sixth day, symptoms were more pronounced. The peristaltic waves could be seen to start from the epigastrium and pass down to the pelvic region. There was much distention. During the sixth day, the gauze was removed and the bowels acted slightly with enemata. Patient restless and haggard. The condition was explained to the patient and her husband, as being one of obstruction of the bowels, due to adhesions and that the obstruction could probably be relieved by a slight operation, but both patient and husband refused to have the wound opened. Patient died on the ninth day.

Case IV.—Male, age 20 years. Patient had had the usual symptoms of acute appendicitis with rupture. Temperature 101°, pulse 110. The abdomen was opened and a gangrenous appendix removed. The abdomen was filled with a milky fluid containing colon bacilli. Two tubes were carried down into Douglas' cul-de-sac and the abdomen washed out with an acetazone solution, 1 to 10,000. The patient was put to bed in a sitting posture and did well for the first week, at which time the discharge had practically ceased. The tubes had been shortened and were then removed, being replaced by a small wick of gauze. The bowels had acted regularly with some slight assistance. The fever had practically disappeared and the pulse was ranging about 80. At the end of the first week, there was abdominal disturbance, with increased peristalsis, difficulty in getting the bowels to move, a rise in temperature to 100°, and an increase of pulse rate to 104. On the ninth day there was nausea and vomiting, marked abdominal distention, absolute constipation, increased peristalsis, and an anxious careworn expression on the patient's face. The patient was now losing ground rapidly in consequence of the pain, autointoxication, inability to sleep or take nourishment, and it was apparent that something must be done to relieve the condition. The gauze was withdrawn, the fistulous tract carefully washed out, and the wound slightly enlarged. A finger was introduced into the wound and followed a dilated coil of intestine which extended down to the region of the cecum, where the obstruction seemed to be caused by kinking of the bowel from adhesions. These were broken up, releasing the coil and a gauze wick inserted. The symptoms of obstruction immediately disappeared and the patient made a good recovery.

Case V.—Woman, age 32 years, had been ill two days with appendicitis, when admitted to the hospital. Temperature 102,° pulse 120. There was a rather small abscess situated in the right iliac region which was drained through an incision about two and one-half inches long. The appendix was removed and a drainage tube and a wick of gauze inserted. After the operation, the patient's pulse and temperature dropped to about 100. The fourth day following operation, the patient was nauseated and vomited several times. The gauze was removed. There was some distention of the abdomen and the stomach was washed out and the patient fed per rectum. On the sixth and seventh days, peristalsis and vomiting were markedly increased. The pulse was 120 and the temperature 102°. The patient looked careworn and much distressed. The abdomen was very sensitive to pressure. The tube was removed following thorough irrigation and two stitches and the wound broken apart, when a very much distended coil of intestine came into view. This was well packed off with gauze and a purse string suture of catgut introduced. The intestine was then opened and a small drainage tube inserted. The drainage was pronounced and gave great relief. After five days, the tube came away, when the wound was packed with iodoform gauze. The drainage became gradually less and ceased on the eleventh day following the introduction of the tube. The patient made a good recovery.

Case VI.—Mrs. J. entered St. Joseph's Hospital, November 4, 1909. For several years she had suffered from retroversion, with pelvic distress and pain in the back. For two weks before she entered the hospital, she had been confined to her bed with severe pelvic pains and a temperature ranging about 100°. On entering the hospital her temperature ranged from 99° to 101° and pulse about 80. The pelvis was filled with an inflammatory mass. She was kept in bed two weeks longer, during which time several hot vaginal douches were given each day and the bowels kept open. The fever disappeared and much of the inflammatory mass. The patient was very uneasy and impatient with her confinement and anxious to get home, consequently operation was undertaken. A curettement was done and then the abdomen opened. The appendix was enlarged, inflamed, and its tip imbedded in a mass of adhesions which covered over the entrance to the pelvis. The appendix was removed. In breaking up the adhesions, a small abscess connected with the right ovary was opened. The right ovary and tube, the latter much enlarged, were removed. The left tube and ovary were also in a mass of adhesions and were liberated. The left tube was greatly enlarged and was removed, but the ovary left. The uterus was brought into position. Several coils of small intestine were matted together

and adherent in the pelvis to the adjacent structures, especially was this true of the lower portion of the ileum. These coils were liberated. There was considerable bleeding following the operation and three strips of iodoform gauze were carried down into the pelvis. There was profuse drainage from the gauze and the patient suffered from gas. On the second day following the operation, her temperature was 99.6°, while the pulse ranged from 100 to 118. On the third day, her bowels moved three times, the highest temperature was 99.5°, highest pulse reached 116. She vomited twice on the third day. On the fifth day, pulse was 116, temperature 99.8°. There was a good bowel movement as the result of the enema. The patient was now very restless and suffered a great deal from gas, while peristalsis in the small bowel was very marked. The onward rush of the bowel contents could be easily heard, occurring every few moments. On the sixth day the stomach was washed out. Bowels moved twice by enemata. Temperature 100.2° and pulse 120. On the seventh day, the patient rested fairly well, temperature 99.5° and pulse 108 to 116. Following an enema there was a good bowel movement with considerable gas. The stomach was washed out and the patient vomited once during the day. On the eighth day, the patient looked haggard, the face was pinched, and there was very marked and painful peristalsis with distention. The peristaltic waves started in the epigastric region and passed downwards toward the pelvis where they became arrested. There was no relief from gastric lavage or colonic flushings. The patient was now losing strength and hope. She presented the picture of despair, and was willing that anything should be done that would give her the slightest promise of relief. The gauze pack had been removed on the fourth day. The wound was thoroughly washed out, the tubes were removed, and the wound was broken open, after giving the patient a few whiffs of ether. At once a greatly distended coil of small intestine appeared in the wound. This was attached to the parietal peritoneum with a few sutures of catgut and the coil packed around with strips of gauze. A purse string of catgut was inserted into the intestine and the patient turned upon her side and the bowel opened. This must have been during one of the peristaltic waves, for a stream of fecal matter was projected with force from the bowel over the side of the table for at least three feet. A quart or more of liquid feces was thus discharged in a few moments. A small tube was placed in the opening and fastened by the purse string suture and two additional catgut sutures. The drainage tube was secured in the mouth of a large bottle; the amount drained during the next few days was very large. Excessive peristalsis, nausea, vomiting, and the inability to take food were at once relieved and the patient's feeling of despair was replaced by hope. The patient improved daily and on the fifth day the tube came away. The leakage from the bowel was very considerable and an effort made to control it with gauze packing was only partially successful. The patient's bowels moved every day with an enema. On the tenth day following operation the patient was given a slight amount of anesthetic, the bowel separated from the abdominal wall, and the wound in the bowel closed by a continuous row of catgut sutures for the mucosa and a row of interrupted sutures for the peritoneum and muscular layers. The intestine was dropped into the abdomen and a small wick of gauze inserted down to the suture line, and the remaining portion of the wound closed. There was no leak from the suture line and the wound healed practically by first intention. The patient made a complete recovery.

The following conclusions may be drawn:

1. Obstruction of the bowels is not infrequent in abdominal work.

2. When obstruction occurs, it usually follows either local or general peritonitis, in which drainage has been resorted to.

3. In the mechanical form, peristalsis is increased.

4. In the dynamic form, peristalsis may be increased if but a coil of intestine is inflamed, while if general peritonitis occurs, peristalsis will be arrested.

5. The obstruction may often be relieved by inserting the finger and breaking up the adjacent adhesions.

6. No matter what the cause, whether mechanical or dynamic, providing general peritonitis be not present, if the stasis of the intestinal contents be overcome, great relief and probably a cure will be affected.

7. The securing of a distended coil of intestine in the wound and establishing of drainage is probably the most rational procedure.

8. The mechanical and dynamic forms may be distinct and separate, but are often combined.

THE MORE LIBERAL DIET IN ENTERIC FEVER.*

By THOMAS A. CLAYTOR,

WASHINGTON, D. C.

In November, 1905, I read a short paper upon this subject, which later appeared in the Medical Record of March, 1906. In this contribution was embodied a report of twenty-six cases of typhoid fever successfully treated upon a diet about as advised by Dr. F. C. Shattuck. As the severity of enteric fever varies so greatly it seems but fair to make a further record of the results in cases similarly treated since. The more liberal diet in this disease is gaining supporters year by year, as is evidenced by papers which appear in medical literature from time to time. Of course, many sufferers from typhoid fever are sure to die no matter what form of treatment is followed, but, from personal observation I am fully convinced that under this method the patient is far more comfortable and contented, is no more subject to hemorrhage, perforation, or other complications, and recovers his former flesh and vigor far more rapidly than when kept upon a liquid diet. If this is the case, there seems absolutely no reason for retaining the older method of feeding.

It is my custom to be guided largely by the appetite of the patient; that is, not to give anything but liquids until there is a desire for food. My daily question put to the sick man is—Are you hungry? If the reply is "yes," a soft boiled egg is ordered; the next day, two eggs, and on the following day, soft toast is added; then rice which has been boiled for four hours, scraped meat, apple sauce or baked apple, custards, etc. I have not yet resorted to forced feeding as advocated by Coleman (*Journal of the American Medical Association*, October, 1909). This author's results were excel-

*Read before the Medical Society of the District of Columbia, November, 1909.

lent but his dietary is, I think, somewhat more expensive than the average hospital could afford. His effort was to give food producing from 3,000 to 4,000 calories per day or about as follows: 1½ quarts of milk, 1 to 2 pints of cream, ½ to 1⅔ pounds of milk sugar, and from 3 to 6 eggs, with the addition of small slices of stale bread or toast, with as much butter as the patient wished. On this diet his patients lost but little weight and some even gained during the disease period. I shall present no argument either for or against this method of feeding as I have had no personal experience with it.

History of Dietetics in Typhoid Fever.—The history of dietetics in fevers has been well presented by Dr. J. B. Nichols in his Fisk Fund Prize Dissertation of 1907. Briefly, it is as follows: Hippocrates fed his fever cases chiefly upon "ptisan," or barley decoction; he also allowed, under proper conditions, wine, hydromel (honey boiled in water), or oxymel (honey acidulated with vinegar or acetic acid), but did not favor the free use of plain unflavored water and especially stated that milk was a bad thing to give in fevers. From the time of Hippocrates to that of Sydenham in the Seventeenth Century, the antiphlogistic method of treating fevers prevailed. Reasoning from the basis that fevers were sthenic, it was deemed proper, apparently, to reduce the vitality of the patient as far as possible by bleeding, purgation, emesis, and starvation. The food was limited largely to gruels and acidulated waters and occasionally acid fruits.

In the Eighteenth Century and down to about 1815 the antiphlogistic treatment was greatly abated in vigor, as it had been recognized that all fevers were not sthenic, some being of the asthenic or opposite type. The food used was chiefly farinaceous, thin gruels, etc., milk, and even eggs were allowed by certain physicians. From 1815 to 1840, the antiphlogistic plan of treatment again became very prevalent.

Graves, whose influence was chiefly felt between 1835 and 1850, has the credit of having fed his fever cases. When, however, we hear that he recommended well-boiled gruel with sugar and lemon juice or panada of which a spoonful was given every third hour during the day time only, we are able to form some idea of what the starvation plan must have been in those days. He also gave animal broths in the middle and later stages of the disease.

Since the seventies of the past century milk has been almost the universal diet in fevers. So wedded has the profession become to this diet that it takes considerable courage to brave the unfavorable criticisms of our brothers and make use of a more liberal food supply. I have passed through this stage myself, but every now and again have the fact recalled to me by the men who have followed my clinical work as students, who, while they are themselves fully convinced of the advantages of more liberal feeding, are afraid to advise it in their own cases, because of the popular prejudice of the laity, fostered by the profession, against anything but an absolutely liquid diet.

Many physicians are unnecessarily alarmed by a rise of temperature which not very infrequently is recorded upon the chart very shortly after the first digression from an absolutely liquid diet. This elevation of fever in some instances may be a coincidence, in others it may be more, but it should not deter us from the more liberal feeding. It has been my experience frequently to find that an interne, who has not yet become accustomed to my methods, has countermanded my orders of the previous day for an increase of food, because there has been a slight exacerbation of fever which he has attributed to the effect of the egg or the soft toast. I at once renew the order and assure him that there is no cause for alarm, and that in due time the temperature will again reach its former level. It has seemed to me that those patients who are fed from the time that they are first willing to take soft food are far less likely to show any ill effects from feeding than are those who have been so long starved. The latter are so ravenous when food is as last allowed that they are likely to bolt it without proper mastication; and it also seems reasonable to believe that the digestive juices, having been so long comparatively idle, may have diminished in amount and potency.

The Amount of Food Required in Typhoid Fever.—Anyone who has watched a case of typhoid fever through its usual course of six weeks, and has seen a strong and robust man reduced to a living skeleton scarcely able to drag himself around for weeks after the temperature has become normal, will be willing to concede that there has not been sufficient food given anywhere nearly to maintain the equilibrium between intake and output. But the fact can easily be reduced to figures. Thus it appears, according to Voit, that the average man weighing from 150 to 160 pounds (70 to 75 kilos) doing a moderate amount of work, requires a total food value of 3,000 calories per day to maintain the body in a good physical condition. It has also been estimated that the body at rest requires 2,300 calories. Now, the man suffering from fever, because of the greater energy evolved by that fever, would certainly require a larger food value than the same man in health. It has been estimated that the ordinary typhoid fever patient requires a 25 per cent. increase to meet the febrile increase in heat production, or approximately 2,875 calories. If 180 c.c. (6 ounces) of milk, representing 122 calories, be given every two hours day and night, the total food value received is but 1,464 calories, or 1,411 calories less than is required. It is not customary to wake these patients through the night to feed them, so that few receive more than nine feedings or a food value of but 1,098 calories or 1,779 calories less than they require. Those who have tried to raise the value of the daily food supply for a case of typhoid fever to the theoretically required 2,875 calories will be willing to agree that it is not an easy matter, chiefly because, until convalescence actually sets in, the patients have no desire for so large an amount of food. It is possible, however, materially to increase the caloric value by a varied diet over the 1,098 calories represented by the amount of milk ordinarily given. But even though the actual food value be not greatly increased, the variation from liquid seems to have a most beneficial effect. Those who have to chew their food seem to be much more alive than those who are not obliged to perform this function.

The selection of a diet for typhoid fever patients should depend upon the following: 1. It should represent a food value sufficient to maintain the body equilibrium as nearly as possible under the circumstances. 2. It should be easily digested. 3. It should be innocuous. Neither by its coarseness, bulky residue, gas-producing or other proper-

ties, should it have a tendency to cause hemorrhage or perforation. 4. It should be palatable, because it has been shown that this factor has an important bearing upon a food's digestibility.

As a practical illustration of a varied diet during the active course of the disease, I quote from the chart of one of my patients in the Garfield Hospital: F. F., a white boy, 16 years old, whose occupation had been that of a messenger. He was not large for his age, weighing probably in health not more than 112 pounds. He was admitted on the fifth day of the disease; his temperature reached normal on the thirty-ninth day, and he left the hqspital on the fifty-eighth, weighing 106 pounds, strong and well. His diet on the twenty-second day of disease, on which the temperature reached 104.4° F., was as follows:

	Amount	Caloric Value
Milk	38 oz.	782.8
Toast	2.13 oz.	266.56
Rice	6 oz.	192.6
Eggs	4 oz.	216.9
Butter	1 oz.	227.8
Sugar	3 drs.	47.4
White of egg (albumen water)		16.1
Total		1,750.16

It may be seen thet the caloric value is not very high, but the food was varied and all that the appetite demanded and was sufficient to maintain the patient in good physical condition. (It is easy to raise the caloric value of such a diet by increasing such elements as sugar and butter.)

In order to draw conclusions from a large number of cases as to the relative advantage of the liquid or liberal diet, Kinnicutt (Trans. Ass. Amer. Phys. 1906) has collected the following statistics: Those for the liberal diet are taken from the Massachusetts General Hospital, the Presbyterian Hospital of New York, the Monsall Fever Hospital, and the Kief Military Hospital, 733 cases in all. Those for the fluid diet were from the Johns Hopkins, the Presbyterian Hospital of New York, the Massachusetts General Hospital, the New York Hospital, and the Presbyterian Hospital of Chicago, 4,654 cases in all. While the 733 cases were the basis for computation for the percentage of perforation and hemorrhage, only 315 were available for the estimation of relapses, and 633 for mortality. The full number of 4,654 were available for all percentages under the fluid diet.

	Hemorrhage	Per Cent.	Perforation	Per Cent.	Relapse (315 Cases)	Per Cent.	Mortality (633 Cases)	Per Cent.
Liberal Diet; 733 cases	35	4.37	10	1.36	48	15.2	60	9.47
Fluid Diet; 4654 cases.	411	8.83	111	2.38	507	10.89	491	10.55

From this table, it may be seen that the relapse column is the only one showing any advantage in favor of the liquid diet, while the hemorrhage, perforation, and death rate are all less among the liberally fed.

I wish here to call your attention to the tabulated record of 44 cases of typhoid fever treated by me in the Garfield Hospital since my last report, published in 1906. The first table contains the 38 cases which recovered, the second, the 6 which died.

My cases treated at the George Washington Hospital and my private cases treated outside of any institution, I have not tabulated as yet, but I might say that I have been very fortunate with those which I was able to put upon a liberal diet.

TABLE NO. I—THOSE ON A LIBERAL DIET

Case No.	Day of Disease on Admission	Day of Disease Temperature Normal	Day of Disease Out of Bed	Total Hospital Days	Relapse	Hemorrhage	Highest Temperature	Complications	Result

TABLE NO. II—THOSE ON LIQUIDS ONLY

Case No.	Day of Disease on Admission	Total Hospital Days	Hemorrhage	Highest Temperature	Complications	Result
39	14	5	Yes	107	Perf.	D
40	7	10	Yes	105.4	Perf.	D
41	8	8	No.	106	Perf.	D
42		9	Yes	106.4	Hem	D
43	1	7	Yes	104.8	Hem.	D
44		5	Yes	104	Hem.	D

(I wish to thank Dr. Stewart, interne at Garfield Hospital, for his aid in the preparation of the tables here given.)

Among the 38 cases who recovered the shortest duration of fever was 10 days, the longest 66 days—average 28 days. There were nine relapses, rather a high percentage, but only one instance of hemorrhage and none of perforation.

These tables are, in a way misleading, since it would appear that all the patients who were fed recovered, while all who were not, from one cause or another, died. It should be pointed out that those who died were so ill from the very day of admission that they never became hungry, and, therefore, following the rule already mentioned, they were never offered anything but liquids. At the same time, it might also be claimed that some of those who were fed might have died, had their vital forces not been kept up by a sufficient amount of nourishment. If such a diet as Coleman recommends were given, it might be made use of in just such cases as are here described, that is, with patients who were too ill to chew their food.

Conclusions.—From the published reports of others, and after a trial of the more liberal diet in typhoid fever in my own practice, irregularly for about eight years and as a routine, when possible, for the past five years, I draw the following conclusions:

1. The patients are far more comfortable.

2. When it is possible to begin the varied diet early, they do not fall into that profoundly nervous state so often seen in the insufficiently nourished.

3. Neither hemorrhage nor perforation is more frequent than among those kept upon liquids, and delirium is less pronounced.

4. Convalescence is far more rapid. The patients get up in good condition and rapidly return to a normal physical and mental state.

1315 New Hampshire Avenue.

THE DOWD PHOSPHATOMETER:

FOR TAKING THE PHOSPHATIC INDEX OR PULSE OF THE NERVOUS SYSTEM.

By J. HENRY DOWD, M.D.,

BUFFALO, N. Y.

In the Medical Record of May, 1908, and June, 1909, the writer fully described the phosphatic index or pulse of the nervous system with the method of phosphatic estimation. Since that time many reports have been received where the index has made an open book of obscure conditions, also numerous inquiries regarding the apparatus.

The method and apparatus as described in the original articles are very simple, but of course necessitate either making measurements each time in cubic centimeters, or having a tubular glass marked showing the amount of urine or solution to be used, and the normal index. That an estimation and study of the phosphates in the urine is an important procedure in diagnosis and treatment, both of medical and surgical conditions, is fully borne out by, not only cases in the writer's practice, but in numerous reported instances occurring in the practice of others.

The taking of the phosphatic index can be compared only with urinary or blood examination, but is much farther reaching in importance. It must be remembered that the nervous system controls the whole economy in health and disease, and if this system is unduly excited or rendered almost useless by heavy withdrawal of its reserve energy, conditions may be aggravated or cease to improve as the case may be. The elimination of the phosphates shows most positively which of the conditions are present in the same way that the thermometer shows fever or oncoming collapse from a subnormal temperature.

Not only for the reason quoted heretofore, but for the benefit of the profession, the author has constructed a simple, cheap but accurate apparatus whereby the general practitioner can in ten minutes make many complicated conditions clear. This instrument, made by the Sands Surgical Instrument Company of Buffalo and the Adolph Levy Surgical Instrument Company of New York, is shown in the above illustration. It is a simple tube graduated to show the amount of urine and the amount of the solution to be added, and below are graduations showing the normal phosphatic index.

40 North Pearl Street.

Immediate and Remote Results of Resection of the Knee Joint in Youth for Tuberculous Lesions.—Pietro Calcagni reports 102 cases of resection of the knee joint, in children, which were done in the last ten years in the Hospital for Incurables in Naples. Of these he gives the detailed histories and many photographs of the condition before and after operation. Out of 102 cases, 8 were operated on by amputation; 5 were treated with cautery and immobilization; 89 were resected. Of these, 75 were completely cured; 7 had secondary amputation; 5 were incompletely cured; 2 died of intercurrent disease. After a cure has been obtained with deformity the author operates to remove the deformity, which is contrary to the general practise. It has resulted successfully in the author's hands. An osteocuneotomy of wedge shape, with the base in whatever direction was required, is done.—*Giornale Internazionale delle Scienze Mediche.*

Remains of Verbal Hearing in the Deaf Mute; Their Utilization in the Family and Socially.—Vincenzo Cozzalino represents the value of educating the remains of hearing, however small, in the deaf mute. Itard and Toyubu have systematized a method for this education. The first thing necessary is to arouse the interest of the deaf mute. The mind is undeveloped, images are those obtained by sight alone, intelligence and memory are torpid in a baby who has never heard. In a child older when deafness occurred there are generally remnants of hearing for portions of the scale, with lacunæ between, in which there is no hearing. If these remnants of hearing are not exercised they gradually become less from atrophy of the portions of the internal acoustic apparatus involved, and inertia of the cerebral center. By patience and careful training they may be reeducated and increased in amount. The joy of these poor people when they first hear something is pathetic, and their anxiety to improve and increase the amount heard. Education is carried out by acoustic-phonic exercises, used with care not to tire out the dulled hearing organs. The patients must be selected with reference to the condition of intelligence, and of the central and peripheral organs of hearing. Apparatus is used in the nature of a telephone which increases the volume of sound four or five times to the listener.—*Giornale Internazionale delle Scienze Mediche.*

The Climacteric and Preclimacteric Arteriosclerosis, a Consequence of Internal Secretory Disturbances.—Schuster of Bad Nauheim says that the frequency of the appearance of an early climacteric or rather preclimacteric arteriosclerosis, especially of the aorta, is notable in the female sex. The phenomena of the natural cessatio mensuum or artificial menopause find vent to a great extent on the circulatory apparatus causing rushes of blood, palpitation of the heart, or tachycardia. They should, therefore, be considered as a hyperfunction of the sympathetics, the suprarenal, and to a less extent of the thyroid and hypophysis, which we know, with certain restrictions as regards the two last named, stand in apposition to the ovaries, which belong to the autonomous group of organs. If the suprarenal bodies during the preclimacteric gain predominance over a hypo-, or even hyperfunctioning, thyroid, an adrenal influence is established which has been experimentally shown to produce changes, especially in the aorta, closely resembling arteriosclerosis. In hypofunction of the ovaries, enlargement of the suprarenal bodies has been observed. Hypofunction of the ovaries is often associated with hyperfunction of the suprarenal glands. The ovaries have, however, still other intensive relations above all with the thyroid. Hypofunction of the thyroid occurs with hypofunction of the germinal gland. Hypofunction of the ovaries is thus often combined with hypofunction, or with hyperfunction, of the thyroid. Excision of the thyroid may produce arteriosclerosis of the aorta and hypertrophy of the suprarenal gland. Briefly, the preclimacteric hypofunction of the ovaries, alone or coupled with hypo-, or eventually with hyperactivity, of the thyroids, leads to hyperfunction of the suprarenals and to arteriosclerosis, particularly of the aorta. There are other similar combinations, *i. e.* diabetes (hypofunction of the pancreas with hyperfunction of the suprarenal bodies) is often complicated with impotence (hypofunction of the germinal gland) and arteriosclerosis.—*Fortschritte der Medicin.*

HEREDITY AND ENVIRONMENT.

As the earth becomes more populated, far-seeing persons are turning their attention to the conservation of its natural resources. The question of public health is closely allied to the conservation and care of natural resources. It is for both the material and the physical welfare of man that the country should not be wholly denuded of its forests, and it is certainly for the good of his health that rivers, lakes, and streams should not be foully polluted. In the United States and in Canada the principles of conservation have been adopted, and it is to be hoped that in the near future the water supplies on the entire continent of North America will be thoroughly safeguarded against contamination. When this has been done, a step in advance as regards public health will indeed have been made, but there are other matters intimately related to public health which also call for immediate notice. The cities congested with people are producing a physically and mentally inferior stock and at so rapid a rate that the average ability and capability of the whole community are being lowered. In Europe the situation has reached the acute stage, but it is only in England that the question has been seriously considered from the standpoint of eugenics. Emigration used to afford a safety valve to some extent, but now neither this country nor Canada will admit those termed undesirables, the people that Europe is most anxious to get rid of, so that the problem of how best to deal with this class must be faced at home.

The problem is intricate. In Europe and especially in Great Britain, and in this country in a lesser degree, the state of affairs is this: In the large cities and in the poor parts of these in particular, the population is increasing by leaps and bounds. That is to say, the most prolific urban inhabitants are generally speaking wretchedly poor and not infrequently vicious and criminal. The point is, what is to be done to stay this form of propagation of the human species, or, perhaps, rather what steps shall be taken to uplift the masses. The decision to be arrived at is whether the next generations of city dwellers are to be recruited from the five-cent show, the music hall, the skating rink, the unsanitary dwelling and factory, or from a healthier, purer, and more elevated environment and class. In brief, it is a question of breeding and environment.

Galton says that the possibility of improving the race of a nation depends on the power of increasing the productivity of the best stock. This, he believes, is far more desirable than that of repressing the production of the worst. Civilization has done away with the elimination of the unfit to a great extent. The days when an individual who could not earn his living or get his living had to die have gone, and man is no longer subject to the unrestrained laws of natural selection. For example, he prevents some diseases and cures others, makes life possible for the feeble, the ailing, and the malformed and affords them the opportunity of propagating their kind. By some of his laws and customs, indeed, he sets the principle of natural selection at defiance and seems to pave the way for physical and mental deterioration and even for degeneration. Rousseau and his school held that civilization involved degeneration, but without going so far as this it may be said that where civilization is, there also is degeneration.

Are the schemes of Galton and of others for improving the human stock feasible or, if feasible desirable; and are the plans for limiting the reproductivity of degenerates and of diseased persons practicable or do they commend themselves to the intelligence and sense of justice and humanity of scientific men and of the community at large? The measures suggested up to the present time for improving the human stock by careful mating or by judicious repression of reproductivity do not come within the sphere of practical politics, or, at any rate, the mass of the people are not educated to that point as yet; nor if feasible are these measures altogether desirable. After all man is more dependent upon brains than upon muscle. The mental powers of a Pasteur, a Koch, or a Lister are worth more to the world in every way than the muscles of a Jeffries, a Johnson, a Grace, or a Hanlan. The puny, sickly, or deformed child, which in primitive circumstances would have succumbed to the law of nature known as the survival of the fittest, may possess, often, indeed, has possessed, the brain of a great discoverer. As a matter of fact such a child in civilized life is as fit to survive as the primitive splendid *animal*. Both are creatures of their environment. Physical excellence is to be desired and every legitimate means should be taken to attain it for a race, but this does not prove that it would be wise, if possible, to try to improve the species by select mating and by methods to prevent the breeding of the unfit. Manifestly, there are congenital animals and persons suffering from certain physical and mental diseases who should not marry, and it would be to the benefit of all if such were not permitted to propagate their species, but to lay the ban upon those wishing to marry because some scientists might say they were unfit will not, in existing circumstances, meet with the assent of the laity. The most potent remedy for the present condition of things is to render it easy for people to live

under healthy conditions, in the country for choice, but if in the city in as healthy a manner as can be attained therein. If little or nothing can be done now to improve the breed by the methods discussed above, much can be effected as regards environment in country as well as in town.

THE FUNCTIONS OF THE THYMUS GLAND.

To the majority of medical men the chief, if not the only, function of the thymus gland appears to be that of scapegoat for all cases of sudden death under anesthesia, an opinion which receives but little enlightenment from a consultation of the standard text books of physiology, in which the articles upon the subject are vague in the extreme. During the past few years, however, a number of experimenters have been investigating this little-known organ, and some have drawn some definite, though not unfrequently contradictory, conclusions as to the part which it plays in the regulation of the animal organism. In the *Berliner klinische Wochenschrift* for May 2, 1910, Hart and Nordmann report a long series of painstaking and elaborate researches into this subject, which have led them to the opinion that the thymus gland may be an important, and possibly an essential, organ in the life history of the animals.

By developing a careful technique they have succeeded in completely extirpating the gland from a large number of young puppies, in each case an entire litter being used, part for the extirpation operation, and part for controls. The most striking result obtained was that, though the puppies stood the operation well and recovered quickly from its immediate effects, in no instance did an animal live longer than a year afterwards. The effect of the removal of the thymus gland upon the general condition of the animal appeared to be to inhibit its power of making proper use of its food. Though kept in the best of hygiene conditions, and given plenty of good food to satisfy the inordinately voracious appetite which they developed, the dogs did not develop as did their normal brothers; they were distinctly below the average weight and their muscles were flabby and soft; they tired easily, and showed no inclination to romp and play as does the healthy puppy. Signs of rickets which have been reported by other observers were not present, the bones being quite normal and the backwardness being confined to the soft parts.

Some distinct correlation between the action of the thymus and the other ductless glands was suggested by the experiments. That with the generative organs was shown by loss of all sexual instincts in the dogs, by sterility, and by atrophic changes in the testes and ovaries. The antagonistic relation of the thymus to the adrenals was indicated by a hyperemia of the latter, and a constant arterial hypertension in the animals from which the thymus had been removed. The combined action of the lowered nutritional power of the muscles and the increased blood pressure was marked in the effect upon the heart, while the increased resistance caused marked cardiac dilatation, the lowered nutrition prevented compensatory hypertrophy, and in practically every case the dogs died from paralysis of the over-distended flabby heart. The power of the animals to combat infection also seemed to be greatly reduced. This was especially pronounced in the lowered resistance to pyogenic infections of the skin, successive crops of boils appearing, showing very sluggish powers of healing, and recurring quickly in nearly all of the thymectorized dogs, while the normal control animals, occupying the same kennels, were not attacked.

These experiments, when coupled to our anatomical knowledge of the large size of the thymus gland in infancy, and its gradual decrease and almost disappearance at or near puberty suggest that the organ has an important function in regulating not only the bodily but the sexual growth of the young animal. The uniformity of the symptoms produced by total extirpation of the thymus, and their complete absence whenever intentionally or by accident even a small fragment of the gland remained, rules out the possibility of the results being due to the general manipulation of the operation, and makes it appear probable that the internal secretion of the thymus gland is as vital to the animal organism as that of the thyroid and the other ductless glands.

THE QUESTION OF BOVINE TUBERCULOSIS.

Recent statistics seem to show that tuberculosis is not decreasing in civilized lands at a rate commensurate with the trouble and expense which is being put forth to stay its spread. In all countries there has been an energetic crusade against tuberculosis during the past two decades, and while much success has met these efforts, there is still plenty of opportunity for the expenditure of zeal. The vexed question as to the transmission of bovine tuberculosis to man has been by no means settled, and this point has been clearly brought out within the past few weeks. Arthur Latham, a recognized British authority on the subject, has contributed to the *Medical Chronicle* for May an article entitled "The Conquest of Consumption," in which he indicates two main sources of the seed supply of consumption: (1) expectoration of sufferers from the disease, and (2) the products of the cow—milk and butter. At the present time, no disagreement exists among medical practitioners with regard to the spread of pulmonary tuberculosis by means of expectoration. Germans, Americans, and British, as well as students of other nations are all agreed in this connection. But, with respect to the other somewhat dogmatic statement of Latham, opinions differ. The German school generally, with some brilliant exceptions, take the view that bovine tuberculosis is not transmissible to man, while a few hold that if it is transmissible, it is only so to such a small extent as to be almost a negligible quantity. Many Americans are in accord with this belief and are sceptcal as to the transmissibility of the cattle form of the disease to the human being, or, grant-

ing that the two diseases are practically identical and therefore transmissible, contend that only a small percentage of young children are susceptible to infection. On the other hand, British observers almost as a body, believe in the transmissibility of bovine tuberculosis to man, and with them in this belief are a very large number of the medical profession of this country.

Latham, being as he is, a hard and fast exponent of the British views, is, of course, convinced that a very considerable amount of the disease is disseminated by the agency of milk. He states that 20 per cent. of the milk supplies of towns in Great Britain and 10 per cent. of the butter supplies contain living tubercle bacilli capable of causing disease, and that one glass of milk out of every five sold across the counter may carry the seed of death to one of the adult British population and to children. This language, perhaps, will strike one who has made any study of the matter as scarcely sufficiently restrained. As said before, it is likely that the majority of American physicians do believe in the possibility of bovine tuberculosis being transmitted to young children by infected milk, and in Great Britain the greater part of the medical profession is of the opinion that infected milk is an important factor in the spread of tuberculosis among children. But they are comparatively few in number who assert that infected milk is the cause of pulmonary tuberculosis in adults.

In prescribing a remedy which is at once simple and inexpensive, Latham urges pasteurization, which, he declares, destroys all the germs of consumption and of other diseases in milk, does nothing to diminish its food value, and does not materially affect the taste. Most authorities in this country will agree with the writer on this point, though in Great Britain he will find many opponents. Pasteurization is not looked upon there as an ideal method, but as, at present, perhaps, a necessary means for avoiding infection. Indeed, many British medical men still hold that pasteurization injuriously affects the nutritive properties of milk. Of course, stringent inspection of milk from the cow to the consumer is the ideal solution of the problem, but, like most ideals, it is unattainable, though ever to be striven after. In the meantime pasteurization is called for as the one absolute safeguard.

The Wassermann Reaction in Hodgkin's Disease.

Though the affection which is known as Hodgkin's disease, malignant pseudoleukemia, malignant lymphoma, and various similar names is fairly well recognized as a clinical entity, there are many observers who are unwilling to accept the condition as an idiopathic disease, and have tried to associate it with one or other of the well known infections, especially tuberculosis or syphilis. In the *Münchener medizinische Wochenschrift* for May 10, 1910, Albert Caan presents a small contribution to this subject, by finding that four typical cases of Hodgkin's disease, which gave no previous history of syphilitic infection, nevertheless gave positive, though not very strong, Wassermann reactions, both by the Landsteiner modification of the Wassermann reaction and the v. Dungren and Hirschfeld modification of the Noguchi method. Such results suggest two possibilities as to the etiology of Hodgkin's disease. It may, on the one hand, be a late manifestation of hereditary or acquired syphilis. On the other hand, as it has been shown that the complement fixation reaction is not absolutely specific for syphilis, but is present in such diseases as leprosy, relapsing fever, and sleeping sickness, all of which are caused by organisms somewhat closely related to the *Treponema pallidum*, it is possible that the presence of the Wassermann reaction in the blood serum of Hodgkin's disease indicates that this affection also is produced by some organism closely related to the spirochetes or trypanasomes.

News of the Week.

The Conference on the Care of Sick Babies held its second meeting at the Department of Health building, New York, on Thursday, June 16, 1910. The meeting was called to order by Dr. William P. Northrup, chairman. The committee on literature recommended that the lithographed card and literature as adopted in the year 1909 be adopted for the season of 1910. A most important step was taken in authorizing the compilation of a directory embodying the organization, objects, and facilities of each agency represented in the conference. This ready reference book will be distributed gratis to all the child-caring agencies throughout the city. It was requested that each agency report what it was prepared to do in instructional work, medical care, and convalescent care. Through the Department of Health as a clearing house, the work of each agency could be controlled and protected against duplication of effort, and overlapping of district.

The Birth Rate in France.—According to the French vital statistics for 1909, a further decrease of 22,000 has occurred in the birth rate. The total births in 1908 were 792,000, while in 1909 there were only 770,000.

The Mortality Statistics in Chicago for the first five months of 1910 show an increase in death rate of 4.7 per cent. over 1909. Increases in deaths were noted as follows: Measles, 5; scarlet fever, 18; pertussis, 55; diphtheria, 11; tuberculosis, 58; pneumonia, 488. Decreases in the number of deaths occurred in typhoid fever, 44; diarrheal diseases under two years of age, 2.

Plague Ship Quarantined.—Owing to the development of bubonic plague among laborers landed in Honolulu from the Japanese Oriental liner *Nippon Maru*, the ship was quarantined on her arrival at San Francisco recently.

Smallpox in Mexico.—An epidemic of smallpox has prevailed in the district of Ozumba, Northern Chihuahua, Mexico, for the past six months. There have been six hundred deaths from the disease during that period. An appeal has been made to the Federal Government for medical officers and soldiers to enforce quarantine.

New York State Board of Regents has annulled its action taken in 1906 which established medical reciprocity between New York and New Jersey. The following appointments have been made to the State Board of Medical Examiners for a term of three years: Dr. William Warren Potter and

Dr. Lee H. Smith of Buffalo, and Dr. Wentworth Reeves Butler of Brooklyn; to the State Board of Nurse Examiners, to serve five years, Miss Lydia B. Anderson; to the State Board of Examiners in Optometry, Charles F. Prentice of New York and George R. Fox of Buffalo; to be secretary of the Board of Pharmacy, William T. Bradt; to be State Dental Examiners, Dr. A. M. Holmes, Dr. H. J. Burkhart, and Dr. E. G. Parker; to the State Board of Veterinary Examiners, Prof. James Law of Ithaca, Dr. F. C. Greenside of New York, Dr. R. C. Reed of Elmira, Dr. H. S. Beebe of Albion, and Dr. George A. Knapp of Millbrook. Miss Annie W. Goodrich of New York was appointed inspector of nurse training schools.

Ambulance Board in New York.—Mayor Gaynor has instructed the police commissioner of New York that the director and deputy director of the new ambulance board be appointed from a classified civil service list. This necessitated the withdrawal of the men recently appointed to these positions.

The Sea Side Hospital at New Dorp, Staten Island, belonging to the St. John's Guild has been opened for the season for the care of sick infants. The floating hospital of the Guild will make its first trip July 5.

The Sanatorium for Hebrew Children at Rockaway Park, Long Island, will open on or about June 20.

Antimeningitis Serum.—The Rockefeller Institute for Medical Research, which has been supplying the antimeningitis serum gratis for several years, has announced that it may discontinue, at any time after the expiration of the next six months, its preparation and distribution on a large scale. The consensus of medical opinion, based on the employment of the antimeningitis serum in widely separated epidemics of meningitis, is to the effect that it is of undoubted value in reducing the mortality and preventing the severe consequences of the disease. The serum is without effect in any other form of meningitis than that caused by *Diplococcus intracellularis* (Weichselbaum) and its favorable action is most pronounced when it is applied early in the course of the disease. Hence it is desirable that State and municipal laboratories engaged in the preparation of diphtheria antitoxin and allied products should undertake the preparation of the serum and provide means for controlling the bacteriological diagnosis of meningitis, as they now do that of diphtheria and some other diseases.

The Peter Bent Brigham Hospital, for which ground has been broken on land adjoining the new buildings of the Harvard Medical School, has announced the appointment of Dr. Harvey Williams Cushing, associate in surgery to the Johns Hopkins Hospital and associate professor of surgery in Johns Hopkins University, to the position of surgeon-in-chief, and of Dr. Henry A. Christian, dean of the Harvard Medical School, to that of physician-in-chief. The funds of the hospital, originally $1,800,000, have been increased by investment to $8,000,000. About $1,000,000 will be spent upon the erection of the new buildings.

The Boston University School of Medicine has announced a gift of $200,000 from Mrs. Robert Dawson Evans of Boston for the purpose of erecting an Institute of Clinical Research and Preventive Medicine in memory of her late husband. This institute will be under the direction of the Massachusetts Homeopathic Hospital, and will be for the mutual benefit of that institution and the Boston University School of Medicine. It will be built upon a lot of land immediately adjoining the Medical School. As planned, the building will consist of a large structure four stories high with a roof sun-parlor. The first floor will be devoted to auditoriums in which public lectures will be given, and to the various administrative offices. On the next floor will be wards for neurological patients, forming a psychopathic department. The third story will also be devoted to wards for patients who are being studied and treated by the various members of the staff of the Institute. The uppermost floor will be devoted to laboratories of pathology, bacteriology, physiology, chemistry, and drug pathogeny.

The New York University held its annual commencement exercises on June 8, 1910. The degree of Doctor of Medicine was conferred upon sixty-four students of the University and Bellevue Hospital Medical College. The degree of Doctor of Laws was conferred upon Dr. Egbert Le Fevre, professor of clinical medicine and dean of the medical faculty.

The Long Island College Hospital held its annual commencement exercises June 1, 1910. The degree of Doctor of Medicine was conferred upon sixty-six candidates.

Jefferson Medical College of Philadelphia.—At its annual commencement, June 6, the college conferred the honorary degree of Doctor of Laws on Dr. S. Weir Mitchell in recognition of the sixtieth anniversary of his graduation from the college. Dr. J. Chalmers Da Costa has been elected Samuel D. Gross Professor of Surgery.

University of Pennsylvania.—Dr. Louis A. Duhring has resigned from the chair of dermatology on account of ill health. Dr. A. M. Richards of Northwest University has been elected professor of pharmacology, Dr. K. F. Meyer of South Africa assistant professor of veterinary pathology, and Dr. C. H. Shaw of the Medico-Chirurgical College assistant professor of botany.

Fordham University.—At the graduation exercises held recently announcement was made that a building for the School of Medicine will be erected and ready for occupancy this coming fall. The building will be on the university grounds facing Pelham avenue. As planned it will be 200 feet wide and 100 feet deep and will be equipped with laboratories and a clinic. The dean also announced the erection of a maternity hospital in connection with the university in the near future.

Drake University Medical School.—It is announced that the campaign to raise $150,000 to endow the medical department of Drake University has been successful.

Dr. J. J. Henna of New York has been made a chevalier of the Legion of Honor by President Fallières, in commemoration of the one hundredth anniversary of the French Benevolent Hospital, of which the French Hospital in New York is a branch. Dr. Henna is dean of the medical staff of the French Hospital and the only survivor of the founders of the hospital.

Dr. Walter R. Brinkerhoff, who for the past five years has been working among the leper colonies of the Hawaian Islands, has been appointed assistant professor of pathology at Harvard University.

Dr. James B. Dinnan of Meriden, Conn., has been appointed medical superintendent of the Undercliff Sanatorium by the Connecticut State Commission on Tuberculosis.

The Associated Physicians of Long Island will hold their midsummer meeting June 25, 1910, on an unused estate on the banks of the Nissequoque River. A special train will leave Jamaica at about 11 A. M. The members will alight at Smithtown and travel by automobile and boat to the place of meeting. Dr. Harvey W. Wylie will speak on Preventive Medicine from a chemical standpoint.

The Homeopathic Medical Society of the County of New York, at a regular meeting held June 9, 1910, passed a resolution favoring the establishment of a National Department of Health, as follows: Whereas, in the public print representations have been made that the practitioners of the Homeopathic School of Medicine are opposed to this bill, the Homeopathic Medical Society of the County of New York, at its regular meeting, passed the following resolution. *Resolved*, that the Homeopathic Medical Society of the County of New York heartily endorses the proposed National Department of Health, feeling that such a department will increase the efficiency of State Boards of Health, and produce a unanimity of action which is essentially lacking under the present conditions. William Francis Honan, M.D., president; John Strother Gaines, Jr., M.D., secretary.

The American Hospital Association will hold its twelfth annual conference at the Planter's Hotel, St. Louis, Mo., September 20-23, 1910.

American Gastroenterological Association.—At the thirteenth annual meeting of this association, held at St. Louis, Mo., June 6 and 7, 1910, the following officers were elected: *President*, Dr. Walter B. Cannon, Boston; *First Vice-President*, Dr. John A. Lichty, Pittsburg; *Second Vice-President*, Dr. George D. Kahlo, French Lick, Ind.; *Secretary and Treasurer*, Dr. Charles D. Aaron, Detroit; *Member of Council*, Dr. Julius Friedenwald, Baltimore.

The Massachusetts Medical Society held its one hundred and twenty-ninth annual meeting in Boston June 7-8, 1910. The election of officers resulted in the following: *President*, Dr. George B. Shattuck of Boston; *Vice-President*, Dr. Henry B. Stetson of Greenfield; *Secretary*, Dr. Walter L. Burrage of Boston; *Treasurer*, Dr. Edward M. Buckingham of Boston; *Librarian*, Dr. Edward H. Brigham of Brookline; and *Orator*, Dr. Maurice H. Richardson of Boston. The section on tuberculosis elected the following officers for 1910: *Chairman*, Dr. Arthur L. Cabot of Boston; *Secretary*, Dr. Thomas F. Harrington of Boston; and *Recording Secretary*, Dr. John Hawes, 2d, of Boston.

The Rhode Island Medical Society meeting at Providence, R. I., May 31, 1910, elected the following officers: *President*, Dr. Augustine A. Mann of Central Falls; *Vice-Presidents*, Dr. Frederick T. Rogers of Providence, Dr. Alexander B. Briggs of Ashaway; *Secretary*, Dr. Stephen A. Welch of Providence; *Treasurer*, Dr. Winthrop A. Risk of Providence. The society voted to purchase a house to be used as a club house and library.

The Connecticut State Medical Society held its 118th annual meeting at New Haven, May 26, 1910. The following officers were elected: *President*, Dr. Frank K. Hallock of Cromwell; *Vice-President*, Dr. E. P. Douglas of Groton, and Dr. E. T. Bradstreet of Meriden; *Secretary*, Dr. Walter R. Steiner of Hartford; *Treasurer*, Dr. J. H. Townsend of New Haven. *Delegate to the American Medical Association*, Dr. E. J. Knight of Hartford.

The Franklin County (Vt.) Medical Society held its annual meeting at St. Albans on May 26, 1910. The following officers were elected: *President*, Dr. C. A. Pratt of Enosburg; *Vice-President*, Dr. J. Reynolds Patton of Fairfield; *Secretary*, Dr. E. A. Hyatt of St. Albans.

The White River Medical Society met at Hartford, Vt., May 17, 1910, and elected the following officers: *President*, Dr. George W. Weymouth of Lyme, N. H.; *Vice-President*, Dr. J. D. Brewster of Windsor; *Secretary and Treasurer*, Dr. G. N. Cobb of White River Junction.

The Association of the Alumni of the St. John's Guild Hospitals for Children was organized at a meeting held in New York City on May 26, 1910. Those physicians who served as regular appointees of the St. John's Guild, either as residence physicians at the Seaside Hospital or as physicians on the Floating Hospitals, for one or more seasons, are eligible for active membership. The following officers were elected: *President*, Dr. Medwin Leale; *Vice-President*, Dr. Russell Bayly; *Secretary*, Carlisle S. Boyd, 46 West 84th street; *Treasurer*, Dr. Ten Eyck Elmendorf.

The Connecticut Homeopathic Medical Society held its annual meeting in Hartford, May 17, and elected the following officers: *President*, Dr. H. A. Cameron of Waterbury; *Vice-President*, Dr. Samuel Worcester of South Norwalk; *Treasurer*, Dr. Henry P. Sage of New Haven; *Secretary*, Dr. W. W. Christian of Berlin.

The Vermont Homeopathic Medical Society held its sixtieth annual meeting in Montpelier on May 18 and elected the following officers: *President*, Dr. Fremont Hamilton of Brattleboro; *Vice-President*, Dr. James Haylett of Moretown; *Secretary*, Dr. George O. Forbes of Burlington; *Treasurer*, Dr. Fred E. Steele of Montpelier.

The Ninth District Society of the Indiana State Medical Association held its annual meeting at Tipton, May 20. Ft. Wayne was chosen as the place for the next meeting, and the following officers were elected: *President*, Dr. A. S. Dickey of Tipton; *Vice-Presidents*, Dr. Edgar Cox of Kokomo and Dr. W. H. Fernald of Frankfort; *Secretary and Treasurer*, Dr. Paul Barcus of Crawfordsville; and *Assistant Secretary-Treasurer*, Dr. George T. Williams of Crawfordsville.

Obituary Notes.—Dr. Camillus Bush of San Francisco died on May 28, 1910, aged 32 years. Dr. Bush received his bachelor's degree from the University of California, in 1898, and in 1902 was graduated with honors from the Johns Hopkins Medical School. After serving for one year as surgical house officer, and one as assistant resident surgeon in the Johns Hopkins Hospital, he returned to California to become an instructor in surgery at the University of California and attending surgeon to the St. Helena Sanatorium. He was a member of the San Francisco County Medical Society, the Medical Society of the State of California, and the American Medical Association.

Dr. Simon L. Elsner of Rochester, N. Y., died suddenly of heart disease June 5, 1910, while driv-

ing his automobile. He was a graduate of the College of Physicians and Surgeons of New York in 1887, and was a member of the Medical Society of the County of Monroe, the Medical Society of the State of New York, the American Medical Association, the American Urological Association, and the Rochester Academy of Medicine, and was assistant physician to the Rochester City Hospital.

Dr. Louis Clark Pettit of New York died on June 2, 1910, aged 53 years. He was a graduate of the University of Pennsylvania in 1883, and at the time of his death was second assistant at the Manhattan State Hospital on Ward's Island. Dr. Pettit was a member of the American Medico-Psychological Society, the New York Academy of Medicine, and the New York Neurological Society.

Major John S. Kulp, Medical Corps U. S. Army, retired, died in Seattle, Wash., June 2, 1910, aged 44 years. He entered the army in 1893.

Dr. Daniel Merritt Griffen of Portchester, N. Y., died suddenly June 4, 1910, at Hot Springs, Va., aged 43 years. He was a graduate of the College of Physicians and Surgeons in New York in 1890.

Medical Director Richard C. Dean, U. S. N., retired, died at his home in Washington, June 9, 1910, aged 77 years. He entered the navy as assistant surgeon in 1856, after graduating from the Jefferson Medical College. During the Civil War he served on the Tuscarora. From 1870 to 1874 he was assistant chief of the bureau of medicine and surgery. From 1876 to 1877 he was fleet surgeon of the North Atlantic fleet. After his retirement he performed varied board duty in Washington until August 10, 1904, when he was ordered to his home. He was advanced to the grade of medical director with the rank of Rear Admiral on the retired list because of his Civil War service.

Dr. Warren Andus James of Brooklyn died at his home, June 9, 1910, aged 71 years. He was a graduate of the Bellevue Hospital Medical School in 1865, and was physician to the Children's Aid Society of Manhattan and consulting physician to the St. David's Society.

Dr. Clarence L. Addleman of Mammoth, Utah, died at Green Castle, Pa., May 28, 1910. He was a graduate of the University of Pennsylvania in 1875.

Dr. George Waldron Bartlett of Brooklyn, N. Y., died at his home, June 5, 1910, aged 57 years. He was a graduate of the New York Homeopathic Medical College in 1895, and was a member of the American Institute of Homeopathy and the Homeopathic Medical Society of the State of New York.

Dr. Rio Delos Barber of Corona, Cal., died May 26, 1910, aged 72 years. He was a graduate of the Harvard Medical School in 1867, and a veteran of the Civil War.

Dr. Stiles Kennedy of St. Louis, Mich., died at his home, May 27, 1910, aged 73 years. He was a graduate of the University of Pennsylvania in 1858, and was a member of the Gratiot County Medical Society and the Michigan State Medical Society.

Dr. Robert Gordon Leverty of Bridgeport, Conn., died May 28, 1910. He was a graduate of the New York University Medical College, in 1895, and was physician to the Emergency Hospital.

Dr. Angus McDonald of Boston died at his home, June 1, 1910. He was a graduate of the Boston University School of Medicine in 1876, a member of the Massachusetts Homeopathic Medical Society, and a visiting physician to the Homeopathic Hospital.

Dr. Alexander C. Smith of Sterling, Ill., died at his home, May 30, 1910, aged 70 years. He was a graduate of the Long Island College Hospital, in 1877, and was a member of the Whiteside County Medical Society and the Illinois State Medical Society.

Dr. John Philip Henrique of Providence, R. I., died at his home recently, aged 53 years. He was a graduate of the Yale Medical School in 1878.

Dr. James Holmes Wikoff of Princeton, N. J., died at Atlantic City, June 8, 1910, aged 78 years. He was a graduate of the New York University Medical School in 1854, and was a member of the Mercer County Medical Society and the Medical Society of New Jersey.

Correspondence.

THE ANNUAL MEETING OF THE CANADIAN MEDICAL ASSOCIATION.

(From Our Regular Correspondent.)

Toronto, June 5, 1910.

The address in surgery was given by Dr. John B. Murphy of Chicago, on the afternoon of June 3, and dealt with the surgery of joints. Dr. Murphy pointed out that it was the anatomy and pathology of the capsule that gave the surgeon the most work in treating the injuries of joints. The fact that the capsule was non-vascular and composed of fibrous tissue and of inelastic structure, had an important bearing on the correction of joint deformities. In treating such deformities Dr. Murphy said it was a mistake to use force, that cutting was the remedy and not force. Infection of joints was difficult to treat, because the capsule did not inflame. Draining a joint was, as a rule, the wrong procedure, as the endothelial layer was thereby destroyed. In order to save a joint from any loss, the closing of the joint was indicated. Rheumatic joint-infection had no definite pathological significance and covered a lot of surgical sins. Ankylosis was not the result of rheumatic infection, but of metastatic. Many cases of joint infection were ushered in by chills, metastatic infection began with chills; infection of the rheumatic type did not so commence. Dr. Murphy said that he had convinced himself by close observation of human subjects, aided considerably by animal experimentation, that in a large number of cases of infection of joints the primary infection should be looked for, and that it should be assumed that the infection was metastatic and not rheumatic. Having settled this point, the treatment should be to relieve the destructive pathological processes, and this object should be achieved by aspirating joints and not by opening. Therefore, aspirating with formalin and glycerine, and sometimes with turpentine, should be done before pathological processes had had time to effect their work of destruction, for it must be borne in mind that every acute infective process in joints might lead to a ankylosis by pressure. Further, the injured limb should be kept extended. Dr. Murphy drew attention to the fact that the knee was the part of a limb on which it was most difficult to operate, for the reason that it could not easily be kept plumb. He advised, too, that the patella should be injected with formalin and glycerine eight or nine days before operating, so that there might be no effusion. Dr. Murphy illustrated his address by a very large number of beautifully taken photographs, which showed the results of his operations in various stages, and which also gave ocular evidence of their successful issue. Dr. Murphy's address was brilliant and followed with deep attention by a very large audience.

Dr. S. P. Beebe of New York City opened a symposium on exophthalmic goiter, discussing the disease from the pathological aspect. Dr. Beebe reviewed our knowledge, or rather our lack of knowledge, as to the cause of Graves' disease, and as to what particular influence the functions of the thyroid had on the origin and on the course of the disease. That the thyroid gland was always hypertrophied in exophthalmic goiter seemed evident, and there was also an alteration in the type of its secretions during the disease, but as Dr. Beebe showed clinical conclusions could not be reconciled with pathological findings. It was likewise pointed out that it was not necessary to have a definite goiter in Graves' disease with regard to the administration

of iodine in the treatment of the disease. Dr. Beebe stated that such treatment should be followed with caution, as iodine was readily taken up by the thyroid gland in Graves' disease, and fatal clinical results might ensue. A serum for the treatment of exophthalmic goiter is prepared by inoculating animals with proteins from human thyroid gland, and according to Dr. Beebe, its use has been attended with fair success. Dr. Beebe said that he was opposed to operative measures.

Dr. Alex. McPhedran discussed the malady from its medical aspect. He said that it was not prevalent in Canada. In the General Hospital, Toronto, during a period of five years, there had been 55 cases of Grave's disease out of 8,000 medical cases treated. Dr. McPhedran gave an exhaustive description of the various phases of the disease and observed that surgical writers did not believe in its medical treatment. Statistics seemed to justify the opinion but he remarked that medical treatment did not lend itself favorably to statistics. He recommended rest, proper feeding, and general care, with the administration of drugs found to be suited to the case. If under such treatment improvement did not follow in a few weeks' time, surgical aid should be sought.

Dr. F. Shepherd of Montreal considered the disease from the surgical aspect. He recognized that surgical treatment of Graves' disease was not the ideal treatment, and thought that the only rational mode of treatment was to remove the cause by means of vaccine or serum. Pending the successful prosecution of methods of this nature, he was of the opinion that operative measures were called for in many cases. He had not found local anesthesia when operating for Graves' disease satisfactory. Dr. Shepherd pointed out that early cases lent themselves far more favorably to operation than cases of longer duration, and therefore thought that physicians should be urged to send cases to surgeons before the disease was far advanced.

A lengthy discussion followed, physicians and surgeons debating the pros and cons of the matter from their different standpoints, with earnestness not unmingled with a certain degree of heat. Dr. Heringham of London stated that he had examined several patients, both before and after operation for Graves' disease, and that in all cases he had found tachycardia had not been relieved by operation. In this opinion many concurred. In the *British Medical Journal* for May 28, 1910, Dr. F. P. Sturm Leigh of Lancashire, England, wrote to say that he had recently been wholly successful in an operation for exophthalmic goiter of long standing, and that in three other operations for the same condition the results had been very satisfactory.

On the evening of June 3, Dr. Henry C. Coe of New York City gave the address in gynecology, treating of the old and new gynecology. Whereas, Dr. Murphy in his address conveyed the impression that not only had the limits of surgery not been nearly reached, but that in some respects surgery was almost in an elementary stage. Dr. Coe was distinctly conservative and expressed the opinion that the surgical side of gynecology, at any rate, would soon become less prominent, and rather unkindly went on to say that the trained man of mature experience would supersede the half fledged specialist. Dr. Coe classed gynecology and obstetrics together, and while predicting for these allied branches of surgery a glorious future, seemed more inclined to dwell upon their glorious past. In these days of self-glorification, such an attitude is healthy and refreshing. Dr. Coe recalled many of the great names in abdominal surgery of the past two or three generations, as Lawson Tait, Emmet, and Thomas, and gave them their due meed of praise for rendering possible the vast progress in this branch of surgery. Dr. Coe referred to the many and various surgical fads, and extraordinary operations which had sprung up from time to time in the past twenty or thirty years, and said that American surgeons were somewhat akin to the French, in that they embraced with enthusiasm every and all the out-of-the-way operations that were introduced on the Continent of Europe. However, indiscriminate operating seemed to be passing away and conservatism appeared to be setting in. Dr. Coe confessed to a considerable degree of pessimism in regard to surgical treatment of malignant disease of viscera. He was of the opinion that there were more inoperable cases of cancer than operable cases. Generally operation was delayed too long. However, he thought its cure must be sought for in serum therapy and not in surgery. On one point in Dr. Coe's most excellent address there will be by no means complete agreement. He placed himself in the category of those who hold that marriage will one day be subject to State control. He said that this view was no mere fanciful dream, but at the present time was being worked out. There must, he thought, be a survival of the fittest among human beings as among the animals of the lower order.

Dr. J. C. Connell of Kingston, Ont., gave an able and thoughtful address on the much vexed question of medical education. Dr. Connell, who has had twenty-two years' experience as a teacher of medicine, is like many another in a similar position, uncertain as to whether present methods of medical education are best fulfilling the object for which they were intended. Dr. Connell in his paper compared the curricula of Canadian universities twenty-five years ago and of the present day, not altogether to the advantage of the former curriculum. He said that the burdens of students and professors alike were now much heavier than in 1885, and that there was a considerable amount of wasted effort. A quarter of a century ago every professor was a general practitioner; now every teacher was a specialist, and the student must become a sort of general specialist. The curriculum was now overcrowded thereby defeating its own ends. Dr. Connell proposed the appointment of a committee of the association to deal with the subject of medical education. His proposal was accepted and a committee appointed.

The program of papers to be read in the section was extremely long. Without any desire to be hypercritical, it may be perhaps said that it was even too long. The average standard of papers was high, while some were of great merit. On the whole, the most instructive and interesting subject dealt with at the meeting was that of the psychoneuroses. The question of nervous complaints of all kinds is of medical and of general interest. The neuroses and psychoneuroses, under their various appellations, are the most common and increasing maladies of the present time. Further, it is argued, and doubtless with truth, that our conceptions of these affections have been wrong and that consequently treatment has been of little avail. It is argued, too, that recently a school has arisen, or perhaps it would be correct to say that teachers have arisen, who have at last grasped the fundamental truths in connection with the causation of the psychoneuroses. In the Section of Medicine of the Canadian Medical Association on June 1, a symposium on the psychoneuroses was held, and papers were read and the matter discussed by some of the foremost neurologists of America.

The first paper read was by Dr. J. J. Putnam of Boston on psychoanalysis, and was in effect an account of the method of treatment initiated, developed, and pursued by Professor Sigmund Freud of Vienna. Dr. Putnam is a friend and disciple of Freud, and has treated patients by his methods during the period of a year, and, of course, was fully qualified, both from the standpoint of theory and practice, to present the matter in its true light. It is needless to say that Dr. Putnam fulfilled these expectations. The next paper read was by Dr. August Hoch of New York City on the same subject. Dr. W. H. Hattie of Halifax, read a paper on the psychoneuroses in asylum practice, and Dr. Ernest Jones read a paper on the general significance of these conditions. Dr. Jones was a pupil and is a friend and staunch follower of Freud. Dr. Jones is a most voluminous writer on various mental states, and more especially on the psychoneuroses in relation to Freud's theory and treatment. In fact, it would have been scarcely possible that the Vienna professor's tenets should have been better set forth than they were in Toronto. Several took part in the discussion that followed. Among these were Dr. C. K. Clarke of Toronto and Dr. D. C. Meyers. However, no one took exception to the statements which had been made until Dr. Joseph Collins of New York sharply criticised Freud's theory and therapeutic methods. He complained that the followers of Freud regarded him as almost inspired and seemed to resent criticism of his teachings. After all, Dr. Collins said, neither his theory nor practice had been as yet proved to be right, and would be subjected to very destructive criticism ere this were accomplished. One June 2, in the Section of Medicine, Dr. Collins read a paper entitled "The Psychoneuroses," an interpretation, in which he dealt with Freud's theory and treatment at length. According to Dr. Collins, the theory of Freud was an extension of the doctrine propounded by Janet, that hysteria was a psychosis belonging to a group of mental diseases due to cerebral insufficiency. It was characterized especially by moral symptoms. The essential feature was the weakening of the faculty of psychological synthesis. The hysterical process caused a splitting, a disintegration, a doubling, of personality. Freud adopted this theory and contended that the disintegration was initiated by a force which he termed sexual trauma. In short, hysterical phenomena are the outward expression of the unpleasant element in an idea, while the idea itself exists but is repressed in the subconscious mind. In addition, all ill-health which can be

referred to psychic cause is due to sexual life. Even in early childhood this is the case.

The treatment by Freud's method is denominated psychoanalysis. Dr. Putnam has defined it as "his method of analysis into the structure of the working of the whole mind, the whole man carried out with a searching and merciless vigor which is in the end justified by the fact that it brings at last a sense of freedom and manhood."

Dr. Collins' objections to Freud's theory and practice were that his mode of interpretation was too arbitrary, that the psychoanalysis became a source of autosuggestion, and that it gave a conspicuousness to the sexual factor as a causative agent which it had not yet proved to be. Even admitting that sexual factors had the importance in the psychogenesis of hysteria that Freud maintained, very little had yet been vouchsafed us upon which to base the belief that psychoanalysis was a reliable therapeutic agency.

Dr. Putnam stated that during a period of a year he had had much success in treating the psychoneuroses by means of psychoanalysis. Whenever a new theory is originated, although Freud's theory of psychoneurosis had been in vogue for several years, there is certain to be much opposition before it is established on a firm base. The discussion at the Toronto meeting was timely, and the arguments advanced on both sides were calculated to arouse increased interest in the matter. It may be pointed out that, outside Germany and France, America takes the lead in the study and practice of neurology. Indeed, in so far as practice of neurology is concerned, there is no country which is in advance of America.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

MEETING OF MEDICAL COUNCIL—ORATION OF MEDICAL SOCIETY OF LONDON—INTERNAL INJURIES—ANKYLOSTOMA DUODENALE—CONFERENCE AS TO A SANATORIUM—REDUCED DEATH RATES—MIDDLESEX HOSPITAL—ANTIVIVISECTIONISTS' CONTRITION AND EXCUSES.

London, May 27, 1910.

The General Medical Council met on Tuesday for its ninety-first session and on the proposal of the president, Dr. Donald Macalister tendered a loyal address to the King expressive of sympathy with the personal sorrow of the royal family in its sudden grief and of devotion to the throne. All other medical corporations, like all national institutions, have adopted similar resolutions. This, therefore, may be taken as representing the whole of the profession. In proposing it the president said they could appreciate better than many the kingly courage of their late beloved sovereign, who refused to yield to any but the last inexorable summons, and while consciousness remained strove to carry on the duties of his state. Nine years ago the Council hailed His Majesty as one who ever evinced a wise and effectual interest in his people's health, and his reign would be memorable for what he initiated or fostered as well as for what he accomplished. Happily King George has shown the same interests and sympathies.

The president then referred to the recent legal decision that the Dentists' Act does not prevent unqualified practice, as for a time it was thought to do. It is as ineffectual as the Medical Act. It did not seem to occur to the president that the Council cannot be exonerated from blame in this matter. They have not made any efforts to protect the profession and in this respect their ninety sessions have been useless. Even now the president looks "for the formation of enlightened public opinion" from arrangements he hears are in progress for publishing a parliamentary paper of information collected by the Local Government Board on unqualified practice, and such a compilation he thinks "almost a pre-requisite." Was there ever such a case of how not to do it?

The president also referred to the revision of the Register, which has been completed and which he thought a heavy task, calling for thanks to the Registrar for superintending and the other employees for carrying out with efficiency. The "labor involved has been heavy," he said, and the cost moderate. Of course, it is well to have the Register corrected as may be required. But the task is no greater than the Medical Directory undertakes every year, giving, moreover, much more information as to every name contained in it.

The remainder of the session has been occupied with formal proceedings and the consideration of cases under the penal clauses of the acts.

The Medical Society of London held its annual conversazione on Monday. The president, Dr. Samuel West, was supported by Sir William Church and a number of leading members of the profession. Sir William was elected an honorary Fellow on the occasion. A good entertainment was provided, the Blue Viennese Orchestra contributing the music. The feature of this gathering is the annual oration, which this year was delivered by Mr. W. H. Battle, who took for his subject the "Treatment of Internal Injuries."

In the course of his oration Mr. Battle made some interesting observations on rupture of the spleen—an accident common enough in malarious countries, where the organ is so constantly diseased, but rarely met with here except as the result of great violence, a large proportion occurring in children "run over" in the streets. He said the view that adhesion to the diaphragm must occur before rupture of the spleen could be produced was now abandoned. So it was proved that every rupture was not necessarily fatal, for healed cicatrices had been found at necropsies. Cases had also been reported in which life had been much prolonged after rupture, but it was not possible to exclude doubt as to the diagnosis. There must be clear evidence of great hemorrhage into the peritoneum. This is so great that death generally occurs in a few minutes. But sometimes there is delay perhaps from clotting about the laceration. Then there will be recurrence. If the patient survive and no relief be given, peritonitis will be added to the other symptoms. In such cases the orator thought it advisable to remove the spleen and empty the peritoneum. Tamponage was sometimes of use, but efficient pressure on such a vascular organ might produce sloughing. In one case with adhesion to the diaphragm he had ligated the splenic vessels and so arrested the hemorrhage. Then saline infusion seemed to be of use, but the patient only survived four days.

At the previous meeting Dr. F. M. Sandwith made an interesting statement about *Ankylostoma duodenale,* illustrated by lantern slides from Prof. Looss of Cairo, who had experienced infection through the skin in his experimental work. Previously it was not believed that this could take place, and it can scarcely be said now that such infection is accepted. Dr. Sandwith assumed that his audience were well aware of the entry by the mouth, and so he devoted his time to giving an account of the discovery that the larvæ may enter through the skin, a fact of great significance in the study of other parasites whose life histories are not yet fully elucidated. It was in 1898 that Looss accidentally dropped on his hand a drop of water containing more than 1,000 lively larvæ. Local irritation was produced, followed by anemia, debility, and the eggs of the parasite were found in the feces. When cured this involuntary experimenter proceeded to repeat his experiment voluntarily, with the same results. Next he tried whether the larvæ would enter a piece of skin taken from a patient immediately after death and kept at 99° F., but this they would not do. He then applied a compress containing larvæ to a living patient's leg one hour before it had to be amputated. After the operation the hair follicles under the compress were infected. Later he used an analagous worm which infests dogs (*Ankylostomum caninum*) and after a long course of experiments in those animals he was able to declare that the larvæ entered the skin, passed into the lymphatics, and thence into the subcutaneous veins, and so to the heart, lungs, larynx, winding round the epiglottis, and so passed down the esophagus to the duodenum, their natural goal, where they grow and multiply. Schaudinn confirmed this by experiments on monkeys and showed that the larvæ remained of the same size until they reached the air vesicles, when they began to grow rapidly.

On Wednesday a conference of London Borough Councils was held to consider the question of producing sanatorium accommodations at the cost of the boroughs, of which about twenty-five sent delegates. The debate was rather confused, amendments were piled up on one another, and a number of suggestions were adopted in parts, so it is only safe to say that it was pretty generally agreed that there should be a central sanatorium for consumption in London. I have gathered since that the Medical Officer of Health for Shoreditch desired such accommodation for the working classes, to be maintained by the several boroughs in proportion to their rateable values and under the control of the Asylums Board. The Medical Officer of

Health for Woolwich held that it was better for each borough to lease beds at an existing sanatorium for favorable cases and for the Asylums Board to provide for the advanced cases. He said Woolwich had sent during the last six years 160 patients to existing institutions at a cost of £500 and had thereby saved the rates four times as much by preventing the spread of the disease and helping the wage earners to continue their work. The Medical Officer of Health for Kensington suggested that it would also be desirable to establish in each borough dispensaries for treating consumptives.

The Registrar-General in his annual summary mentions the need of a quinquenial census, as in its absence, he says, the rates will hereafter require revision to an appreciable, many of them to a serious extent. The death rate of the year was 14.5 per 1,000; this was 0.2 per 1,000 below the rate of 1908 and was lower than the rate in any other year since civil registration was established. The rate in London was 14; that is 0.9 below the average for the five years, 1904-1908. For Greater London (corresponding to the police districts) the crude death rate was 13.3, as compared with 14.4, 13.9, and 13.2 in the three preceding years.

Yesterday was foundling day at the Middlesex Hospital, when a service was held in the chapel and a recital given on the new organ. There was also a meeting of the Court of Governors, at which Prince Francis of Teck presided for the first time in the capacity of chairman. He referred in his address to the loss of their patron—and such a patron—the great King they had laid to rest. He said the patients in the cancer ward had subscribed pence to send a wreath to Windsor, and he felt sure the patronage of his successor would be given to the hospital, for King George had been all along so closely associated with King Edward's hospital fund and the working of all the other big hospitals in London.

The antivivisectionists have this week managed to draw upon themselves an unexpected amount of contempt. They circulated a leaflet about King Edward's illness and the vaccine treatment, the falsehood of which was stated in a notice authorized by the Queen-Mother. The offending society has met and recorded expressions of contrition and regret, adding that steps would be taken to place the issue of leaflets upon a proper basis. The other society, carried on by Lord Llangattock and Mr. Coleridge, hastened to inform the public that the "smaller society" was not theirs and they disassociated themselves from the issue. No doubt, now they see the public contempt and indignation, they think themselves happy that they did not hurry in the same direction. They condemn their "smaller" rivals. They should ask themselves whether they did not teach those rivals this method of advertising.

Progress of Medical Science.

Boston Medical and Surgical Journal, June 2, 1910.

Graves' Disease.—J. G. Mumford reviews the recent results of the treatment of this disease and presents the following summary: (1) Graves' disease is due to abnormal activity of the thyroid gland. (2) In advanced Graves' disease degenerative changes in the thyroid gland may lead to a shifting symtom complex, ending at last in the positive signs of myoidema. (3) The histology of the gland in this malady indicates shifting, advancing, and retrograding symptoms. (4) An enlarged thymus is nearly always found on postmortem in patients dead of the disease. (5) Advanced Graves' disease may exist without the presence of all the symptoms. (6) The disease can nearly alway be cured if taken early. (7) The sera of Rogers and Beebe cure a goodly number of cases. (8) Through hydrobromate of quinine (neutral) as used by Forcheimer and Jackson we find a great percentage of improvements and of cures. It is a pity that so few cases have been reported. (9) The great and increasing experience of qualified operators is showing that more than seventy per cent. of Graves' disease patients are now being cured by partial thyroidectomy and the percentage of such cures is rising. (10) Treat the cases seen early by rest, by sera and by hydrobromate of quinine; if no improvement results in two months, operate by throidectomy and always regard the operation as the surest cure.

Tonsillectomy, with Special Reference to Recent Points in Technique.—O. A. Lathrop comments on the recent change of view in the minds of the profession regarding the advantages of tonsillectomy over tonsillotomy and gives in detail the method of his own procedure. He operates under ether anesthesia, the patient being upright in a chair, and requires only one assistant. He counsels against haste and says that it is well to devote about ten minutes to the removal of both tonsils. The after-pain in his method is very slight and, he claims, much less than that following the method of finger dissection. He says in regard to the checking of hemorrhage which is liable to occur in any and in all methods, to first press a pledget of gauze on a holder into the tonsillar sinus for at least three minutes. If this does not suffice, the anterior pillar may be retracted, and perhaps a bleeding point caught with a long hemostat. If these attempts are unsuccessful the pillars may be sutured together over a pledget of gauze. This should check any ordinary hemorrhage. As a last resort, a tonsillar clamp may be applied. Astringent applications and adrenalin are not efficient in the presence of much blood, and are not reliable. They render the tissues more susceptible to infection and secondary hemorrhage. The surgeon should see that all bleeding has stopped before leaving the patient. Because of the liability to hemorrhage tonsillectomy is more safely done in a hospital.

New York Medical Journal, June 4, 1910.

The Relation of the Nervous System to Diseases of the Skin.—J. A. Fordyce summarizes the rôle of the nervous system in the production of skin diseases by saying that from the higher centers in the brain to the peripheral distribution of the nerves the skin may reflect circulatory or trophic disturbances, some of which are typical and others only suggestive of a relationship. In the one case the etiological factor is single and specific, and in the other the rôle of a nervous influence is only contributory in a complicated causation which our present knowledge does not permit us to interpret in an exact manner. The nervous system is directly concerned in sensory disturbances, as the hyperesthesias, anesthesias, and paresthesias. The posterior root ganglia and their analogues, the Gasserian and geniculate, together with the peripheral nerves are concerned with the most characteristic skin lesions due to primary nerve involvement. Next to these are the skin lesions of syringomyelia, the changes which follow disease of the peripheral nerves in leprosy, and other forms of neuritis, or after division, partial or complete, of nerve trunks. The nervous system may act as a predisposing or contributory cause in eczema, dermatitis herpetiformis, lichen planus, pemphigus, etc., by lowering the nerve tone. Psychic shock, mental strain from anxiety, grief, or overwork are states which are often invoked in such conditions. Hysteria leads to selfmutilation—the so-called feigned eruption—sensory disturbances, and possibly to spontaneous bullous affections and gangrene. It is possible that the nervous system through the sympathetic, the adrenals, and other chromaffin tissue related to the sympathetic, is concerned in certain pigmentary and leucodermatous changes.

A Possible Method of Infection in Acute Poliomyelitis.—N. M. Shaffer refers to the possibility of infection through a solution of continuity of the skin. He asks that close observations along this line shall be made by medical observers. He has found several town-bred patients who, going to the country for the summer, preferred to run about barefooted, to paddle in the water (especially fresh water), or to play about without foot protection in wet or sodden soils—and who had either skin abrasions, bruises, or cuts, or had acquired them in so doing. Given, as has been demonstrated by Flexner, the nasopharynx as a well defined, and perhaps the favorite, seat of infection, and given an infected secretion from this region, a further point of infection may exist in an abraded skin, through, for example, a neglected handkerchief or an infected finger. While Flexner has demonstrated the certainty of an infection via the nasopharynx, it does not follow that this is the only way. It is not impossible that a prolific source of infection may exist, especially in a sporadic case, in the earth, or water, or in some form of insect life, peculiar to their everyday association, which reaches the nerve centers through an abraded cuticle in a manner not unlike that which occurs in rabies or tetanus. The infection, occurring in a sporadic case, under favorable conditions, either in the city or country, may easily become the focus of an endemic of the disease, through, if not easily traced, well known channels of transmission.

Large Vesical Calculus.—H. W. Austin reports this case, the calculus being attached to a catheter in the urethra and being successfully removed by the suprapubic method.

His patient was a man of forty-nine years, who was using a catheter on his own responsibility, and lost it in the urethra, though this fact was not known when he was admitted to hospital. He suffered from complete incontinence and was having chills and slight fever. An obstruction was found just forward of the bulbous urethra. A urethral forceps grasped what was apparently an elastic catheter, but its removal by the natural passage was impossible. So the suprapubic incision was made and a lithotomy forceps (a stone having been detected in the bladder) inserted and the calculus was removed without breaking. The catheter was coiled up in the stone, the free end extending into the urethra. However, with a little manipulation stone and catheter were cleanly withdrawn. The stone was of the phosphatic variety, weighed ninety grams and measured six inches in its smallest circumference, and over seven inches in its longest. It is, the author believes, about as large as any which has been reported.

The Surgeon's Responsibility in Anesthesia.—R. H. Greene recommends a closer differentiation of the type of patient, a fuller realization that anesthetics are drugs which have an immediate direct effect on metabolism and a closer correlation between the surgeon and anesthetist. He confines his observations entirely to general anesthesia. Concerning spinal anesthesia he is not much in favor of it. He has found a tendency to secondary hemorrage the after effect of spinal anesthesia, a fact not mentioned by previous writers. In general work he has noted two facts: (1) Whether the anesthesia is to be of long or short duration it is a very general fault for the attending surgeon to delay the commencement of the operation unnecessarily for a greater or less length of time after the patient has been anesthetized. (2) The next most prevailing fault during the conduct of an operation in his opinion, and one from which he feels he is not entirely free, is the lack of cooperation which so often exists between the surgeon and the anesthetist, and, in his opinion, the fault is more apt to be with the surgeon than with the anesthetist. Following the operation ordinarily an enema of salt water is of use, to which one ounce of whisky may be added. Hot water bottles are not required, but many blankets, and the patient should be kept warm and dry. One or two glasses of water to drink may be of benefit from the autolavage instituted. If this is done four hours after the last vomiting has taken place a tablespoonful an hour of some predigested beef preparation is indicated. Patients ordinarily do better if no fluid is given for twenty-four hours, or until the marked effects of the anesthetic have passed off. If the thirst necessitates, however, the autolavage mentioned above should be tried. If the patient is kept from draught following operation, pneumonia can be largely prevented. Sepsis from which the patient suffers at the time of operation will be found to be the main causation factor. For the relief of nerve shock medically the writer has little to offer. The Murphy drip when kidney inefficiency is present seems popular. Internally an infusion of dried violet flower is of benefit as a sedative and diaphoretic, while the calming properties of ignatia and passiflora have been found preferable to those of the more commonly used sedatives and narcotics.

Journal of the American Medical Association, June 4, 1910.

Some Public Health Problems.—G. N. Linthicum, after first reviewing the successes of the past in the management of important diseases, such as smallpox, yellow fever, cholera, scurvy, typhus, and diphtheria, and the increased average length of life due to the development of sanitary science, notices the problems of the present and the future. The first of these mentioned is tuberculosis, and he says that when we realize that probably 90 per cent. of all persons are at some time in their lives affected with tuberculosis, and that only 10 per cent. die, we are justified in saying that in few diseases, not self-limited, is there a greater tendency to recovery. Owing to better housing and sanitation, the death rate in Great Britain from this cause is only one-third of what it was 70 years ago. The pollution of water supplies is the second problem, and it is becoming daily a more and more serious one, which must be met by proper legislation and sanitation. Pneumonia is another important problem, as it causes more deaths than tuberculosis at the present time in the United States, and it must be solved largely as a laboratory problem. Malaria is a preventable disease, and its prevalence is far greater than it should be and the more formidable disorder as regards mortality, plague, is now known to be controllable if only certain domestic pests, like the rat, can be exterminated. Hookworm is another disorder that can be controlled, and the increasing prevalence of mental disorders, drug habits, and venereal diseases, as well as cancer, nephritis, and diabetes, are all subjects for careful study. Of some of these we do not yet know the real causative factors, but we are hopeful that we sometime will. The great problem of the future is the betterment of health by the education of the whole people as to its possibilities. Why, he asks, should not the physician take the place of an advisor in health? Would it not be an economical move to have an inspection of the vital resources at regular periods, as is done of the financial resources? Certain recent legislation in Maryland is noticed with commendatory comment, and Linthicum speaks a good word for animal experimentation as a means of saving life, and for the advancement of our knowledge of disease, and also for the proposed department of health.

A Water Curtain.—W. J. Manning suggests the use of a water curtain for cooling purposes and avoidance of dust in work rooms, factories, tenements, etc. It may also be available in residences in tropical countries. As advised by him it consists of a curtain with a perforated tin tube thrust through its upper hem, like an ordinary curtain stick, and connected by a rubber tube with a water faucet. At the bottom of the curtain is suspended a tin trough on a slight slant to carry off the water dripping from the curtain. He also adds an electric fan placed at one end of the curtain to hasten the evaporation. Formalin or similar agents may be used with the same apparatus when germicidal effects are required. Tests made in the emergency room in the government printing office in Washington showed a reduction of seven to eleven degrees F. during the hot weather of last summer. This, when a temperature of 96 or 98 degrees in the shade exists outside, is a very much to be appreciated reduction. The apparatus is inexpensive and very adaptable to any quarters. The curtain can be removed for washing and its clean duplicate put in place in a few minutes. The method is illustrated.

Respiratory Crepitus.—C. M. Cooper says that for years he has occasionally noticed confusing adventitious sounds over the scapular region during auscultation that are not mentioned in text books. These sounds may be of a creaking, crunching, or bubbling character and occur during both phases of respiration. They are somewhat superficial and are confined to the scapular areas, or if they extend beyond are less intense. Displacement of the scapula forward causes them to disappear. He has hitherto called these sounds the "scapular rub" in his clinics, but three cases recently seen have enlightened him as to their origin. In all three cases they were produced in the apparently healthy shoulder joint during its respiratory movements. From this point of maximum intensity they were propagated over the scapulæ and down along the humerus. In two cases they aroused a suspicion of tuberculosis and on account of this possibility he thinks them worthy of mention. It seems not improbable that similar confusing joint sounds may be produced in the sternoclavicular and acromioclavicular joints.

Bronchial Vincent's Angina.—J. H. Rothwell reports two cases of bronchial affection following pneumonia in which the bloody sputum was full of Vincent's spirilli, which indicates to him that this infection may sometimes attack the bronchial mucosa without showing itself in the pharynx or throat or tonsils. He has not seen such reported so far. He has also had another similar case, and mentions still another in the practice of another physician.

Renal Senescence.—Joseph Walsh calls attention to an observation made by him of a thickening of the interstitial tissues at the apex or capillary end of the kidney as age advances. He has found this so uniformly that he says the age of the individual can be estimated by the amount of interstitial tissue found. The following precautions should be taken, however: "First, the apex of the pyramid should be in view. Sometimes a cross-section of the kidney is made in such a way that we see a long stretch of pyramid but instead of one we are looking at two pyramids, end to end; in other words, a specimen may be cut across two pyramids in such a way that the apical portion of one pyramid will run into the apical portion of the other so as to make the end of the specimen actually near the second cortex though the second cortex is not in view. Second, edema must be differentiated from thickening of the interstitial tissue. Third, the amount of interstitital tissue should be estimated, not from one single location, but from several fields of a two-third lens. Fourth, interstitial nephritis increases the amount of interstitial tissue at the apex of the pyramid and must be accounted for. Fifth, pyelonephritis and hydronephrosis obscure completely the thickening due to age."

Tampon for Nasal Hemorrhage.—M. D. Stevenson uses a tampon composed of compressed cotton modified

from Simpson's tampon, three inches long by one-half inch wide by one-sixteenth thick, wrapped as in a cigarette with gutta percha tissue, the free edge being gummed down by some sterile ointment except at the ends. These smooth-surfaced tampons are easily and usually painlessly removed, and he thinks they are much better than trusting to local medicinal applications in cases of postoperative hemorrhage. Sterile water or salt solution should be dropped at the ends to cause the tampon to swell and fill the passage. Two can be used side by side in very wide fossa and they can readily be narrowed by clipping.

The Lancet, May 28, 1910.

Intracranial Complications of Middle Ear Disease.—A. J. Hutchinson gives in detail the histories of four cases. He says that the principal complications are meningitis, intracranial abscess, and sinus phlebitis and pyemia; also that the question is often asked "What proportion of the general death rate is due to middle ear suppuration and its sequelæ?" Taking four series of consecutive post-mortems in general hospitals amounting to 23,838 cases, it is found that death in 198 resulted from middle ear suppuration. A second question often asked is "What percentage of patients with middle ear suppuration die of that disease or its results?" To this question no satisfactory reply has as yet been given, as all investigators mention the elusiveness of their material. One author estimates the death rate at two and one-half per cent. Of 973 cases reported by several writers as to complications, 362 had meningitis, 355 abscess, and 256 sinus phlebitis. Of the author's four cases, two had temporosphenoidal abscess, one not recognized during life, the other diagnosed correctly, opened, and drained, but ending fatally from septic encephalitis, the third had extradural abscess and the fourth lateral sinus thrombosis. Both of the latter made good recoveries.

Demonstration and Study of Spores in the Schizomycetes.—A. F. Stanley Kent says that in his researches on this subject it occurred to him that the old idea of there being an envelope or film of a fatty nature in the neighborhood of the spore, shutting it off from evaporation and from contact with aqueous solutions, while providing some explanation of the difficulty of decolorizing already stained spores might also give some indication of a method for enabling the stain to penetrate more readily. The method ultimately elaborated by him consisted at first in the solution of the staining agent in a fatty solvent, and some success was attained in this way, but soon another procedure was adopted and a different principle employed. The peculiarity of the method consisted in the employment of an alkali for the purpose of rendering the resisting envelope of the spore permeable and readily penetrated by the staining solution. The desired result was found to be actually brought about by the alkali employed, and the resulting preparations showed the spores sharply stained, while the cell body was uninjured and might readily be tinged with a counter stain if necessary. Briefly, then, the process consists in preparing a film in the usual manner and fixing it by heat or by other means. Solution of sodium hydrate is then flowed over the film and allowed to act for some seconds, after which the still wet (and alkaline) film is flooded with carbol-fuchsin solution and heated as usual. This heating, which adds considerably to the intensity of the staining, need not be at all prolonged, a few minutes being amply sufficient. It will be found that a precipitate is produced by the soda solution in the carbol-fuchsin stain, but this may be neglected, as it will to some extent disappear as the temperature rises, and in any case does not appear to damage the preparation. The ordinary 25 per cent. hydrochloric acid is next flowed over the film and allowed to act for a second or two, then washed thoroughly off and the film flooded with 1 per cent. aqueous solution of methylene blue, which may be slightly heated if an intense stain is required. Thereafter nothing remains but to wash, dry, and mount as usual.

A Case of Cephalic Tetanus.—A case of this disease (known also as Kopftetanus of Rose), is reported by C. V. Kebbell, his patient being a boy of five years, who had fallen from a wagon. A large flap of scalp had been torn from the skull, exposing about one square inch of bone over the right parietal bone in the region of the eminence. One week later the boy was doing well. Then commenced right facial paralysis, and in a few days there was slight head retraction, with rigidity of the arms and legs. The possibility of a localized inflammation or suppuration was recognized, and it was decided to trephine. A piece of bone was removed at a point three-quarters of an inch above and behind the right external auditory meatus. The meninges bulged and pulsation was slight. A director inserted toward the base of the brain revealed no pus. On the following day three spasmodic seizures occurred, and there was now some rigidity of the abdominal muscles between the attacks, and tetanus was diagnosed. Two c.c. antitetanic serum were injected. The further clinical course is given in detail. In a month the patient had no more seizures, but it was three months after the original injury before the trismus was completely gone. The interesting point in the case is the association of the facial paralysis with tetanus. This condition is uncommon, and is very fatal, the mortality in the acute form being 41 out of 45 cases, while in the chronic form 8 out of 32 died. The origin of the paralysis of the facial muscles may be suggested as due to other causes apart from tetanus. An isolated facial palsy, due to involvement of the cerebral cortex or internal nucleus, as a result of injury is uncommon. There is usually hemiplegia as well. Damage to the nucleus of the seventh nerve from hemorrhage is likewise unusual. There were no signs of concussion or affection of other nerves to suggest a fracture of the base of the skull. A very localized patch of meningitis involving the seventh nerve, or hemorrhage, affecting the face center only from contre-coup, might be possibilities. There was no evidence of any bruising or damage at the level of the stylomastoid foramen to occasion an injury of the nerve there. There were no signs of ear disease, or involvement of the eighth nerve, and paralysis of the face of this duration due to cold is not common, so far as the author has noted, in children. After considering all the above points, he thinks the diagnosis was correct, and that this was undoubtedly an unusual form of infection with the tetanus bacilli—cephalic tetanus.

The Specificity of Cancer and the General Principles of Its Treatment and Prophylaxis.—A. W. Brand says that no disease more plainly bears upon itself the impress of specificity than does cancer. It is not due to a parasite in the shape of the cancer cell. No somatic cell can be a pathogenic parasite so there must be an intracellular influence which endues it with malign parasitic power. Why the extrinsic origin of cancer is not universally accepted is to the author incomprehensible. The infective agent of the disease resides in the invaded cell, since from a single cell a cancerous tumor is capable of reproducing the disease in another host. Unless distant extension is obvious, free excision of the accessible diseased area including infected lymph vessels glands and adjacent structures as muscles and especially fascia may be attempted as the first line of treatment. It is a marked characteristic of cancer and one which it shares with syphilis that it may remain quiescent for a time. It is evident from accumulated experience that lack of success after surgical treatment must be attributed either to incomplete removal or to the occurrence of distant dissemination prior to operation. Dark, indeed, says the author, must the prospect be to the man who believes that cancer is a constitutional affection with local manifestations and having an intrinsic origin, for the surgeon can then do nothing for its removal. If cancer is ever to be successfully treated the cause must be attacked, and this can be done only by specific means. Should the infective agent prove to be a protozoon, as in syphilis, malaria, etc., and the author believes that this will be shown to be the case, then a paraciticide is indicated, and among the methods of exhibition, kataphoresis of the accessible neoplasm would doubtless commend itself. On the other hand, if the causal agent be proven to be a bacterium, then success may follow the use of a cancer vaccine prepared after the methods of Wright. From the foregoing statements the author submits that the successful treatment of cancer will consist in the removal by surgical means of accessible tumors, more especially those threatening life from mechanical causes, combined with the internal exhibition of specific remedies, the latter being relied on to check the further spread of the disease and neutralize that already existing by destroying the causal parasite, while inoperable disease, whether accessible or inaccessible from the first, can be treated only with the specific remedies and such non-operative mechanical means as fulguration, *x*-rays, radium emanations, kataphoresis, etc. Cremation of the cancerous cadaver is imperative. This means of disposal would remove a very obvious risk obtaining where earth burial is resorted to. Earthworms, which convey soil from a depth of six to eight feet to the surface, might communicate by the contamination by percolation and the poison to water supplies. All dressings from cancerous wounds, all discharges and dejecta from cancerous patients should be destroyed by fire. Finally, all cases of cancer should be subject to notification.

British Medical Journal, May 28, 1910.

Artificial Respiration in Newborn Infants.—B. F. Pendred relates a most unusual occurrence. A woman

was delivered of twins, no skilled attendant being present. The first child cried lustily, was separated, and put aside as usual. The second child was born *en masse* with the placenta, without rupture of the second bag of membranes, there being but one placenta, with two cords and two separate bags. The attendant, thinking the whole mass was afterbirth, put it in a pan and to one side. The physician did not arrive until forty-five minutes later. The child (male) was then removed from the bag and showed some feeble signs of circulation. Artificial breathing induced respiration after half an hour. The child is now three months old and has doubled his weight since birth. The author's theory as to the survival of the child is that as the placenta lay exposed to the air in the pan, an opportunity was afforded for a small amount of oxygen to enter the fetal circulation. The method of respiration he employed was to apply the lips to the mouth of the child, only a handkerchief intervening, and "blowing up" the lungs, then compressing the chest with the hands, and so on. One great advantage of this method is that it can be carried out while the child is immersed in warm water, and another is that the hand grasping the chest can feel a definite and highly satisfactory expansion at each "blow," and one is not left in doubt as to whether air enters or not. Further, there is no fear of injury to the child's shoulder joints or neck muscles by over-vigorous stretching. He always employs this method and believes it superior to any other.

Preparation of the Skin for Operation by Means of Dichloride of Ethylene and Iodine.—After a brief description of the physical and chemical properties of dichloride of ethylene, A. J. Wallace says that when it is painted on the skin temporary mild tingling or pricking sensations are produced, and as the violet liquid quickly dries the light brown iodine stain appears. Immediately—a few minutes to an hour—before operation, swabbing with sterile swabs, saturated with a mixture of equal parts of dichloride and alcohol (metholated spirits). (2) Swabbing with sterile swabs saturated with pure dichloride. (3) Painting with iodine-dichloride—ethylene solution—about 2½ per cent. (4) Application and fixation of sterile lint over the prepared area. The iodine is added directly to the dichloride ethylene solution in the proportion of about 2½ per cent., giving a violet color which in bulk looks black. The general effects seem equal to those of the iodine-acetone solution previously recommended by the author, without the irritant effects of the latter.

Some Ophthalmic Conditions Caused or Influenced by Diseases of the Upper Respiratory Tract.—A. S. Cobbledick says that in every obscure eye case, especially where there is a complaint of a long-standing nasal or post-nasal catarrh, the accessory sinuses should be examined by an expert, and if diseased they should be radically treated for the benefit of the eye trouble. When an eye operation is contemplated, not only should a careful examination be made of the conjunctiva, but the mouth and nose with its diverticulum, the nasal duct, and lacrymal sac should be examined. If pyorrhea is present, no operation should be entertained until the mouth is perfectly clean. Even then the system may be so permeated with staphylococcus toxins as to render the likelihood of an endogenous eye inflammation possible as a result of the traumatism of the operation. The same remarks apply to atrophic rhinitis and chronic sinusitis. The condition of the operator's mouth and nose must also be considered in this connection; carious teeth, pyorrhea, or nasal trouble, including acute coryza, should be looked upon as a possible source of infection, and precautions taken; speaking during the operation should be forbidden for obvious reasons. The bacteriology of post-operative inflammatory eye troubles indicates that the pneumococcus and staphylococcus play an important part; these microorganisms are not frequently found in the conjunctival sac, but the mouth is a common habitat, hence the great likelihood of infection arising from the operator's or assistant's exhalations. Mention must be made of blindness resulting from the onset of optic atrophy, caused by intranasal operations. Such cases are, of course, not frequent, but there are a number on record. Perhaps the most common accident has been entry of the orbit when exploring the antrum of Highmore with a trocar or cannula, or in forcibly boring a hole in the alveolus of the superior maxilla, for drainage purposes; loss of control and the absence of a stop on the drill has resulted in puncture of the floor of the orbit and either injury to the optic nerve or infection of the orbital contents. Forcible removal of bony nasal spurs and of the middle turbinal bone may produce a fracture involving the optic canal, the formation of callus, pressure of the callus on the nerve, and subsequent atrophy.

Berliner klinische Wochenschrift, May 16, 1910.

Hemolytic Free Fatty Acids in the Liver of Acute Yellow Atrophy and Phosphorus Poisoning.—Joannovics and Pick have made a study of the extraction of hemolytic substances from the liver of a man who died of acute yellow atrophy, of a man who died of phosphorus poisoning, and of dogs and rabbits which were killed by phosphorus. They summarize their results as follows: (1) Hemolysins of exceptional activity may be obtained from the liver in acute yellow atrophy and phosphorus poisoning in both man and animals. (2) These hemolytic substances are soluble in ethyl and methyl alcohol, ether, and acetone, and are made up almost entirely of fatty acids; the lipoids insoluble in acetone are practically without hemolytic action. (3) In experimental phosphorus poisoning this hemolysin is present in the blood in large quantities. (4) The subcutaneous fat in phosphorus poisoning does not contain this hemolytic substance. (5) The presence of such an intensely active hemolysin in the liver is valuable for the demonstration of free fatty acids. (6) The fatty acids which come in consideration in hemolysis in organic extractions, appear from the manner of their hemolytic action to belong to the higher unsaturated fatty acids. (7) In acute yellow atrophy and phosphorus poisoning it would appear that these unsaturated fatty acids, which normally are combined in lecithin, are set free by the destruction of the latter.

Münchener medizinische Wochenschrift, May 10, 1910.

The Lymphocytosis in Basedow's Disease and "Basedoid."—Max Bühler has examined the blood of twenty definite cases of exophthalmic goiter and a considerable number of the abortive forms and pseudo-Basedow cases. He finds that in true Basedow's disease and in the *formes frustes*, there is almost constantly a relative lymphocytosis. The identification of a doubtful case may be aided by a blood examination, when a relative increase of the lymphocytosis gives evidence of the thyreotoxis basis of the condition. The presence of a lymphocytosis is of considerable value in differential diagnosis. The absence of a lymphocytosis, however, in a case of Basedow's disease or pseudo-Basedow is not sufficient to reject the diagnosis.

The Growth of the Eye After Iridectomy in Early Youth.—L. Schomburg calls attention to the work of Wessely, who found that if he performed the operation of iridectomy and sclerotomy on rabbits during the second week of life, and then weighed the eyes of the animals after they had reached maturity, that the eyes which had been operated on showed distinctly a lesser development than did the normal eyes. Schomberg then reports his observations on two twin boys of 7 years of age, who on account of blennorrhea neonatorum had had iridectomies done at the age of eight months. Examining the eyes of these two boys by the Hertel exophthalmometer and the Juval ophthalmometer, he found that in one boy the iridectomized eye was larger than its mate, and in the other boy it was smaller. He was thus unable to confirm Wessely's experiments on animals.

Skin Hemorrhages in Typhoid Fever.—Adolf Huber reports three cases of hemorrhage into the skin in the course of typhoid fever, and says that this complication may occur in mild as well as severe cases of the disease. They appear at the height of the disease and are not of necessity associated with intestinal hemorrhage. These hemorrhages cannot be called roseola hæmorrhagica, either if one under this title places the hemorrhagic infiltration of the usual rose spots, or if one considers the hemorrhages to occur instead of the rose spots. The characteristics of the special typhoid bacillus does not determine the occurrence of the hemorrhages, but the relation of the human organism thereto; this is usually called the hemorrhagic diathesis. No such diathesis was present in the three cases reported either before or after the disease. It must have developed and disappeared during the course of the disease. The prognosis of the disease must not be based entirely upon the presence of hemorrhages in the skin, though if they are very numerous they are an unfavorable sign.

Sterilization of Habitual Criminals.—Santos Fernandez and F. M. Fernandez call attention to the advantages that this method would bring to all civilized countries. They are in favor of the method recommended by Dr. Sharp in 1899. The authors review the subject and mention the several methods recommended by Sharp, Carrington, and Belfield. They conclude by urging the Cuban Government to try the method in its penal institutions.—*Crónica Médico-Quirurgica de la Habana.*

Sixty-first Annual Meeting, Held in St. Louis, June 6, 7, 8, 9, and 10, 1910.

(Special Report to the MEDICAL RECORD.)

(*Continued from page* 1033.)

HOUSE OF DELEGATES.

Wednesday, June 8—Third Day.

DR. WILLIAM H. WELCH, PRESIDENT, IN THE CHAIR.

Report of Public Health Education Committee.—Dr. ROSALIE SLAUGHTER MORTON of New York presented the work of this committee which it seemed had not been appointed with due regard to parliamentary law and was, therefore, not an integral part of the A. M. A., but not being aware of this the committee had prosecuted a vigorous campaign in educating the public in matters of health and hygiene. Courses of lectures were given under the auspices of the women of the A. M. A. working through their various county societies. In all, 2,250 lectures were given in forty States and were listened to by 102,575 people. They were given on twenty-eight subjects chosen by the committee. Dr. G. W. Wagoner, in his presidential address before the Medical Society of the State of Pennsylvania, said that doctors were losing confidence and receiving the criticism of the laity, and this was due to the fact that throughout the country the public was being exploited by pseudoscientists who affirmed that the so-called drug doctors were commercially interested in keeping the people ill while they were working to prevent disease. The laity was interested in public health education. The psychological moment had come and it would be a serious reflection on their profession if they did not educate the public to an appreciation of the position of the doctor as the protector of the health of the community. The fact that such a movement was being carried on as a national movement under the auspices of the American Medical Association carried much weight with it. They felt sure that another year would give opportunities for a wider usefulness. They had had the cooperation of the United Charities Association and were helping to extend the work of the Special Committee on the Prevention of Blindness. Evidence was presented to show that the work was commended by physicians who were leaders in the profession. They had refrained from a discussion of vivisection in their lectures until the aims of their work should be better understood as the opening of controversial questions might lead to misconstruction of their motives and thus limit their influence.

The House of Delegates voted to make provision for a continuation of this work when revising the by-laws.

Report of Reference Committee on Medical Legislation.—Dr. J. W. CLEMMER of Ohio urged that the committee working on a uniform medical practice act be continued. He reported great progress with optometry bills, five new bills having been passed. They now had optometry bills in twenty-two States. They urged the trustees to have court decisions on medical practice acts published as soon as possible, and congratulated them on having obtained the cooperation of the Civic Federation and the Commission on Uniform Laws. They recommended the adoption of a resolution urging greater effort to secure amendment of State food and drug laws so that they would conform to the Federal laws. After having amended this resolution to read "Providing the standard of drugs demanded by Federal law conformed to that of the U. S. Pharmacopeia and the National formula." This resolution was adopted.

Report of Reference Committee on Officers.—Dr. GEORGE W. GUTHRIE of Pennsylvania presented this report which recommended that the resolution authorizing the appointment of a commission of seven to draft a plan for the organization of a National Bureau of Public Health be adopted, after being amended so that Dr. Welch be included as a member of this commission. They also recommended that a resolution be adopted approving of the principles of the Owen bill, having for its object the creation of a National Department of Health, and that they send resolutions expressing their approval and thanks to Senators Owen, Creager, and Hanna and also to Mr. Irving Fischer and other coworkers who had assisted in the solution of the greatest problem now confronting the people, the conservation and promotion of health. The House adopted these resolutions.

Resolutions on the Death of Dr. Ricketts.—A committee appointed by the House of Delegates, consisting of Drs. T. D. Tuttle, Frank Billings, and Alexander Lambert, presented resolutions on the deaths of Dr. Howard Taylor Ricketts and of Dr. Conniff of Ohio, who contracted typhus fever while assisting Dr. Ricketts and had since died at his home. These resolutions were adopted by a rising vote with the request that they be published in the *Journal of the American Medical Association.*

Report of the Reference Committee on Insignia.—This committee reported that in accordance with the decision at the meeting of 1909 that it was desirable to change the insignia of the association owing to the fact that it contained the Red Cross, designs had been submitted to them. They had chosen one in scarlet and gold, one-half inch in diameter, and having in the center a rod and serpent in a red field, surrounded by a band of gold in which appeared the words, American Medical Association. The house ratified this selection.

Committee on Award of Medals.—This committee, consisting of Drs. E. E. Southard, T. D. Coleman, and Hugh H. Young, awarded the Gold Medal to Dr. Claude A. Smith of Atlanta, Ga., for research work in hookworm disease. No medal was awarded in clinical surgery. Certificates of honor were awarded to the following: University of Minnesota; St. Mary's Hospital, Rochester, Minn.; St. Louis City Hospital; Indianapolis Department of Health; University of Michigan; Special Committee on the Prevention of Blindness of New York; Northwestern University, Chicago; St. Louis Medical History Club, and Dr. J. J. Houwink of St. Louis for an exhibit of skin diseases.

Thursday, June 9—Fourth Day.

DR. ALEXANDER LAMBERT, THIRD VICE-PRESIDENT, IN THE CHAIR.

This session was devoted to a revision of the By-laws in accordance with recommendations made by the Reference Committee on Amendments to Constitution and By-Laws. A thorough revision of the By-Laws was made; most of the changes, however, did not affect the meaning but only modified the wording for the purpose of securing greater lucidity. The amendments that involved a change provided for the coordination of standing committees; limited associate membership to physicians who were members of chartered national societies of foreign countries adjacent to the United States, dentists holding the degree of D. D. S., who were members of State or local dental societies, and pharmacists who were active members of the American Pharmaceutical Association; and provided rules for the establishment of a council on Health and Public Instruction which should have an office at the headquarters of the Association and whose work should embrace the following subjects: Legislation, organization, publicity, defense of medical research, and public health. An amendment was also adopted striking out the word "General" throughout the By-Laws when followed by Secretary

so that the office heretofore known as that of General Secretary would henceforth be known as Secretary.

The House of Delegates also adopted a resolution providing that certified copy of the Constitution and By-Laws of the American Medical Association as amended at this session be sent to the secretary of each constituent association with the request that the changes be brought to the attention of the House of Delegates of the constituent association.

Election of Officers.—The following officers were elected by the House of Delegates of the American Medical Association for the ensuing year: *President,* Dr. John B. Murphy, Chicago, Ill.; *First Vice-President,* Dr. E. E. Montgomery, Philadelphia, Pa.; *Second Vice-President,* Dr. R. C. Coffey, Portland, Ore.; *Third Vice-President,* Dr. W. G. Moore, St. Louis, Mo.; *Fourth Vice-President,* Dr. H. L. E. Johnson, Washington, D. C.; *Secretary,* Dr. George H. Simmons, Chicago, Ill.; *Treasurer,* Dr. Frank Billings, Chicago, Ill.

Election of Trustees.—Three trustees were elected to serve until 1913: Dr. W. W. Grant, Denver, Col., to succeed himself; Dr. Frank P. Lutz, St. Louis, Mo., to succeed Dr. Philip Marvel of New Jersey; Dr. C. E. Cantrell, Greenville, Texas, to succeed himself. Member of Council on Education to succeed Dr. E. E. Southard. Massachusetts, Dr. George Dock, Washington University. Appointed to the Council of Health and Public Instruction, Dr. H. M. Bracken, Minneapolis; Dr. Hugh Cabot, Boston; Dr. Henry B. Favill, Chicago; Dr. J. N. McCormack, Bowling Green, Ky.; Dr. W. O. Woodward, Washington, D. C.

Election of Honorary Members.—The House of Delegates elected Dr. Alfred Saenger, Hamburg, Germany; Dr. J. Herbert Parson, F. R. C. S., London, Eng.; and Dr. H. J. Honan, Berlin, to honorary membership in the American Medical Association.

Place of Meeting.—Los Angeles was selected as the place of meeting for 1911.

Resolutions Adopted.—Among resolutions adopted by the House of Delegates were the following: Resolutions providing for the publication of journals of pediatrics and surgery similar to the *Archives of Internal Medicine.* This action was taken in accordance with the requests from the sections on pediatrics and surgery in order to provide for the publication of a class of special articles not suitable to a journal like the *Journal of the American Medical Association.* These journals were to be published as soon as publication facilities were available.

A resolution providing that, in view of the fact that suicides had increased 50 per cent. during the last seven years and in view of the fact that the publication of such facts in the daily papers had a bad effect on account of their suggestive influences, a recommendation be sent to the public press requesting that material of this kind be omitted from the newspapers.

A resolution to the effect that inasmuch as much of the teaching of hygiene in normal schools and colleges was defective and based on misinformation, a movement be initiated to provide proper instruction for such institutions.

A resolution expressing regret that an institution of such standing as Columbia University had seen fit to establish a school of optometry thus giving countenance to the practice of optometry by persons not having a medical education.

Resolutions from the Section on Ophthalmology protesting against the appointment by governors of the States of assistants to examining ophthalmologists who were not medical men. Physicians should not encourage this by sending patients to optometrists to have their eyes examined. Also resolutions to the effect that every general practitioner should receive such training as would fit him to treat infectious disease of the eye and errors of refraction. Another resolution requesting that steps be taken to establish a definite standard for the examination of the eyes of pilots. And a resolution extending the scope of the work of the Committee on Ophthalmia Neonatorum so that it would embrace the prevention of blindness from other causes as well as changing the name of the Committee on Ophthalmia Neonatorum to Committee on Preventable Blindness.

A resolution recommending the drawing up of a plan whereby every member of a county society should be *ipso facto* a member of the State society and every member of a State society should be *ipso facto* a member of the American Medical Association. At present every State had a plan of its own.

SECTION ON SURGERY.

Tuesday, June 7—First Day.

DR. CHARLES H. MAYO OF ROCHESTER, MINN., CHAIRMAN.

Prophylaxis of Cancer.—The chairman, Dr. CHARLES H. MAYO of Rochester, Minn., said that the mass of recent studies on the subject of malignant growth had revealed the fact that malignancy was very common throughout the vertibrate kingdom. The domestic animals were more subject to it than the wild, probably because of their living longer. As to prevalence by regions, it was least common in Japan and most frequent in England, with the United States as very close second. It might be described as a lawless proliferation of epithelial cells destroying and ultimately itself destroyed. All studies tended to show that a precancerous state existed and this had its most common seat in the regions of chronic irritation. It was significant that the "organs of convenience—the stomach, great gut, and bladder, and their appendages—were the common seat of cancer. There was no question following the researches of McCarthy and Wilson that cancer was relatively common in the appendix and had its too frequent seat in the base of gastric ulcers. The high per cent. of malignant growths developing in the prostate was in itself alone an important factor in determining operation. Unable to verify the parasitic theory, we were forced to the hope that some cytolytic agent would be found, either from autogenous sources or possibly from extracts made from embryos of the same species. Whatever the future of these experiments held in store, the present duty of the profession was clear. All tumors should be subject to surgical consultation and it should always be remembered that risk lay not in surgery but in delay.

Surgical Treatment of Compression Paraplegia.—Dr. A. PRIMROSE of Toronto said that hemorrhage, the cause of compression in the dural canal, might be either intra- or extradural. The symptoms differed from those of congestion by the greater speed of onset. It was very probable that certain cases of Potts disease remaining paraplegic after months of rest and extension should be laminectomized, for there occurred occasionally a small localized abscess which would respond to no treatment save evacuation. Indeed, in rare cases of specific spines, where the pressure was so great as to cause danger of degeneration before relief could be expected from medication, immediate operation might be indicated. There was no possibility of restoration of function of the severed cord, but recent researches suggested the possibility of gaining some control over the bladder and rectum by splicing the lower dorsal to the sacral nerves.

Anastomosis of Facial and Spinal Accessory Nerves and the Distal End of Spinal Accessory with Descend-

ing Hypoglossal.—Dr. W. W. Grant of Denver said that the success of this operation demonstrated that the proximity of the cortical centers of anastomosed nerves had not the value which had been ascribed to it. The advantage of using the spinal accessory was a technical one, it being far the most easily reached.

Dr. J. T. Bottomley of Boston said that the subject of Dr. Primrose's paper was still very undeveloped. Laminectomy in itself was not considered a dangerous operation, and he wished to make a strong plea for its early employment.

Injuries of Abdominal Viscera Without External Signs of Violence.—Dr. H. H. Sherk of Pasadena, Cal., said that of utmost importance was the history of the injury and particularly the nature of the violence which had been applied. The condition of the clothing, the region of the impact, the degree of fullness of the hollow organs—these were considerations of great importance. Often the nature rather than the degree of traumatism was the determining factor. Some symptoms, of course, were peculiar to certain groups of organs. Pain, while important, was often inverse to the degree of injury. In early stage it was due to tearing of the peritoneum, in late to inflammation following the course of extravasations. The first would be local, the second general. Distention occurring early suggested rupture, that appearing late, intestinal paralysis. Cessation of peristalsis, if occurring late, was suggestive of gut perforation.

Dr. M. H. Richardson of Boston was glad this timely and trustworthy paper had been read. For, after years of experience, he had come to regard surgical diagnosis as of much greater importance than mere technique. Except in obvious emergency cases, the most extreme of which were furnished by the class under consideration, he stood for conservatism. There was, however, reason in all things, and he felt convinced that, given an adequate blow on the belly and some signs, one should operate without ever waiting for vomiting and distention.

Present Status of Vaccine Therapy.—Dr. E. E. Irons of Chicago said the method was far from being a cure-all and was in danger of being brought into disrepute because of its employment by ill-qualified persons. Its realm lay in conjunction with surgery rather than as a substitute for it. The use of vaccines as a last resort was to be discouraged. The autogenous were usually preferable to the stock vaccines. The therapeutic use was best shown in chronic conditions, such as pyuria, acne, colon bacillus infection, etc. In general the infections due to the staphylococcus responded better to vaccination than did those arising from the streptococcus and other more active forms. The status of gonococcus preparations was still unknown. The protection afforded in tropical diseases was encouraging and in Russia definite results had been claimed in the therapy of scarlatina. Pneumonia was being treated with some success by injections of detoxicated virus. Finally, these little known agents were powerful and dangerous and were as yet adjuncts only to other therapeutic measures.

Dr. J. B. Deaver of Philadelphia regarded the opsonic index as clinically valueless; thought that the vaccines should be used with great care, and admitted that tuberculin had given some promising results in bone tuberculosis.

Dr. Cram of Kalamazoo, Mich., reminded Dr. Deaver of his attitude some years ago as to the clinical uselessness of the leucocyte count and reminded him that the opsonic index could be obtained to-day almost as rapidly as this now widely adopted diagnostic agent. The index was the chief agent whereby we could with certainty determine the degree and frequency of dosage of vaccines.

Appendicitis in Children, with Report of 500 Cases.—Dr. H. C. Deaver of Philadelphia said it was epigrammatic that every bellyache in a child should be considered appendicitis until proved otherwise. Rectal examination was of the utmost importance. The chief differential diagnosis to be made was from right-sided pneumonia. Infantile appendicitis was far more frequent than generally supposed. Operation was imperative in the first twenty-four hours. No opium or purgatives was to be given.

Dr. L. S. McMurtry of Louisville said that the difficulties of diagnosis were greatly increased by the absence of subjective symptoms, as well as by the known variability of position of the appendix in children.

Wednesday, June 8—Second Day.

Final Results in Congenital Dislocation of the Hips.—Dr. E. H. Ochsner of Chicago said that the sixth year in double and the eighth in single dislocations were about the age limits for the bloodless operation. The open operation probably was never justifiable in double dislocations, but was frequently indicated in single. The functional, weight bearing method in early life was ideal, but not frequently reached because of inability of the average general practitioner to recognize the lesion. He reported 71 per cent. of successes with the congenital condition treated under the age limit. He advocated the employment of moderate force only and urged that the head must be brought over the posterior border of the acetabulum. The hamstrings need not be stretched. A cast should be rigidly applied and kept in position for one year with but a single change.

Dr. A. J. Gillette of St. Paul thought that considerable force might be employed. The only danger was fracture and temporary paralysis. Neither was serious. In any event, an ankylosed hip was much better than an unreduced one, because of the freedom of motion of the sacroiliac joint. He advocated leaving the cast on for from three to six months.

Dr. J. P. Lord of Omaha had for the past two years used Bradford's device for replacement and regarded it as far superior to anything yet devised. He kept the cast on for three months, after which atrophy of disease was apt to take place.

Tuberculosis of Adult Knee Joint, with New Theory and Plan of Operation.—Dr. Leonard W. Ely of New York said that his report was based on the study of sixty-two specimens in the laboratory. Ignorance of fundamentals underlying the physiology and pathology of joint conditions alone was responsible for the chaotic condition in which the study was still found. The facts were these: Synovia and bone marrow were the only tissues ever involved in tuberculosis. Furthermore, the author's studies had shown that not all bone marrow was susceptible, for the shaft or yellow marrow was much less vulnerable than the red. This probably explained the nonoccurrence of tuberculosis in bone shafts. An interpretation of nature's attempt at cure shows that she strives to deprive the joint of function. By human agency this could best be done by simple resection. After this operation the author had observed that at once there was a disappearance of the synovia and of the red marrow, followed by cure. No elaborate dissection was necessary and no more than three-fourths of an inch of bone should be lost. This was a great improvement over the old operations, which blindly sought to remove all foci of disease. All scraping and packing should be abandoned; the crucial and lateral ligaments should be left *in situ* and the least trauma possible should be inflicted, for

the *sine qua non* was primary union. He denied that means at present existed whereby the best clinicians could make a positive diagnosis of joint tuberculosis.

Dr. Binnie of Kansas City said that the paper was a most important contribution to the surgery of joints. Of course, he understood that the operation advised was intended solely for joints without mixed infection. If pyogenic, a very radical operation was immediately called for, and it was extraordinary what extensive regeneration was possible after such mutilating operations.

Dr. Ely in closing said that no matter how thorough the operation no one could help leaving some tuberculous tissue. Recovery was made possible because loss of function had allowed of the absorption of all vulnerable tissue. It must be a true and not a pseudo-anklyosis and this was the only form produced by rest.

Acute and Chronic Joint Infections and Their Surgical Treatment.—Dr. J. B. Murphy of Chicago said that metastatic infections of bone rarely entered the joint. "Rheumatism" as a term must go in time, as "malaria" had gone, for all acutely inflamed joints were undoubtedly septic. The all-important question was the degree of injury to the synovia. It was capable of protecting against any degree of infection if uninjured. Hence the treatment of all acute joints lay in aspiration and extension, and the injection of a fluid calculated to increase the polymorphonuclear reaction about the joint. A 2 per cent. solution more than twenty-four hours old of formalin in glycerine served this purpose.

Radium: A Contribution to Surgery.—Dr. Robert Abbe of New York delivered this oration. We know to-day as little of so-called radiant energy as of the vital forces of our own bodies. What was known of the instability of the atoms, of the speed of transmission, of the actual nature of the bombardment which seemed at all events to take place when one's eye traversed the spintharascope? What, therefore, could we be expected to know of the action of this magic force which was perhaps a vital manifestation of life itself on the cells of aberrant growths? In using radium we probably were supplying electricity in + or — form. Less complex in cellular as in physiologic development were plants, and on them radium exerted extraordinary reactions. Seeds exposed for a few hours were delayed in germination, and all germination stopped if exposed for two days. While there was marked reaction to radium in all forms of dry skin growths, unhappily on the wet surfaces there was little if any reaction. What determined this was unknown. In embryonic tissue there was a response to the specific element in radium which always caused retrograde degeneration of the cells.

Open Treatment of Fractures.—Dr. A. F. Jonas of Omaha said that most fractures would in the future as in the past be treated by the general practitioner. Screws in bone held for two or three days only, because of physiological softening. He advised early decision as to employment of open or closed methods because of this softening. He urged especially general anesthesia in reduction of fractures of the humerus and femur because the decision as to treatment depended on getting good definite crepitation. In the presence of this sign the closed method should be used.

Dr. Pease of Kansas City said that most cases coming to open operation were in fractures near the joints. Bone was merely the crystallization in the muscles of lines of force. If this force were removed atrophy would result. The rarefaction referred to as physiological did not occur in the presence of perfect apposition which preserved the lines of force.

Congenital Atresia of the Ureter.—Dr. J. T. Bottomley of Boston said that the embryonic development was important. He had found 56 cases reported. It occurred at the extremes of life and was often associated with supernumerary ureters. The ureter usually reached the bladder where the stricture most frequently was found. It might be passable or impassable, but usually ended in a blind sac. The important thing was to remember the condition as a clinical entity, for it gave rise to a sausage-like dilatation of the ureter which clinically resembled intussusception. Infection of this sac was disastrous, but otherwise the cyst might continue throughout life unrecognized.

Dr. D. M. Eisendrath of Chicago reported a case and presented a specimen which demonstrated the condition as occurring in a ten-day-old child.

Extracapsular Fixation of the Kidney.—Dr. C. A. L. Reed of Cincinnati said that this operation was based on the presence of fibrous elements in the fatty capsule, which, on wiping away the fat content, made it possible to utilize this capsule for suspension without damaging the intima.

Surgical Diseases of the Umbilicus.—Dr. T. S. Cullen of Baltimore said that secondary carcinomata of the umbilical region were not rare. Autopsy had shown the primary focus usually to be in the stomach, whence the growth passed via the liver and suspensory ligament to the belly wall. Many cases of peritonitis in children were evacuated through the umbilicus, but this avenue was closed in adults. In cases where the omphalomesenteric duct remained open, round or even tapeworms were sometimes evacuated at this point, as also might be gallstones and hydatid cysts.

Traumatic Rupture of the Fixed Portion of the Male Ureter.—Dr. Otto C. Gaub of Pittsburg said that this injury occurred either by falling astride an object or else by the crushing of the pelvic bones. He described a method which consisted practically in the application of Young's technique to the direct repair from below of the torn organ. Proust's position was of the utmost value, as the extreme flexion brought the parts into view under tension.

Dr. Harry Sherman of San Francisco said that the mechanics of wounding the urethra by bones was either by their being crushed together when the rami acted as scissors or else by the separation of the bones when the soft parts were torn. It was very important to drain the space of Retzin's.

Dr. Hugh Cabot of Boston said that the immediate posttraumatic care comprised preferably a simple drainage of the bladder. The subsequent care consisted in very free mobilization of the anterior urethra, even to the extent of 1½ inches. This secondary operation should not be undertaken until the crushed parts had had some time in which to recover from the primary injury and immediate suture was rarely indicated. There was no danger of devitalization of urethra by freeing it.

Surgical Considerations in Treatment of Chronic Suppurative Nephritis.—Dr. D. S. Fairchild of Clinton, Ia., said that mild infections of the kidney were more frequent than generally supposed. For these radical treatment was not necessary, decapsulation accomplishing everything necessary for cure. This operation had unjustly fallen into disrepute.

Kidney and Ureteral Stones.—Dr. Miles F. Porter of Fort Wayne, Ind., said that concretions, sometimes of extraordinary size, might be carried for years without giving the slightest sign or symptom. Stones in the bladder usually accompanied ureteral calculi, and stones in any part of the canal might frequently be the cause of cancer. The *x*-ray was the most valuable we at present had in diagnosis.

Dr. Hugh Young of Baltimore said that, despite all modern methods, stones were frequently wrongly diagnosed. He recalled no less than 25 cases of periprostatitis which closely simulated stone. In multiple abscess, nephrectomy was almost always indicated. For a stone in any position in the ureter the extraperitoneal route should be used. In removing stones via the bladder by means of the operating cystoscope great care should be taken not to injure the ureterovesical sphincter.

Dr. Maurice Richardson of Boston said that while nothing human was infallible, the modern *x*-ray came as near to being so as anything could be. Yet healed infarcts, for example, might cast good dense shadows.

Dr. A. D. Bevan of Chicago preferred pyelotomy to nephrolithotomy because of the danger of subsequent hemorrhage. The incision should be small, then stretched by forceps. He used a perineal incision for stone in the lower urethra.

Surgery of Congenital Cystic Kidney.—Dr. T. C. Witherspoon of Butte, Mont., said that all cystic conditions of the kidney were related and that all suggested new growth. The diagnosis was based on four symptoms: Blood, size of organ, discomfort or pain, and uremia. Nephrectomy should not be employed, but if possible the cysts should be removed from the organ.

Dr. Daniel Eisendrath of Chicago said that the disease was almost always bilateral and led to a fatal termination.

Dr. Witherspoon in closing said that the difficulty in determining the underlying cause had left us in the dark as to treatment.

Phrenitis Prostatica.—Dr. J. F. Percy of Galesburg, Ill., said that pelvic rather than cerebral pathology was responsible for many sexual excesses. The microscope often failed to show the relation of the glands either to each other or to the general economy. Many cases of dementia were relieved by prostatectomy.

SECTION ON MEDICINE.

Thursday, June 9—Third Day.

Election of Officers.—*Chairman,* Dr. A. Allen Jones of Buffalo; *Vice-Chairman,* Dr. C. L. Green of St. Paul, Minn.; *Secretary,* Dr. Wilder Tileston of New Haven, Conn.; *Delegate,* Dr. J. A. Capps of Chicago, Ill.; *Alternate,* Dr. Alexander Lambert of New York; *Orator,* Dr. C. F. Hoover of Cleveland, Ohio.

Persistent Patency of the Ductus Arteriosus, Stenosis of the Isthmus of the Aorta, with Degeneration of the Coronaries, of the Cardiac Muscle, and of the Sinoauricular Bundle.—Dr. Kate C. H. Mead of Middletown, Conn., said that out of 400 cases of congenital defects of the heart, Abbott found 106 cases of patency of the ductus arteriosus in combination with other cardiac defects. In the case she reported the patient had at the age of ten years an attack of measles which first brought to notice a heart already dilated and laboring under mitral incompetency and aortic stenosis. The congenital lesion was overlooked for many years. Repeated attacks of influenza further weakened the heart, and the patient died in 1909, at the age of twenty-five, of rupture of the right auricle.

Dr. Wilder Tileston of New Haven, Conn., said that Schroetter of Vienna a few years ago reported a case of patency of the ductus venosus with paralysis of the recurrent laryngeal nerve which resulted from pressure upon that nerve. At that time this was the only case that had appeared in the literature.

Regional Vasomotor Hypertonus, with a Report of a Case.—Dr. C. F. Hoover of Cleveland reported the results of a study of the cephalic, brachial, and femoral arteries which was required in making an estimate of the mass movement and distribution of blood in the arterial system. The sphygmomanometer might be misleading unless controlled by palpation of the arteries. The distinction between vascular tension and endovascular pressure was recognized by palpation. He reported the case of a patient, fifty years old, with symptoms characteristic of angina pectoris; during the past fifteen years scarcely a week had passed without an attack. He discovered that these attacks could be prevented by the use of nitroglycerin, and he also discovered that they were accompanied by a high blood pressure. A striking thing in this case was that the patient had no enlargement of the heart. For two years he had had a variation in the blood pressure between 250 and 350. Therefore the blood pressure did not mean as much as it was generally supposed to mean in these cases. Trinitin was given in this case and then nitroglycerin. Afterwards there was found apparently a normal resistance in the arteries. An interesting point in this case was the disparity in the blood pressure readings between those taken of the upper and of the lower extremities.

Dr. Judson Daland of Philadelphia called attention to the fact that the blood pressure varied at different times of the day and was notably influenced by many conditions. Even the mere application of the pneumatic cuff in certain neurotic patients oftentimes caused an increase of the blood pressure, sometimes as high as 30 or 40. He had no recollection of any case in his practice giving such a disparity in the readings of the blood pressure in the upper and lower extremities, and he said he would be glad to know some theory explaining such a condition.

The Electrocardiogram in Clinical Diagnosis.—Drs. L. F. Barker, A. D. Hirschfelder, and G. M. Bond of Baltimore presented this communication. This consisted of a lantern slide demonstration illustrating the value of electrocardiograms as a supplement to other methods of investigation of cardiovascular conditions. The curves were especially helpful in the diagnosis of cardiac arrhythmias, including the extrasystoles and heart block, in hypertrophy of the right and left ventricles, in arterial paralysis and the pulsus irregularis perpetuus, in tachycardias and bradycardias, and in fibrillation of the atrium. The work was done with Einthoven's string galvanometer, the smaller model of Edelmann's.

Hookworm Disease; Infection and Its Prevention.—Dr. Claude A. Smith of Atlanta reviewed the experimental work previously reported through which he had proved that infection through the skin was the most common mode of entrance into the body. Comparatively few physicians realized the full extent of the prevalence of this disease and the majority of physicians were apt to overlook all cases of the mild or medium variety. A clear history of ground-itch was a much surer means of diagnosis than mere inspection of the patient. In producing experimental hookworm it was found that polluted soil could not transmit the disease unless there was sufficient moisture through which the parasite could pass from the soil to the skin. He had also called attention to the fact that soil pollution could not take place during the fall, winter, and early spring in most sections of the South. The parasite might develop during the winter when the temperature did not go much below 50° F., but it was so sluggish that it was unable to penetrate the skin. The larvæ had a tendency to climb to the highest point attainable in the soil and remained there as long as the moisture was present, but they shrivelled up and died if the moisture completely evaporated. After a long dry spell there was almost no pollution of the soil; a certain amount of larvæ might retain their vitality upon green plants, but they had no chance of producing infection until rainy weather intervened. Thus it was possible for hookworm

infection to take place only at certain seasons. Soil pollution was due to unsanitary conditions and if it were possible to stop this soil pollution the disease would die out in a few years even if no cases were given treatment. Theoretically the prevention of soil pollution was possible but from practical investigations he felt convinced that it was an impossibility. The habits of the people were so thoroughly fixed that it would take years of education and training to make any appreciable progress. After a careful study of the subject and a practical investigation he had become convinced that the most effective procedure in eradicating and preventing the disease was to have it thoroughly understood in all country districts that wading in the mud or sand or shallow ditches after rains during the summer months was to be strictly forbidden. Also people should be taught that ground-itch was the beginning of a serious disease and not to be treated lightly. It had been his experience that the disease was not nearly so frequent nor so severe among negroes as among whites. Some were of the opinion that he had acquired immunity through long exposure to the disease but he had found that frequently negroes were careful to avoid wet soil and dew. There were many points that indicated that the mildness of the disease in the negro was not altogether due to the possible immunity. He hoped to report further on these points at a future time.

Dr. Henry B. Ward of Urbana, Ill., said it was very necessary that they should determine the number and the life history of these parasites because it would lay the foundation of prophylaxis, and he felt positive that all were indebted to Dr. Smith for his extensive, careful, and scientific investigations of this problem. Every detail in the life history of the hookworm was of great importance in connection with this problem of the transmission of the disease and its suppression.

Dr. B. B. Bagby of West Point, Va., said that at a recent meeting of railway surgeons who were connected with Southern railroads the question was asked as to the number of cases of hookworm disease met with and one-half of those present said they had met with it in their locality; the other one-half had met with no cases. The reason it was not diagnosed in one-half of the cases, in all probability, was because the men were looking for typical symptoms of the disease. There were no typical symptoms of hookworm disease.

Dr. Morgan Smith of Little Rock, Ark., asked Dr. Smith if he had ever been able to produce the disease in the negro experimentally.

Dr. Smith replied that he had not attempted to produce the disease experimentally in the negro.

Dr. William Litterer of Nashville, Tenn., said it was very difficult to recognize mild cases of hookworm disease unless an examination of the stools was made. In an examination made in one of the industrial schools of the South, out of 58 worms, 42 were found to be females, and every one of these had ova. The longest infection in a patient that he knew of was eleven years. This was not a case of reinfection.

Dr. John William Colbert of Albuquerque, N. M., told of his experience with hookworm disease in Porto Rico, during the early days of the campaign there.

Dr. Claude A. Smith of Atlanta, Ga., closed the discussion.

Pathological Relationship of Ulcer and Carcinoma of the Alimentary Canal.—Drs. Louis Blanchard Wilson and Byrd Charles Willis of Rochester, Minn., stated that the pathological material studied embraced 167 cancers of the lip, 46 of the mouth, 2 of the esophagus, 189 of the stomach, 15 of the gall-bladder, 22 of the appendix, 20 of the cecum, 42 of the remainder of the colon, and 67 of the rectum, making a total of 570 cases. They had found that 30 per cent. of the cases of cancer of the lip gave evidence of previous isolation of epithelium; such evidence was given in 67 per cent. of the cases of cancer of the stomach, in 33 per cent. of cases of cancer of the gall-bladder, in 100 per cent. of cases of cancer of the appendix, in 10 per cent. of cases of cancer of the cecum, in 40 per cent. of cases of cancer of the colon, and in 31 cases of cancer of the rectum. Their study led them to the following conclusions: 1. The relationship to cancer of simple chronic irritation of the unbroken free surface of the mucosa of the alimentary canal, as indicated by clinical data, was not readily demonstrable pathologically. 2. Scar tissue at the bases of ulcers and obliteration of the lumina of appendices and diverticula segregated portions of mucous epithelium from the neighboring epithelium and from the lumen of the alimentary canal. 3. These portions of segregated mucous epithelium tended to degenerate from pressure and diminished the blood supply, or they tended to proliferate and infiltrate the surrounding tissues, thus forming cancer. 4. These islands of segregated epithelium should be regarded probably as points of least resistance only, and requiring the presence of other factors for the production of carcinomata.

Drs. H. E. Roberts of Minneapolis, Minn., Frank Wilbur Foxworthy of Indianapolis, Ind., D. C. Walt of Little Rock, Ark., Charles G. Stockton of Buffalo, N. Y., Richard Weil of New York, A. Jacobi of New York, Hugo A. Freund of Detroit, G. C. Smith of Boston, Mass., Frank Smithies of Ann Arbor, Mich., John A. Potter of Indianapolis, Ind., and others discussed this paper.

The Importance of a Low Protein Diet in Chronic Nephritis.—Dr. H. D. Arnold of Boston said that in planning a diet for chronic nephritis three cardinal principles must determine their selection of food. (1) They must limit the amount of protein food. (2) They must furnish a sufficient amount of nutrition. (3) They must provide variety. With regard to the limitation of protein food he thought it was safe to say that an average adult in health did not require more than 90 grams of protein in his food daily. For practical purposes he took 90 grams of protein a day as the maximum for cases of chronic nephritis, and had taken 50 grams as the minimum. Roughly speaking the average adult required 2,000 calories in twenty-four hours if at rest, 2,500 for light activity, and 3,000 for moderate activity. Loss of strength and energy and a marked feeling of lassitude were symptoms frequently complained of by these patients; this arose in part from insufficient nutrition and in part from the ingestion of too much protein in the food. He alluded to the fad of using soured milk and its dangers. He objected to the use of an exclusive milk diet; to obtain sufficient nutriment one must give an excess of protein, whereas they should diminish it in order to spare the kidneys. Whatever was accomplished by the regulation of the diet depended upon the stage of the disease and its activity. The treatment was both prophylactic and palliative as well as curative. The stumbling block in the past had been not in the absence of sufficient knowledge, but in the difficulty in getting that knowledge into a sufficiently simple form so as to enable the physician to apply it in every day practice. He demonstrated by charts and tables which he presented, how this difficulty might be overcome, in large measure.

The Relationship of Blood Platelets to Bleeding in Certain Cases of Purpura.—Dr. W. W. Duke of Baltimore said he had made a study of cases of purpura with hemorrhage, in several of which the patients had been transfused. Previous to the transfusion in two cases the plates were practically absent from the blood, as determined by stained smear and counting chamber. For three days following, the platelets were observed in moderate numbers, and during this period there was no tendency to hemorrhage. With the disappearance of these platelets

the bleeding continued. The coagulation time in the cases reported was normal throughout. The tendency to bleed seemed to depend upon a low platelet count. From a study of experiments made it could be stated that about one-fourth to one-third of the number of platelets in the body were destroyed and regenerated each day, and that the life of a platelet was between four and eight days.

Clinical Results of Gastroenterostomy for Nonmalignant Diseases.—Dr. JOHN DUDLEY DUNHAM of Columbus, Ohio, based this report on 48 cases in which he had personally examined the cases before operation. Of this number 15 had died, 12 within 17 days of the operation. The total mortality was 31.25 per cent. In this series there were 12 males and three females. The average age was 50 years. In 27 of these patients known to be alive, there were 14 perfect recoveries, four recoveries in which care was required in choice of food who were improved and one unimproved, the cases of ulcer of the stomach or duodenum with stenosis numbering 21. Of three who had ulcer of the stomach or duodenum without stenosis there was one perfect recovery, one improved, and one unimproved. Two cases of nervous dyspepsia were unimproved and one case of atony with diltation was unimproved. From a study of these cases he concluded that: 1. Hyperchlorhydria as a symptom of chronic gastric ulcer was inconstant and should be disregarded. 2. Perfect recovery might occur when atony of the stomach had existed before the development of ulcer and motor insufficiency persisted. 3. Many of the fatalities cited in this report would have been averted had the family physician made a diagnosis before serious complications had developed. Forty cases in this series gave a history of ulcer covering five years or more before the diagnosis was made. 4. Pylorectomy offered a better prognosis for recovery in five of the fatal cases. Several of the patients were lost by fatal hemorrhages from the ulcer area. Two of the patients died as a result of carcinomatous transformation of the pyloric ulcer. 5. The legitimate field for gastroenterostomy in benign diseases of the stomach was in chronic ulcer near or below the pylorus with stenosis.

Influence Upon Gastric Secretions from Perigastric Lesions, Based Upon Clinical and Experimental Study.—Dr. M. J. LICHTY of Cleveland said that in a review of 600 cases who consulted him in private practice who complained of symptoms referable to the stomach, and on whom gastric analyses were made, 318, or more than 50 per cent., had a gastric juice which was hyperacid. Among 56 cases of acute and chronic appendicitis and analyzed, 83 per cent. had an hyperacidity. Among the gall-bladder cases 75 per cent. showed a gastric hyperacidity. A study of the gastric secretions of a number of dogs before and after operations on the gallbladder and appendix showed (1) A decrease of acidity and secretion in starvation; (2) an increase following excitement; (3) a decrease from perigastric lesions causing inflammation and shock; (4) an increase when the function of the perigastric organ was retarded by adhesions.

Preliminary Report on the Clinical Significance of Indicanuria Based on Ten Thousand Examinations for Indican.—Dr. GUSTAV BAAR of Portland, Ore., said that during the past four years he had made it a routine practice to examine the urine of every patient for indican. In 10,000 urinary examinations he had found indicanuria present in about one-third of the cases. True cases of intestinal autointoxication were rare. It was not the quantity of putrid substances formed in the bowel but the quantity of putrid substances entering the blood which caused the symptoms of autointoxication. Ether narcosis had no influence whatever upon the excretion of indican. All gastroenterostomies, enteroanastomoses, appendectomies, showed excessive indican and distinct traces of bile in the urine for a week or more following the operation. Moderate handling of the intestines during the course of an abdominal operation did not cause any indican to appear in the urine, while prolonged handling did cause excessive indican in the urine. Indican was constantly found in cases of constipation which were complicated by cardiac insufficiency. Among the chief emunctories for those products of intestinal putrefaction which were circulating in the blood ranked the kidneys. Any renal insufficiency should lead to the retention of certain products, *i. e.* "autointoxication." In more than 500 examinations of the gastric contents he found that hyperacidity quite frequently was coupled with indicanuria. If there was simultaneously present ulcer of the stomach or duodenum, indicanuria was always present. About 50 cases of icterus, with complete occlusion of the common duct, showed indicanuria in but 10 cases. He said he had endeavored to remove indicanuria, which he had considered for these four years only as an indiator of intestinal putrefaction, by all means advocated heretofor, but without avail. At last he resorted to high enemas in the knee-chest position of 1 per cent. ichthyol; in two cases this was quite successful and thought they were noteworthy enough to report, which he did.

The Roentgen Ray in the Diagnosis of Diseases of the Alimentary Tract.—Drs. JUDSON DALAND and GEORGE E. PFAHLER of Philadelphia presented this communication. They desired to present certain conclusions based upon fluoroscopic and radiographic examinations of the alimentary tract. The time allotted to this paper forbade reporting cases in detail, and furthermore compelled them to limit the lantern slide demonstration to malignant affections of the esophagus, stomach, and colon. (1) The Roentgen ray demonstrated not only the location but also the nature, degree, and extent of stricture of the esophagus. (2) It demonstrated the location, size, and contour of the stomach and intestines; whether they were normally movable or adherent; whether the peristaltic waves were normal, increased, or decreased in frequency and vigor, or absent; and finally, whether food left the stomach normally, too slowly, or too rapidly. (3) The time required for a bismuth meal to traverse the alimentary tract might be determined by x-ray examinations repeated at intervals of four or six hours. (4) Atony might cause delay in transit of the bismuth food through the alimentary tract. This delay might be limited to the stomach, to the splenic flexure; to the transverse colon; to the hepatic flexure, the sigmoid, or rectum. The small intestine was rarely involved. (5) It demonstrated not only the existence, but also the degree of gastroptosis, enteroptosis, or coloptosis. The influence of decubitus, pressure of the hand, massage, electricity, or an abdominal belt might be observed. (6) It demonstrated the existence of hour-glass contraction of the stomach. (7) In cancer, involving the gastric wall, the Roentgen ray sometimes showed a corresponding alteration in the contour of the stomach, and also a cassation of the peristaltic waves at the seat of the tumor. (8) In pyloric obstruction the secondary dilation of the stomach was bowl-shaped, usually occupying the lower region of the abdomen, and strong peristaltic waves were frequently observable. (9) When gastrectasis existed without pyloric obstruction, the peristaltic waves were usually feeble or absent. (10) The existence of tumors of the pylorus might be suspected from alterations in the outline of the shadow produced by the bismuth food in the pyloric portion of the somach and the duodenum, and the relationship of these shadows to each other. (11) Gastric spasm might be diagnosed by observing a deep stricture of the somach, which might remain nearly an hour before disappearing. (12) Pylorospasm might be suspected, when, intermittently, the time required for the bismuth mixture to pass from the stomach into the duodenum was prolonged. (13) In gastric ulcer, spasmodic con-

ditions of the stomach were usually present, in association with frequent and powerful peristaltic waves. (14) A duodenal kink might be diagnosed by observing that the bismuth food in the duodenum was retained for a time just beyond the pylorus. (15) Slight, moderate, or extreme stricture of the intestine might be demonstrated by the accumulation of the bismuth food at the point of obstruction and dilatation of the intestinal tube above the obstruction, as shown by the increased width of the bismuth shadow. A narrow current of bismuth food might be seen traversing the strictured portion of the intestine. The slow, gentle introduction of bismuth and oil by hydrostatic pressure into the sigmoid flexure might demonstrate the location of the distal portion of the stricture of the colon.

Friday, June 10—Fourth Day.

The Different Forms of Mediastinal Exudative Pleurisy, with Report of Three Cases.—Dr. Anders Frick of Chicago read this paper. The clinical manifestations of mediastinal exudative pleurisy differed radically according to the part of the mediastinal pleura which was involved and its contents which were exposed to pressure. For this reason three forms of mediastinal pleurisy were to be distinguished: (1) Pleuritis mediastinalis anterior dextra, the most important symptom of which was a very deep cyanosis due to pressure on the right auricle and on the superior vena cava; (2) pleuritis mediastinalis anterior sinistra, which gave a clinical picture that resembled very much the one of exudative pericarditis; (3) pleuritis mediastinalis posterior, sive dextra, sive sinistra, which would, provided the exudate was sufficiently large, cause stridulous inspiratory dyspnea and sometimes deviation of the trachea by pressure on the trachea, dysphagia by pressure on the esophagus, enlargement of the intercostal veins by pressure on the vena azygos, paroxysmal cough by pressure on the vagus, and dysphonia, spasmus glottidis, or spasm of the pharynx and esophagus by pressure on the recurrent laryngeal nerve.

The Diagnostic Significance of the Paravertebral Triangle of Percussion Dullness (Grocco's Sign).—Dr. Frank Smithies of Ann Arbor, Mich., read this paper and offered the following summary: (1) In cases of fluid existing in the pleural sac and impinging on the spine, it was possible to map out in the average case an area of percussion dullness on the opposite side of the spine to that of which the effusion occurred. This area was an area of relative dullness, and was roughly triangular in outline. It might disappear on change of position of the patient or might show marked variations in shape or size. The triangular area was generally associated with certain auscultatory findings, similar to those found in connection with pleural exudates. (2) Paravertebral dullness might be the result of other pathological conditions than pleural effusion. These might be intrathoracic or extrathoracic. In intrathoracic diseases, such as pneumonia, mediastinal tumor, lung abscess, enlarged mediastinal glands, etc., dullness to the opposite side of the spine might be made out. This was rarely triangular, was usually not a movable dullness and was not generally associated with auscultatory phenomena. In extrathoracic diseases, as ascites, subphrenic abscess, abdominal tumor, or pregnancy, paravertebral dullness sometimes triangular in outline, might be made out. In these instances abdominal pathology was not wanting, whereas thoracic affections were generally absent or secondary. (3) A certain amount of experience with the sign and of skill in percussing was necessary in its demonstration. Even when more than ordinary skill was available, the presence of thick parietes, fibroad pleura, improper position of the subject, etc., might mask the sign.

Autogenous Vaccine Therapy in Endocarditis.—Dr. E. C. Rosenow of Chicago said that the value of the injection of dead bacteria in certain localized infections, particularly those of long duration, could no longer be questioned. Their effect in the more generalized infections, particularly in endocarditis, was still a question. In that form of endocarditis with insidious onset, with a prolonged course which showed a progressive anemia from which organisms with a low grade of virulence were isolated, the type known as chronic septic or infectious endocarditis, all observers reported an invariably fatal result, regardless of the form of treatment employed. All agreed that the injection of large doses (200,000,000 and over) did harm. Most observers had noted temporary good effects from the injection of small doses, ten to one hundred million. The evidence seemed conclusive that the continuation of the infection in chronic infectious endocarditis was due largely to a process of immunization or adaptation of the bacteria to the antibodies of the host. A peculiar behavior of the patient's bacteria and blood was found particularly striking during the time when the number of bacteria were increasing in the circulating blood and for variable periods previous to the occurrence of embolism or arthritis. During the clinical reaction occasioned by the shower of emboli or joint involvement (autoinoculation), or following the injection of dead bacteria, and especially of normal human serum, this peculiar relation of the patient's serum was present, the leucocytes and bacteria disappeared, the destructive power of the patient's blood returned and the number of bacteria in the blood showed a corresponding drop. The patient was temporarily improved but weaker than before. A striking fact was that often during the time when the bacteria in the blood were on the increase and the destroying power of the patient's blood was below normal, the temperature and leucocyte count was lower and the patient seemed better. The temperature, however, at once rose when the drop in bacteria began. In other words the destruction of bacteria liberated a toxic material which poisoned the individual. Hence to combat endocarditis successfully it was necessary to inject in addition to something which activated the patient's blood a neutralizing substance which would prevent the intoxication of the already overwhelmed patient. The outlook for a specific serum was very gloomy because the results of animal experimentation showed that the injection of organisms isolated from chronic infectious endocarditis produced an increased susceptibility to subsequent infections instead of an immunity.

The Treatment of Typhoid Carriers, with Report of a Case Treated by Inoculations of Typhoid Vaccine.—Dr. Willard J. Stone of Toledo, Ohio, said he had made a survey of the literature citing typhoid carriers treated by bacterial inoculations which, although few in number, appeared to warrant the following conclusions: (1) The time element was an important factor in the reaction of susceptibility to inoculations of bacterial vaccines in typhoid carriers. Typhoid carriers injected within a comparatively short time after their infection, would in all probability receive more benefit from properly prepared autogenous vaccine than from any other known form of treatment. (2) "Contact carriers" who never, to their knowledge, had had typhoid, were more susceptible to the inoculations than carriers who had had a definite attack of this disease, and were in all probability more immune. (3) Where the infection had persisted for years, it might be difficult to clear up the condition by bacterial inoculations. The effort should at least be made, since, in the somewhat similar condition, chronic carriers of apparently non-virulent tubercle bacilli, the bacilli often disappears from the sputum during a course of inoculation of some one of the tubercle products. (4) The immunity manifested by typhoid carriers was in all probability a partial immunity in the sense that while these individuals were protected against the infection through an augmented

phagocytic power held by their body cells, the antibacterial substance such as the bactericidins and lysins were lessened to a degree sufficient to exert any destructive power against the infection.

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

Wednesday, June 7th—Second Day.

DR. J. G. CLARK OF PHILADELPHIA, CHAIRMAN.

Plication of the Round and Anterior Fold of the Broad Ligament on the Anterior Surface of the Uterus for Retrodisplacement.—Dr. R. C. COFFEY of Portland, Ore., described this operation, saying that the round ligament was a muscle and not a suspensory fascia. That the support of the uterus depended upon the broad ligament. Hence, he shortened the broad ligament and left the round ligament free to contract and to pull through the tuck taken in the broad ligament. In the 272 cases in which he had done this operation, the results had been uniformly good. There had been eighteen cases of pregnancy follow the operation, all of which had passed off without any interference that could be attributed to the operation. In five cases the abdomen had been opened up after the primary operation and in all of these the uterus had been found in good position. The round ligament had shown a postoperative development so that the round ligament, which was attenuated prior to operation, had developed into a good muscle.

Attachment of Ligaments Posterior to the Uterus.—Dr. J. M. BALDY of Philadelphia thought that the primary anatomy and physiology of the suspensory structures need not be considered but any available structures should be used to correct the pathological conditions. In addition to the mere prolapse of the uterus he considered the fall of the pelvic floor and the prolapse of the ovaries as very important and these were corrected by the posterior shortening of the round ligaments, pulling the round ligaments through the broad ligaments and suturing them together behind the uterus. The point of perforation of the broad ligament should be just below the ovary and close to the uterus. The fact that the uterine end of the round ligament was doubled on itself was not a contraindication to the operation since the attenuated end at the inguinal canal could be cut freely across and the support of the uterus remained. The benefit came from the support given the uterus from the two round ligaments which hugged the uterus. The operation had been widely used and was apparently perfectly satisfactory.

Intraperitoneal Implantation of the Round Ligaments.—Dr. D. TOD GILLIAM described this as the original round ligament suspension of the uterus. The operation was simple, safe, easy to do, and efficient. It had been done in many hundreds of cases, and had given excellent results. The chief argument raised against it had been the possibility of intestinal obstruction from the suspensory band, but no such cases had ever been reported. The operation was applicable in complete procedenture.

Intraperitoneal Shortening of the Round Ligaments.—Dr. F. F. SIMPSON of Pittsburg described his modification of the Alexander operation in which the round ligament was pulled through the inguinal ring over the rectus and sutured in the median line to the ligament of the opposite side. The operation took full cognizance of the functions of the pelvic organs and gave no abnormal intraperitoneal conditions.

Shortening of the Round Ligaments Through the Temporarily Dilated Inguinal Canals, Combined with the Bassini Technique in Closure of the Wounds.—Dr. A. GOLDSPHON of Chicago described the technique of an operation which shortened the round ligaments through the inguinal canal by a pair of forceps being inserted into the canal to grasp the ligaments in the broad ligament. He claimed better results after this operation as shown by the double test of pregnancy and labor which was followed by a smaller number of recurrences than after any other, less than 1½ per cent. But since it was desirable to inspect the peritoneal cavity for one reason or another in a large number of cases in which reposition of the uterus was needed, he had recently given up this operation or done it with the abdomen opened. A transverse skin incision with a median fascial incision gave an excellent exposure for this operation with the abdomen open. Since opening the abdomen, however, he had been using to a large extent the intraperitoneal implantation of the round ligaments.

Résumé of the Surgical Treatment of Retrodisplacements of the Uterus.—Dr. E. C. DUDLEY of Chicago read this paper. He classified all retroversion operations as supporting the uterus either by peritoneal adhesions, or by shortening of ligaments. In the first class the Kelly fixation and suspension of the uterus were the type, and these were not based on anatomical and physiological grounds, and, hence, were unsurgical. The second class by shortening of ligaments, was preferable, and of the ligaments available, the shortening of the uterosacral ligaments was often unsatisfactory in its permanent results. The pure Alexander shortening of the round ligaments was no longer a good routine procedure. The doubling of the round ligaments also was not as permanent in its results as was to be desired. Hence, the Gilliam type of operation was the most acceptable. Personally he now followed (to the exclusion of most others) the pulling of the round ligaments through the broad, carrying with it enough peritoneum to give good peritoneal adhesions.

Dr. E. E. MONTGOMERY of Philadelphia said that his operation was merely an adjustment of other operations. He chose the Pfannenstiel incision and then did a Baldy attachment of the round ligaments to the posterior surface of the uterus.

Dr. J. B. MURPHY of Chicago recognized the relief that came in the replacement with a pessary if no additional damage was done. The objections to the fixation operations lay in the pain caused by sudden abdominal movements and elongation took place and allowed the uterus to fall back again into its old place. The choice of operations depended upon the condition. In the nullipara he thought that Alexander's operation was the choice. While, at the other extreme in complete procedenture, he believed in splitting the uterus, shortening the round ligaments, and supporting the bladder with the uterus.

Dr. HERMAN J. BOLDT of New York said that the pure retrodisplacement gave no symptoms except from pressure or mechanically associated trouble. In such cases a pessary was adequate, or an Alexander's operation. If any adhesions were present or there was any indication for opening the abdomen his choice was for the Gilliam operation.

Dr. CARSTENS of Detroit believed in the use of the pessary after labor to prevent retrodisplacements.

Dr. FARRETT of Chicago believed in inspecting and correcting other abdominal associated conditions, and in using the best part of the natural ligaments so that he did a modification of the Gilliam operation.

Dr. H. O. MARCY of Boston transplanted the round ligaments to a higher level in the inguinal canal and covered them well with peritoneum.

Dr. WARTHIN of Ann Arbor believed that anterior suspension of the uterus gave the best results unless there was some destruction of the pelvic floor.

Dr. G. BETTON MASSEY of Philadelphia considered the chief cause of the symptoms associated with retroversion to be due to the chronic inflammation of the uterus. And

that no operation would relieve these unless they were treated also.

Dr. Gelhorn of St. Louis thought that any operation would suffice so long as it observed certain principals, the chief of which were to avoid fixation in a pathological position, to avoid blind operations, to avoid using the weak end of ligaments, and to avoid the deceptive small ligaments like the uterosacral.

Dr. Byford of Chicago considered the inguinal end of the round ligament as a strong tendon, though it might not be as large as the muscular uterine end. He thought, however, that the uterus should be supported by the ligaments in their normal channels.

Embryological and Anatomical Causes of Obstinate Constipation in Women; Operative Methods for Relief.—Dr. John G. Clark of Philadelphia read this address. He considered, principally, the condition of enteroptosis, which was potential at birth and then developed later with some special strain such as childbirth, persistent crying in infancy, or persistent coughing. In the autopsy study of fifty infants under six months, owing to the embryologic conditions of development, irregular conditions in the colon were not infrequent. A redundant transverse colon was frequent, and there occurred, also, many cases of descent of the colon into the pelvis at the cecum, or a low splenic flexure, or a redundant sigmoid. It seemed as if, normally, at birth one-half of the colon was in the sigmoid. If such a condition persisted the origin of Hirschsprung's disease was evident. In some cases the sigmoid extended up to the liver. In the adult the autopsy study showed the lower border of the transverse colon to be near the line of the crests of the ilium. Descent of the colon and stomach here go together and adhesions of the omentum hold the stomach down, and the traction pulls down the pylorus, giving obstruction and motor insufficiency. Similarly the transverse colon, when full, pulls down on the flexures and at the pylorus. This type of case is nutritionally deficient from birth. The babies are constipated and the deficiency shows in the lack of development of thorax and bones, and the bad posture. The time taken for material to pass through the small intestine is about six hours, and through the large intestine sixteen to eighten hours. If salt solution is injected into the colon with the patient in the Trendelenburg position, the colon is straightened out into its fairly normal position. So that an injection of hot salt solution after an operation, while the patient was still in the Trendelenburg position, tended to straighten out the intestine, supplied an intraabdominal hot water bottle, and supplied fluid to be absorbed. Dr. Clark noted the frequency of deviation of the sigmoid flexure, and reported one case of sigmoid three feet long, when, normally, it should be but from seven to nine inches. The indications for operation on the colon were not in the position of the colon as determined by examination, seen on operation, or in an *x*-ray photograph, but only in the symptoms which arose from these conditions. The cases of enteroptosis associated with neurasthenia, when operated on, gave worse than bad results as the exhausted nerves were only made to go through extra strain. In such cases the elevation of a descended cecum from inside the pelvis might be helpful. The Coffey operation, pulling up the transverse colon and suturing it in folds to the abdominal wall maintained in place temporarily by through and through nonabsorbable sutures tied to gauze pads on the outside of the abdomen, gave 48 per cent. of functional relief. Resection of the transverse colon in the four cases where he had tried it gave excellent results. In the cases where the sigmoid was redundant a lateral anastomosis of the loops of the sigmoid sidetracking the unnecessary length of the sigmoid did good in some of the cases.

Enteroptosis, with Special Reference to Its Etiology and Development.—Dr. R. R. Smith of Grand Rapids described the type of woman in which enteroptosis was most frequently found as one with frail form and features, little fat or muscle, the tissues lax, without vigor, the neck long, the chest collapsed, the lower ribs close together and slanting greatly, and the upper abdomen with very little space. The combination of enteroptosis and a large abdomen was very uncommon. The symptoms most common were the pain in the back and groins, the weight in the abdomen, the upset in the menses and the function of the bladder, and neurasthenia. The time of onset of the symptoms ascribed to the prolapse in the marked cases always went back to childhood but did not follow any special disease. Chronic influences on digestion and nutrition might be a factor; bad hygiene certainly was a factor.

The X-Ray in the Diagnosis of Enteroptosia.—Dr. E. H. Skinner of Kansas City showed pictures of the normal and abnormal position of the stomach and colon as determined by the *x*-ray picture. He showed a series of pictures of prolapse of the stomach in which the stomach retained its tubular form but was dragged down towards the left iliac fossa, maintaining the high position of its fixed extremities, so that the stomach took the shape of a syphon trap. In the colon the splenic flexure remained high and sharp.

Value of the Roentgen Ray in Enteroptosis.—Dr. A. W. Crane of Kalamazoo showed slides demonstrating the development of the drain trap stomach of the tubular type from gastroptosis. The fixed point of attachment was the cardiac orifice and the symptoms were determined by the position of the pyloric antrum. The pain of gastric ulcer might easily be mistaken for any other acute pain in the abdomen and the low position of the stomach very misleading.

The Physician's Viewpoint.—Dr. J. H. Musser of Philadelphia considered this side of the subject. He emphasized the point that enteroptosis was, frequently, present without producing any symptoms. He noted the importance of the environmental conditions which made for effeminacy. The middle and lower classes of society were not victims of the neuroses that afflicted the higher class. Neurasthenia was shown in the dying-out class. Of 100 patients with gastroptosis, 37 had always had poor health and 27 had had poor health since puberty. Analyses to determine abnormal changes in metabolism were made in 10 cases with no abnormal findings which would account for the toxemia. The patient's habits seemed to account for much of the trouble. There were no defensive protections, as yet, found in the system to combat the diseased condition. He thought that the mother could do much in childhood to conserve the health of the child. Attacks of biliousness and headache showed that the child was not resting and should be met by rest and withdrawal of food. So he considered the symptoms of enteroptosis as a condition rather than a disease, and the cure to lie in hygiene with indirect therapy for each organ. There was a certain amount of psychic relief and some physical relief that came from wearing an abdominal bandage in 25 per cent. of the cases. And this period could be used to build up the body hygiene. Secondary enteroptosis following some surgical complication might need surgical treatment. The early diagnosis of enteroptosis in childhood with an early operation might prevent the development of the nervous symptoms, but after the neurosis was present operation only added additional nerve insult. All of the operative procedures so far had been unsatisfactory.

The Surgical Viewpoint.—Dr. A. J. Ochsner of Chicago discussed this side of the question. He considered the disease as secondary to the condition of the patient. He had found the condition most frequent in children with hernia. They had diastases of the recti and pendulous

abdomens. The condition was associated with digestive upsets with the production of gas, constipation, and phimosis, chronic coughs, chronic appendicitis, crying, straining, and so on. In these cases the removal of the cause of the pressure cured the hernia without operation. The conditions could be cured, largely, by rest, putting the patients to bed at 6 P. M., and elevating the foot of the bed so that all strain would be taken off of the abdominal supports for a large share of the time. This preventive work on the children was the most valuable. Surgical treatment failed, or at times made the patient worse. The indications for operation as stated by Blake were symptoms that were due to the enteroptosis; that could not be cured without an operation, and that could be cured by operation. In gastroptosis Bier's operation that did not fix the organ was good. Fixation always did more harm than good. In ptosis of the liver, splitting the right rectus and sewing the gall-bladder to the transverse fascia and then draining the gall-bladder would reduce the size of the gall-bladder and liver. In ptosis of the spleen operation should be done only for obstruction to the blood supply.

Dr. MAX EINHORN of New York City considered that not starvation, but high feeding, was essential to the cure of these cases. The stomach should be educated to digest good food. The enteroptosis as such needed no surgery and gave no symptoms.

Dr. COFFEY of Portland, Ore., said that, while many of the leading men of the country opposed surgery in these cases, yet, in selected cases surgery did good. His first case had been one of obstruction, and he had sutured the omentum to the anterior abdominal wall with relief of the symptoms and the woman had been well now for eight years. In one case he had narrowed the lower abdomen by plication of the fascia, and had done a plastic operation, increasing the size of the thoracic abdomen.

(*To be continued.*)

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

AT a stated meeting held June 1, Dr. ALFRED STENGEL read "A Memoir of the late Dr. J. Alison Scott." Dr. JOHN H. MUSSER presented a communication entitled "The Fundamental Principles of Therapeutics," discussing the subject particularly from a biological standpoint. Dr. ROBERT N. WILLSON, Jr., gave a lantern demonstration illustrative of "The Gross Pathology of the Heart." He depicted affections of the heart wall, such as hypertrophy and aneurysm, dilatation of the cavities of the heart, with its effects on the competency of its valves, diseases of the valve leaflets, endocarditis, sclerosis, lesions of the aorta, atheroma, sclerosis, aneurysm. Dr. HOBART A. HARE read a paper entitled "The Difference Between the Systolic Blood Pressure in the Arm and in the Leg in Aortic Regurgitation," relating observations confirming those previously reported by Dr. Leonard Hill to the effect that in the presence of aortic regurgitation the blood pressure in the lower extremities is considerably higher than in the upper extremities. The higher pressure in the lower extremities could be reduced by immersing the feet and legs in hot water or exposing these parts to the action of the hot pack. Drs. RALPH PEMBERTON and J. EDWARD SWEET presented a communication entitled "The Induction of Pancreatic Activity by the Removal of the Adrenals." Dr. WALTER G. ELMER presented the "Report of a Case of Profound Blood Destruction Following Calomel." He reported the case of a man who took ten grains of calomel at hourly intervals by mistake for 1/10 grain dose. After a short time there developed profound depression, with bloody stools and the signs of marked blood deterioration. It was thought that the unpleasant effects were due to the conversion in the intestinal tract of the mild chloride into the corrosive chloride.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

ALABAMA STATE BOARD OF MEDICAL EXAMINERS.

Montgomery, January 11-14, 1910.

ANATOMY.

(For graduates of less than five years' standing.)

1. Describe the upper third of the femur.
2. Give the class of joint, the articulation, and ligaments of the shoulder joint.
3. Trace blood from the heart by way of the subclavian artery to the circle of Willis, naming the arteries uniting to form the circle.
4. Name the muscles of the anterior chest, and give origin and insertion of the largest one of them.
5. Name the main superficial venous trunks of the upper arm, describing one of them.
6. Describe the gall-bladder and the bile-ducts.
7. Describe the great sciatic nerve.
8. Describe the rectum.

(For graduates of more than five years' standing.)

1. Name the bones of the lower extremity.
2. Name and locate the valves of the heart.
3. Describe in full the sartorius muscle.
4. Locate the spleen and describe its gross anatomy.
5. Describe in full the pulmonary veins.
6. Describe the contents in Scarpa's triangle and give their relations.
7. Name the lobes and ventricles of the brain.
8. Name the ligaments supporting the uterus and describe its blood supply.

PHYSIOLOGY.

1. Explain the functions of the spinal cord.
2. What are the functions of the trifacial or fifth pair of cranial nerves?
3. What is meant by cell action? Give examples.
4. What are the supposed functions of the spleen?
5. What are the supposed functions of the thyroid gland? What symptoms sometimes follow its removal?
6. Explain the glycogenic function of the liver.
7. How is the equilibrium of the circulation of the blood maintained in the body?
8. What are the functions of the skin?

CHEMISTRY.

(Answer eight.)

1. What is the difference between analytic and synthetic methods in chemistry? Illustrate each.
2. Explain the reaction which occurs when the aqueous solutions of the two parts of a Seidlitz powder are mixed.
3. Write the equations which show the reaction occurring when corrosive sublimate and potassium iodide in solution are brought together.
4. What is the essential element of all acids? Differentiate between hydracids and oxyacids?
5. Give a test for H_2SO_4 when an adulterant in vinegar.
6. Give the technical names of (*a*) aqua regia, (*b*) oil of vitriol, (*c*) green vitriol, and the formula of one of them.
7. What is the chemical composition of ordinary alum?
8. Give the chemical reaction of (*a*) tears, (*b*) bile, (*c*) blood, (*d*) saliva, (*e*) milk, and state what salt causes acidity of urine.
9. Give a test for ferrous salts.
10. Explain the difference between a sulphate and a sulphite. Give an example of each.
11. Give tests for albumin and sugar in urine.
12. Describe a chemical test for blood.

PHYSICAL DIAGNOSIS.

1. In what pathological conditions of the lungs is moderate dullness found; in what is absolute dullness found?
2. Give differential diagnosis between acute bronchitis and lobar pneumonia.
3. What are the principal points of difference between pleuritic friction sounds and bronchial râles.
4. Give the diagnostic signs of aortic aneurysm.
5. What are the conditions most favorable for the production of metallic tinkle?
6. Give the differential diagnosis between endocarditis and pericarditis.
7. Give the diagnostic symptoms of emphysema of the lungs.
8. Differentiate between aortic stenosis and mitral insufficiency.

ETIOLOGY, PATHOLOGY, SYMPTOMATOLOGY, AND DIAGNOSIS.

1. Give the etiology of cirrhosis of the liver.
2. Give the etiology of pyelitis.
3. Give the pathology of arterial sclerosis.
4. Give the symptoms and diagnosis of hookworm disease.
5. Give the differential diagnosis between pericarditis and acute pleurisy.
6. Give the pathology of cerebrospinal meningitis.
7. Give the etiology of erysipelas.
8. Give the pathology of pneumonia.

OBSTETRICS.

1. What is meant by the inclined planes of the pelvis?
2. What are the forces by which the child is expelled?
3. Give operation for adherent placenta.
4. Give mechanism of left occipitoposterior position.
5. How would you manage a shoulder presentation?
6. Give causes and treatment of asphyxia in a new-born child.
7. How would you apply forceps at the inferior strait when the occiput has rotated to the pubic symphysis?
8. Give the degrees of perineal laceration and management of each.

GYNECOLOGY.

1. Give causes and treatment of hemorrhage of the uterus.
2. Give the cause and treatment of amenorrhea.
3. Define ectopic pregnancy and give varieties.
4. Give differential diagnosis between fluid and solid neoplasms in the abdominal cavity.
5. Under what conditions and why would you prefer vaginal to abdominal hysterectomy?
6. Give symptoms of fibroid tumors of the uterus.
7. Give etiology of retrodisplacement of the uterus.
8. Describe the technique of a gynecologic examination.

SURGERY.

1. Give general rules for the treatment of wounds.
2. Give symptoms and treatment of traumatic spreading gangrene.
3. Give general rules for the treatment of tubercular abscesses.
4. Give differential diagnosis between chancre and chancroid.
5. Give treatment of a compound, comminuted fracture of the femur.
6. Give symptoms and treatment of subcoracoid dislocation of head of humerus.
7. Give symptoms and treatment of stone in the kidney.
8. Give treatment of penetrating gunshot wound of the abdomen.

EYE, EAR, NOSE, AND THROAT.

1. Give symptoms and management of acute catarrhal conjunctivitis.
2. Give the symptoms, dangers, and management of gonorrheal ophthalmia in the adult and in the new-born.
3. Give the management of ulcer of the cornea.
4. In what part of the ear does cerumen sometimes become impacted, and how diagnosed and treated?
5. What is the seat of acute suppurative otitis media, and what the symptoms, dangers, and management?
6. In the absence of the special instrument for the purpose how would you arrest an alarming hemorrhage from the nose?
7. What is the most conclusive symptom of diphtheria, and how ascertained? What is the most generally accepted treatment? Give in detail the method of administering the treatment, and the dose.
8. Name three instances in which intubation of the larynx would be indicated. Name three in which laryngotomy or laryngotracheotomy would be required, and describe the operation.

HYGIENE AND MEDICAL JURISPRUDENCE.

1. What is the period of incubation of smallpox? Of measles? Give the differential diagnosis between these two diseases.
2. What is immunity? What susceptibility?
3. How is typhoid fever disseminated? Give the hygienic management of a case.
4. Describe briefly the proper location and construction of a school building.
5. Define malpractice.
6. What are illusions? Delusions?
7. Give the differential diagnosis between strychnine poisoning and tetanic convulsions.
8. What are the symptoms of acute poisoning from coal tar derivatives?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

ALABAMA STATE BOARD OF MEDICAL EXAMINERS.

Montgomery, January 11-14, 1910.

ANATOMY.

(For graduates of less than five years' standing.)

1. See Cunningham's "Anatomy" (1909), page 223; or Gray's "Anatomy" (1908), page 223.

2. The *shoulder joint* is an enarthrodial variety of a diarthrosis; it is formed by the head of the humerus being received into the glenoid cavity of the scapula; the ligaments are: Glenoid, capsular, coraco-humeral, and transverse humeral.

3. Heart, aorta (innominate, on right side only), subclavian, vertebral, basilar; then to posterior cerebral (which is part of Circle of Willis). This circle is formed: In front by the two anterior cerebral arteries (branches of the internal carotid), which are connected by the anterior communicating artery; behind, by the two posterior cerebrals (branches of the basilar artery), which are connected to the internal carotid on each side by the posterior communicating artery.

4. Muscles of anterior chest are: Pectoralis major, pectoralis minor, and subclavius. The largest of these is the pectoralis major. *Origin:* Anterior surface of inner half of clavicle, anterior surface of sternum, from the cartilages of the second to sixth ribs, and from the aponeurosis of the external oblique of the abdomen. *Insertion:* Into the outer bicipital ridge of the humerus.

5. See Cunningham's "Anatomy" (1909), page 891; or Gray's "Anatomy" (1908), page 745.

6. THE GALL-BLADDER AND BILE-DUCTS. The *gall-bladder* is a conical bag placed in a fossa on the under surface of the right lobe of the liver. Its upper surface is attached to the liver, and its fundus and posterior surfaces are invested by peritoneum reflected from the adjacent surface of the liver. The body is in relation in front with the liver, and behind with the first part of duodenum, the pylorus, and the hepatic flexure of colon. The fundus is in contact with the parietes opposite the ninth right costal cartilage.

The *hepatic duct,* formed by union of ducts from right and left lobes, issues from the liver at the bottom of the transverse fissure. It passes downward and to the right in the layers of gastrohepatic omentum, having the vena porta behind and the hepatic artery on the left. It joins the cystic duct, the two forming the common bile-duct.

The *cystic duct* passes from the neck to the gall-bladder downward, backward, and to the left, to join the preceding.

The *ductus communis choledochus* or *common bile-duct* is the result of the union of the hepatic and cystic ducts. It passes behind the first part of the duodenum, in front of the vena portæ, with the hepatic artery on the left, between the layers of the gastrohepatic omentum, and, passing between the pancreas and second part of the duodenum, enters the small intestine obliquely a little below the middle of the descending part of the duodenum by an opening common to it and the pancreatic duct.—(From *Aids to Anatomy.*)

7. See Cunningham's "Anatomy" (1909), page 648; or Gray's "Anatomy" (1908), page 1030.

8. See Cunningham's "Anatomy" (1909), page 1087; or Gray's "Anatomy" (1908), page 1320.

(For graduates of more than five years' standing.)

1. Os innominatum (ilium, ischium, pubis), femur, patella, tibia, fibula, os calcis, astragalus, cuboid, scaphoid, three cuneiforms, five metatarsals, and fourteen phalanges.

2. In the *right auricle* are the Eustachian and coronary valves; the former is situated between the anterior margin of the inferior vena cava and the auriculo-ventricular orifice. In the *right ventricle* are the tricuspid and semilunar valves. In the *left ventricle* are the mitral and semilunar valves. Aortic valves, behind the third intercostal space, close to the left side of the sternum. Pulmonary valves, in front of the aortic, behind the junction of the third rib, on the left side, with the sternum. Tricuspid valves, behind the middle of the sternum, about the level of the fourth costal cartilage. Mitral valves, behind the third intercostal space, about one inch to the left of the sternum.

3. See Cunningham's "Anatomy" (1909), page 356; or Gray's "Anatomy" (1908), page 518.

4. The *spleen* is situated in the back part of the left hypochondriac and epigastric regions, being covered by the ninth, tenth, and eleventh ribs, on the left side. It is of an oblong, flattened form, the external surface being convex; on the inner surface is a vertical ridge dividing it

into two parts, the posterior of which is applied to the outer surface of the left kidney, while the anterior one receives the tail of the pancreas and lies against the cardiac end of the stomach. Near this ridge is a fissure, *the hilum*, where the vessels enter. The anterior border is notched and the lower end is pointed and rests on the costocolic ligament, situated in the left hypochondriac region. It is covered by peritoneum, except at the hilum, where it passes forward and inward in a double line enclosing the vessels, as the gastrosplenic omentum, to the fundus of the stomach. It usually measures 5 by 3 by 1 or 1½ inches, and weighs about 7 ounces.—(From *Aids to Anotomy.*)

5. See Cunningham's "Anatomy" (1909), page 870; or Gray's "Anatomy" (1908), page 723.

6. *Contents:* The femoral vessels pass from about the center of the base to the apex, the artery being on the outer side of the vein; the artery gives off the superficial and profunda branches, and the vein receives the deep femoral and internal saphenous; the anterior crural nerve lies to the outer side of the femoral artery; the external cutaneous nerve is still further external, lying in the outer corner of the space; just to the outer side of the femoral artery, and in the sheath with it, is the crural branch of the genitocrural nerve. At the apex the vein (which at the base was internal to the artery) lies behind the artery. The triangle also contains fat and lymphatics.

7. *Lobes of brain:* Frontal, parietal, occipital, temporal, central (or island of Reil), limbic, olfactory, cuneate, orbital, precentral, postcentral, quadrate. *Ventricles:* Two lateral, third, fourth, and fifth.

8. *Ligaments of uterus:* Anterior, posterior, two broad (or lateral), two sacrouterine, and two round ligaments. *Blood supply:* Uterine and ovarian arteries and veins of same name.

PHYSIOLOGY.

1. *The functions of the spinal cord* are: (1) The conduction of nerve impulses; (2) reflex action; (3) coordination; it also contains special centers which preside over definite functions.

In the spinal cord: (*a*) The white substance simply conducts nerve impulses; (*b*) the gray substance contains groups of cells which act as centers for and distributors of nerve impulses, and are also concerned in reflexes; (*c*) the anterior cornua have a motor and trophic function; (*d*) the posterior cornua are sensory.

2. THE FUNCTIONS OF THE FIFTH CRANIAL NERVE. *First ophthalmic branch* supplies sensation to conjunctiva and skin of upper eyelid, cornea, skin of forehead and nose, lachrymal glands, mucous membrane of nose. *Second, or superior maxillary branch,* supplies sensation to skin and conjunctiva of lower lid, nose, cheek, upper lip, upper teeth and alveolar processes, and palate. *Third, or inferior maxillary branch,* supplies sensation to external auditory meatus, side of head, mucous membrane of mouth, anterior two-thirds of tongue, lower teeth, lower lip, and skin of the lower part of the face. This branch, in addition, supplies motion to the muscles of mastication (masseter, temporal, external pterygoid, internal pterygoid), also to mylohyoid and anterior belly of digastric.

3. By *cell action* is meant the function of cells, such as power of movement, of growth, of ingestion, of egestion, of reproduction, of secretion, of response to various stimuli.

4. The *function of the spleen:* The following theories have been held: (1) It is a source of production of the white blood corpuscles; (2) it is a source of production of the red blood corpuscles during fetal life; (3) it is a place where the red blood corpuscles are destroyed; (4) uric acid is produced in the spleen; (5) an enzyme is produced in the spleen and is carried by the blood to the pancreas, where it converts the trypsinogen into trypsin.

5. The *function of the thyroid* is not definitely settled; (1) it has some trophic function, regulating oxidation in the body, and it is supposed to have also a special influence on the vasomotor nerves, the skin, the bones, and on the sexual functions; (2) it is supposed to antagonize toxic substances, and (3) it produces an internal secretion.

Removal of the thyroid gland causes mental and bodily dullness and apathy, tremors, twitchings, overgrowth of the connective tissues, and development of fat; the hairs fall out and the patient becomes unwieldy and clumsy in both body and mind. The complete removal causes death in most animals, and it is not considered justifiable in man.

6. Glycogen is chiefly formed from the carbohydrates. The liver cells act upon the dextrose into which the carbohydrates have been converted by the action of the ptyalin and amylopsin of the digestive juices. This *may* occur by a simple process of dehydration:

$$C_6H_{12}O_6 - H_2O = C_6H_{10}O_5$$

But the precise process by which it occurs in the liver cells is not known.

At a subsequent period the glycogen is transformed into dextrose and is returned to the circulation. Hence the blood of the hepatic veins contains more sugar than the blood of the arteries, and these latter more than the blood in the veins (except the hepatic). This is the generally accepted view, but it is denied by Pavy, and the whole subject is in a state of uncertainty.

7. The circulation of the blood is regulated in (a) *the arteries* by: (1) The elasticity and tone of the arteries, (2) the force and frequency of the cardiac contractions, (3) the resistance in the capillaries; (b) in the *capillaries* it is regulated by (1) the action of the heart, (2) the action of the arteries; (c) in the *veins* it is regulated by (1) the action of the heart, (2) aspiration of the thorax, (3) the contraction of the muscles, and (4) slightly by the valves in the veins.

8. The functions of the skin are: Protection, sense of touch, excretion, regulation of body temperature, absorption, and respiration.

CHEMISTRY.

1. *Anolytic methods* consist in breaking up a compound into its elements or into simpler compounds, as by acting on a carbonate with an acid we get water and carbon dioxide: $CaCO_3 + H_2SO_3 = CaSO_4 + H_2O + CO_2$.

Synthetic methods are the reverse of this, and consist in building up compounds out of simpler compounds or out of elements, as when $2H_2 + O_2 = 2H_2O$.

2. The monosodic carbonate is decomposed by the tartaric acid; sodium tartrate remains in the solution, and the liberated CO_2 causes the effervescence.

3. $HgCl_2 + 2KI = HgI_2 + 2KCl$.

4. Hydrogen is the essential element of all acids. *Hydracids* contain no oxygen; *oxyacids* contain oxygen as well as hydrogen.

5. Add cane sugar and evaporate; if the sugar turns black H_2SO_4 is present.

6.

	CHEMICAL NAME.	FORMULA.
(*a*) Aqua regia.	Nitrohydrochloric acid.	$HNO_3 + 3HCl$.
(*b*) Oil of vitriol.	Sulphuric acid.	H_2SO_4.
(*c*) Green vitriol.	Ferrous sulphate.	$FeSO_4$.

7. Ordinary alum is aluminium ammonium sulphate.

8. They are all alkaline. The acidity of the urine is due to monosodic phosphate.

9. *Ferrous salts,* on the addition of solution of potassium hydroxide, give a greenish-white precipitate, changing to green and then to reddish-brown, soluble in hydrochloric acid, but insoluble in ammonium hydroxide.

10. A *sulphate* is a salt of sulphuric acid, and contains more oxygen than a *sulphite,* which is a salt of sulphurous acid:

H_2SO_3	$CaSO_3$
Sulphurous acid	Calcium sulphite
H_2SO_4	$CaSO_4$
Sulphuric acid	Calcium sulphate

11. *Test for albumin in the urine:* "The urine must be perfectly clear. If not so, it is to be filtered, and if this does not render it transparent it is to be treated with a few drops of magnesia mixture and again filtered. The reaction is first observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral or alkaline, it is rendered *faintly* acid by the addition of dilute acetic acid and heated. If albumin be present a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of HNO_3."

For sugar: Render the urine strongly alkaline by addition of Na_2CO_3. Divide about 6 c.c. of the alkaline liquid in two test-tubes. To one test-tube add a very minute quantity of powdered subnitrate of bismuth; to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color.

12. *Chemical test for blood:* Boil a fragment of dried blood with a drop of glacial acetic acid on a slide; on cooling, hemin crystals separate out. If the blood stain is not recent a crystal of sodium chloride should be added with the acetic acid.

PHYSICAL DIAGNOSIS.

1. *Moderate dullness* is found in: Consolidation of lung (in phthisis, pneumonia, gangrene, tumors), collapse of lung, congestion of lung, thickened pleura. *Absolute dull-*

ness is found in: Hydrothorax or pleurisy with effusion, empyema.

2. *Acute bronchitis* begins with coryza; soreness and tenderness may be behind the sternum; pain may be caused by coughing; expectoration is abundant; dyspnea is in proportion to the extent of the disease; the pulse-respiration ratio is not altered; fever is slight or absent; various râles may be present; the condition is generally bilateral; ends by lysis.

Lobar pneumonia begins with rigors, sometimes also with vomiting; pain on affected side; expectoration is rusty and tenacious; breathing is very rapid; the pulse-respiration ratio is much disturbed; there is considerable fever; crepitant râles are heard in first stage, also in third stage (râle redux); usually only one side is affected; ends by crisis.

3. Râles are produced within bronchi or lungs, while friction sounds occur in the pleura and do not pass away after coughing. The creaking or crackling pleuritic friction is often mistaken for a crepitant râle, and Tyson gives the following distinguishing characteristics: The friction sound does not pass away after coughing, while the crepitant râle may do so; the friction sound is more superficial and localized, while the crepitant râle is deep and more diffuse; the friction sound has a to and fro movement during inspiration and expiration, while the crepitant râle is only heard at the end of inspiration; pleuritic friction sounds are generally heard in the axilla or side of the chest, while the crepitant râle is most frequently posterior, often at the base of the lung.—(From Gould and Pyle's *Cyclopedia.*)

4. See French's "Practice of Medicine" (1907), page 630; or Osler's "Practice of Medicine" (1909), page 857.

5. Pneumothorax, or cavity in the lung.

6. In *endocarditis:* The murmur is soft, not harsh; it is systolic or diastolic; it may be transmitted; it is heard loudest at definite points; it is not followed by signs of effusion; the apex beat may be strong.

In *pericarditis:* The murmur is harsh; is not in connection with the heart sounds: is heard loudest at the base of the heart and over the precordium; is followed by (or accompanied with) signs of effusion; the apex beat is generally feeble.

7. See French's "Practice of Medicine" (1907), page 681; or Osler's "Practice of Medicine" (1909), page 635.

8. See French's "Practice of Medicine" (1907), page 579; or Osler's "Practice of Medicine" (1909), pages 802 and 807.

ETIOLOGY, PATHOLOGY, SYMPTOMATOLOGY, AND DIAGNOSIS.

1. See French's "Practice of Medicine" (1907), page 824; or Osler's "Practice of Medicine" (1909), pages 556, 557, and 560.

2. See French's "Practice of Medicine" (1907), page 907; or Osler's "Practice of Medicine" (1909), page 703.

3. See French's "Practice of Medicine" (1907), page 625; or Osler's "Practice of Medicine" (1909), page 849.

4. See French's "Practice of Medicine" (1907), page 498; or Osler's "Practice of Medicine" (1909), page 45.

5. In *pericarditis:* The friction sound is not affected by the patient holding his breath; the pulse is feeble; the pain is slight and is not affected by respiration. In *acute pleurisy:* The friction sound ceases when the patient holds his breath; the pulse is regular and strong; the pain is sharp and cutting, and is worse on inspiration.

6. See French's "Practice of Medicine" (1907), page 141; or Osler's "Practice of Medicine" (1909), page 150.

7. See French's "Practice of Medicine" (1907), page 218; or Osler's "Practice of Medicine" (1909), page 210.

8. See French's "Practice of Medicine" (1907), page 154; or Osler's "Practice of Medicine" (1909), page 170.

OBSTETRICS.

1. See Williams' "Obstetrics" (1909), pages 3 and 262.

2. *Forces by which the child is expelled:* (1) Uterine contractions; (2) contractions of the diaphragm; (3) contractions of the abdominal muscles.

3. See Williams' "Obstetrics" (1909), page 478; or Hirst's "Obstetrics" (1909), page 436.

4. See Williams' "Obstetrics" (1909), page 267; or Hirst's "Obstetrics" (1909), page 404.

5. In cases of *shoulder presentation*, if seen before labor, version should be performed to correct the malpresentation; in case of impaction a cesarean section is indicated; sometimes decapitation or embryotomy has been performed, but a cesarean section is preferable. Cases of shoulder presentation have been known to terminate spontaneously, but it is not advisable to rely on this possibility.

6. See Williams' "Obstetrics" (1909), page 846; or Hirst's "Obstetrics" (1909), page 939.

7. See Williams' "Obstetrics" (1909), page 403.

8. See Williams' "Obstetrics" (1909), page 325; or Hirst's "Obstetrics" (1909), pages 609 and 867.

GYNECOLOGY.

1. The following (from Gould and Pyle's *Cyclopedia of Medicine and Surgery*) is a useful classification of uterine hemorrhages, and also gives the causes of the same:

I. *Hemorrhages complicating pregnancy, labor, or the puerperium:*

A. Hemorrhages of pregnancy: Caused by (1) placenta prævia; (2) premature separation of a normally situated placenta; (3) apoplexy of the decidua or placenta.

B. Hemorrhages of labor: Caused by (1) placenta prævia; (2) premature separation of a normally situated placenta; (3) relaxation of the uterus; (4) laceration of the cervix; (5) rupture or inversion of the uterus.

C. Hemorrhages of the puerperium: Caused by (1) retained secundines; (2) displaced uterus; (3) displaced thrombi; (4) fibroid tumors; (5) hypertrophied decidua; (6) carcinoma.

II. *Hemorrhages occurring in the non-pregnant woman:*

A. In virgins before the age of thirty: Caused by (1) uterine congestion, the result of cold or exposure; (2) endometritis; (3) polypi and fibroid tumors.

B. In married women before the age of thirty: Caused by (1) subinvolution; (2) laceration of the cervix; (3) endometritis; (4) retrodisplacements of the uterus; (5) polypi and fibroid tumors.

C. In women after the age of thirty: Caused by (1) carcinoma of the cervix; (2) carcinoma of the body of the uterus; (3) sarcoma of the uterus.

The *treatment* depends on the cause. For details see any work on obstetrics or gynecology.

2. *Amenorrhea* may be *due* to: Absence or imperfect development of the generative organs; also to stenosis, obstructions, or atresia of the genital tract; also to operative removal of the uterus or its appendages. Other causative factors are: Acute infectious diseases, anemia, chlorosis, obesity, drug habits, alcoholism, overstudy, lack of exercise, exposure to cold, and various emotional causes. Pregnancy or lactation may be the cause.

Treatment consists in: Removing or treating the cause.

3. *Ectopic pregnancy* is a pregnancy in which the product of conception is not inside the uterine cavity. *Varieties:* Tubal, ovarian, interstitial, abdominal.

4. "The consistency of a tumor is ascertained by palpating it in all directions between the fingers of both hands and by tapping it to determine the absence or presence of fluctuation. The left hand is placed firmly over the abdomen on one side of the tumor and the fingers of the other hand strike or tap the abdominal wall on the opposite side; if fluid is present a thrill or wave is detected. The fluctuation wave, however, may be absent in multilocular cysts and in tumors having thick, tense walls or viscid contents. The length and intensity of the thrill over different parts of an abdominal enlargement are of great diagnostic value in many instances. Thus, in ascites and unilocular cysts there is no variation in the character of the wave, whereas in a multilocular tumor it differs as to length and intensity over different parts of the growth. In obese women the fat contained in the belly walls causes false wave or thrill when the abdomen is tapped, which may be mistaken at times for the presence of fluid. To eliminate this factor an assistant places the ulnar edge of his hand firmly on the abdominal wall in the median line, while the examiner taps the abdomen in the usual manner."—(From Ashton's *Gynecology.*)

5. As to preference between the vaginal and abdominal routes, the following is taken from Garrigues' *Gynecology:* "If the vaginal route is available it should be preferred, because it entails much less shock, requires a simple after-treatment, does not leave any visible cicatrix, predisposes less to hernia, and allows the patient to resume work in shorter time. On the other hand, the vaginal route is more difficult on account of the limited space. Hemorrhage is more troublesome to check, adhesions are harder to separate, and the bladder and intestine more exposed to injury and less accessible for repair. The pelvic cavity cannot be seen so well and the abdominal not at all. If tissue is left to mortify it emits an offensive odor."

6. *Symptoms of fibroids:* Hemorrhage, leucorrhea, pain, pressure symptoms (disturbances and displacements of bladder, rectum, urethra, and uterus), backache, bearing-down sensation, dysmenorrhea.

7. RETROVERSION. *Etiology:* Relaxation of uterine ligaments; increased weight of fundus; subinvolution; ovarian or other tumor pressing on front of uterus; distended

bladder; peritonitis or cystitis; prolonged dorsal decubitus and tight bandaging in the puerperium.

RETROFLEXION. *Etiology:* Tight lacing and tight clothing; congenital conditions; pressure by tumors; metritis and parametritis with adhesions; atonic conditions of the uterus following labor, and the conditions that cause retroversion.

8. A complete gynecological examination would include (1) anamnesis, including family history; personal history, with special reference to menstruation, labors, and miscarriages, and present illness. (2) Examination of the abdomen (and breasts), including inspection, palpation, percussion, auscultation, and mensuration. (3) Inspection of the external genitals. (4) Vaginal examination, digital, bimanual, and with speculum. (5) Bimanual examination of uterus and appendages. (6) Sometimes the sound, or curette, may be required. (7) Chemical and microscopical examination of the urine. (8) Microscopical examination of discharges or uterine scrapings. (9) Rectal examination. (10) Cystoscopic examination and perhaps ureteral catheterization. (11) In case of phantom tumor or pseudocyesis, anesthetization would be required.

SURGERY.

1. *The general rules for treatment of wounds:* Stop the bleeding; remove foreign bodies; make as aseptic as possible; coapt the edges; drain when necessary; dress, and secure rest to the part; bring about reaction; ease pain.

2. See Rose and Carless' "Surgery" (1908), page 112; or Da Costa's "Surgery" (1908), page 174.

3. See Rose and Carless' "Surgery" (1908), page 175; or Da Costa's "Surgery" (1908), page 154.

4.

CHANCRE.	CHANCROID.
First lesion of a constitutional disease, viz., syphilis.	A local disease.
Due to syphilitic infection.	Due to contact with secretion from chancroid.
Generally a venereal infection.	Always a venereal infection.
May occur anywhere on the body.	Nearly always on genitals.
Period of incubation never so short as ten days.	Period of incubation always less than ten days (generally about three).
Generally single.	Generally multiple.
Not autoinoculable.	Autoinoculable.
Secretion slight.	Secretion profuse and purulent.
Slightly or not at all painful.	Generally painful.
As a rule only occurs once in any patient.	May reoccur in same patient.
Buboes are painless and seldom suppurate.	Buboes are painful and usually suppurate.

EYE, EAR, NOSE, AND THROAT.

1. ACUTE CATARRHAL CONJUNCTIVITIS. *Symptoms:* Hyperemia, profuse lacrymation, epiphora, a profuse discharge, sensation of sand in the eye, and sometimes photophobia. *Treatment:* Astringent and antiseptic washes are of value. Ascertain the underlying cause, if possible, and remove it. Anointing the lids with pure or medicated vaseline every evening is necessary. Alum, tannic acid, silver nitrate, and zinc sulphate are valuable as astringents. In intractable cases a 50 per cent. solution of boroglycerid in glycerin should be applied once daily.—(Gould and Pyle's *Cyclopedia.*)

2. GONORRHEAL OPHTHALMIA. *Symptoms:* Swelling and redness of the eyes, the presence of a discharge which soon becomes purulent, the conjunctiva of the lids becomes thickened, the eyelids are edematous, pain is severe, and there is some fever. *Dangers:* Ulceration and sloughing of the cornea, perforation of the anterior chamber, and blindness. *Management:* Protect the sound eye. Wash the eye carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a 2 per cent. solution of nitrate of silver must also be dropped onto the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burnt. In adults the irrigation must be frequent, about every half hour or hour.

3. *Management of corneal ulcer:* The treatment consists in putting the eye at rest, instilling atropin, and the application of a bandage. Leeches to the temple will relieve the pain. Hot compresses have the same effect. The eye should be douched with sublimate solution, 1:5000, and iodoform dusted upon the cornea. Stronger sublimate solution, boroglycerid 50 per cent., and formalin 10 per cent. are sometimes necessary. Cauterization is occasionally indicated. If perforation seems probable, it should be hastened by a puncture.—(Gould and Pyle's *Cyclopedia.*)

4. Cerumen may become impacted in the external auditory canal. It may cause deafness, tinnitus, giddiness, cough; it is diagnosed by being seen (with the aid of an ear speculum). Syringing with warm water containing sodium bicarbonate and glycerin; if near the orifice, it may be removed with a spud.

5. In *acute suppurative otitis media:* Pain (lessened when drum perforates), fever (100° to 104° F.), tinnitus, deafness (usually partial only), and purulent discharge (after perforation). *Treatment:* Dry heat allays the pain. Warmed water or warmed carbolic acid solution (1:40) may be used. Inflations, aspirations, etc., should be avoided. If the nares are filled with tough secretions, a spray of Dobell's solution may be used. If the pain continues over six hours in a child or over twelve hours in an adult without spontaneous perforation of the tympanic membrane, paracentesis of that structure should be performed. The concha and meatus should be smeared with petrolatum to avoid chapping, and the secretions should be gently mopped off as they appear. Under this treatment the ear usually returns to normal in two to three weeks."—(Gould and Pyle's *Pocket Cyclopedia of Medicine and Surgery.*)

6. *To arrest epistaxis:* (1) Try to cauterize the bleeding point; (2) plug the nasal cavity with gauze soaked in adrenalin; (3) inject into the nares a solution of peroxide of hydrogen: (4) plug the nares, anteriorly and posteriorly; (5) an inflating plug may be used.

7. The most conclusive evidence of diphtheria is the finding of the Klebs-Loeffler bacillus. See French's "Practice of Medicine" (1907), pages 192 and 196; or Osler's "Practice" (1909), pages 205 and 209.

8. *Intubation is indicated* in: Diphtheria, edema of glottis, and laryngeal obstruction. *Laryngotomy* in: Spasm of glottis, foreign body in the larynx, and dyspnea due to some sudden obstruction. See Rose and Carless' "Surgery" (1908), page 914; or Da Costa's "Surgery" (1908), page 770.

HYGIENE AND MEDICAL JURISPRUDENCE.

1. See French's "Practice of Medicine" (1907), pages 301, 326, and 307; or Osler's "Practice of Medicine" (1909), pages 115, 141, 120, and 144.

2. *Immunity* is the ability of a tissue or organism to resist infection. The absence or loss of this defensive power against infection is called *susceptibility.*

3. See French's "Practice of Medicine" (1907), page 107; or Osler's "Practice of Medicine" (1909), pages 97 and 99.

4. The school building should be as near as possible to the center of the area which it is to serve; the site should be airy and open, of sufficient size, and somewhat elevated; it should not be too near factories, busy streets, or railways; the soil should be as free as possible from organic matter. The building should be so planned that the corners look towards the four points of the compass. In this way the sun will have access to each side and to every room during some part of the day. The building should have as few stories as possible. The walls should be of brick or stone, and should be pointed with cement: the inner surface of the wall should be cemented smooth. The foundations must be solid. The general arrangement will depend upon size of site, number of scholars, and number of required rooms. Fifteen square feet per child should be allowed. Details will have to be considered on: plans, accommodations to be provided, shape and size of class rooms, distribution of rooms, teachers' rooms, corridors, entrances and staircases, playground, ventilation, heating, lighting, and placing of windows, sanitation, lavatories, water supply, drinking water, sewage disposal, removal of refuse, sanitary appliances, and drainage.

5. *Malpractice* is a failure on the part of a medical practitioner to use such skill, care, and judgment in the treat-

ment of a patient as the law requires; and thereby the patient suffers damage. If due to negligence only, it is *civil malpractice*. But if done deliberately, or wrongfully, or if gross carelessness or neglect have been shown, or if some illegal operation (such as criminal abortion) be performed, it is *criminal malpractice*.

6. A *delusion* is a belief in something which has no real existence, but is purely imaginary; and out of which the person cannot be reasoned. An *illusion* is a false or perverted impression, received through one of the senses.

7. In *tetanus*, the onset is gradual, is apt to begin with trismus, swallowing is difficult or impossible, the condition is persistent, consciousness is dulled or lost, and there is history of a wound or injury. In *strychnine poisoning* the onset is more sudden, the muscles of the jaw and neck are generally the last to be affected, there are marked remissions with muscular relaxation, consciousness is retained, and there is no history of a wound or injury.

8. The symptoms of acute poisoning by coal tar derivatives are given by Riley as follows: After a full toxic dose there soon follows a sense of chilliness and, especially in the case of antipyrin, nausea, and vomiting. The skin becomes cyanosed and covered with cold perspiration. The pulse becomes soft, slow, and weak, and the respirations slow and shallow, death usually resulting from respiratory paralysis. Occasionally paroxysms of sneezing have been observed.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION	
Alabama*	W. H. Sanders, Montgomery	Montgomery	July 12
Arizona*	Ancil Martin, Phoenix	Phoenix	July 4
Arkansas	F. T. Murphy, Brinkley	Little Rock	Nov. 8
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco	Aug. 2

* No reciprocity recognized by these States.

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Massachusetts.—Two new bills were recently introduced in the Legislature: (1) Any person qualified by law to practise medicine in any State may practise medicine in this State provided that he furnishes to the board of registration in medicine satisfactory evidence that he is so qualified. (2) No person shall be permitted to practise medicine or healing in this commonwealth unless he has received the degree of doctor of medicine from some college, university, or school authorized by the laws of the State in which it is situated to confer such degrees.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of June 18, 1910.

	Cases	Deaths
Tuberculosis Pulmonalis	582	168
Diptheria	433	40
Measles	972	21
Scarlet Fever	495	17
Smallpox	1	—
Varicella	176	—
Typhoid Fever	51	10
Whooping Cough	76	9
Cerebrospinal Meningitis	3	8
Malarial Fever	—	—
Totals	2,789	273

Causes of Earache.—Fernandez reviews the different causes of aural pain, taking in the first place aural neuralgia. He uses the pain to differentiate the different causes, and makes an exhaustive research work.—*Crónica Medico-Quirurgica de la Habana.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended June 17, 1910.

THE FUNCTION OF THE CORPUS LUTEUM, THE EXPERIMENTAL PRODUCTION OF THE MATERNAL PLACENTA, AND THE MECHANISM OF THE SEXUAL CYCLE IN THE FEMALE ORGANISM.*

BY LEO LOEB,

PHILADELPHIA, PA.

ON several previous occasions[1] I published some of the results of my investigations into the conditions under which it is possible to produce experimentally the maternal placenta and deciduomata, and into the functions of the corpus luteum. I now intend to communicate some of the results obtained more recently, namely since the summer of 1909. I shall not aim at completeness either in enumerating the new facts ascertained, or in giving a detailed account of the individual series of experiments, but I shall content myself with emphasizing some of the more important conclusions at which I arrived and to point out in what respect my methods and my results differ from those obtained by previous investigators.

I may, however, mention that my conclusions are based on a very extensive series of investigations. In more than nine hundred guinea pigs the time of copulation was ascertained, and in the large majority of these cases the different parts of the uterus were examined microscopically and in several hundred of cases the ovaries were examined on serial sections. Our comparative studies in rabbits were much more limited.

Until recently our knowledge of the functions of the corpus luteum has been very unsatisfactory. I may briefly indicate the status of this problem without going into any detailed discussion of the literature, which is found in the review of R. Birnbaum.[2] L. Fraenkel[3] attributed to the corpus luteum in the main two sets of functions:

1. To prepare the mucosa of the uterus for the reception of the ovum. This the corpus luteum accomplishes by causing a hyperemia and softening of the tissues.

2. To cause the conditions of heat and menstruation.

Fraenkel disclaimed the assumption that the corpus luteum was in any way responsible for the building up of the maternal placenta. He cited as proof of his first contention experiments in which, after cauterization of the corpora lutea in the rabbit, pregnancy was interrupted. Many investigators repeated his experiments with contradictory results, and at the present time a very large number, perhaps the majority of authors, especially gynecologists, have abandoned the hypotheses of Fraenkel as unfounded or improbable.

It is not difficult to recognize why this line of research did not lead to a more satisfactory conclusion. The reason is the following: Fraenkel and all the later investigators used as a criterion for the function of the corpus luteum the effect of certain operative interferences (burning of corpora lutea, excision of ovaries) upon the development of pregnancy. This, in the first place, is an uncertain reaction, inasmuch as pregnancy can be interrupted in the guinea pig as well as in the rabbit by various nonspecific operative procedures: and secondly, even if it could be established that the corpus luteum does influence pregnancy, we would still be entirely in the dark as to the mechanism by which it does so.

We introduced a new test for the influence which various external and internal factors, and especially the corpus luteum, exert upon the sexual processes, namely, their influence upon growth-processes in the uterus. Here we have to deal with an objective reaction free from the many variable factors that interfered continuously with the progress of previous investigations. In order to test the influence of the ovaries and of the corpus luteum upon the growth-processes taking place in the uterus, it was especially necessary to exclude one variable factor of importance, namely, the contact between the ovum and the uterine mucosa. Various previous investigators had attributed exclusively to the contact with the ovum those changes in the uterine mucosa which take place after fertilization. We could easily eliminate this influence of the ovum by ligating the Fallopian tubes near their uterine end within the first forty hours after copulation, or more generally after the rupture of the follicles (ovulation).

Thus we could readily establish the fact that all growth phenomena observed in the uterine mucosa in the early stages of pregnancy can be produced without contact with an ovum.

Quite recently, after publication of several of our previous communications, Bouin and Ancel[4] adopted our method of investigation. For the first time in the course of their investigations they used objective growth phenomena taking place in the uterine mucosa as a reagent for their experimental investigations; they modified slightly our procedure, by ligating the vas deferens of the male instead of the Fallopian tubes of the female in order to prevent the passage of a fertilized ovum through the uterine cavity. Of course their procedure does not exclude the contact of the unfertilized ovum with the uterine mucosa.

We shall now briefly state some of the results which we have obtained in the course of the last year.

1. The corpus luteum exerts an influence that

*From the Laboratory of Experimental Pathology of the University of Pennsylvania.

acts as a formative stimulus upon the mucosa of the uterus and induces here growth phenomena. These growth phenomena are of two kinds.

a. In conjunction with the ordinary metabolic processes taking place normally in the uterine mucosa and in conjunction with those stimuli that induce normal regeneration in the epithelium, the corpus luteum regularly calls forth not very pronounced changes in the mucosa of the uterus. Such changes are found quite independently of the contact action of an ovum in the uterine mucosa of the guinea pig and of the rabbit. In the former they consist in a moderate mitotic proliferation of the interglandular connective tissue which becomes at the same time more succulent, and in the latter we notice a marked amitotic proliferation of the epithelial nuclei. In the guinea pig these proliferative processes reach their maximum about six or seven days after ovulation and very soon come to a standstill; in the rabbit the amitotic proliferation of the nuclei is found approximately fifteen days after ovulation. If we extirpate in the guinea pig the ovaries very soon after the rupture of the follicles these growth phenomena do not take place.

b. If to the action of the corpus luteum a mechanical stimulus is added the changes proceed much further and lead to the production of a maternal placenta which in the case of the guinea pig may assume a tumor-like appearance. A deep cut into the wall of the uterus may act as such a mechanical stimulus. The maternal placenta is, therefore, not produced merely by the action of the corpus luteum, but is due to a combined action of mechanical stimuli and of the influence of the corpus luteum.

Or, we may state it in a somewhat different way: The corpus luteum sensitizes the mucosa and ordinary metabolic or the normal regenerative processes are sufficient to cause slight growth phenomena in the uterine mucosa at a certain stage of the development of the corpus luteum. If, however, more potent mechanical stimuli act upon the sensitized mucosa, a maternal placenta is produced.

In a general way we may, therefore, state the corpus luteum enables the uterine mucosa to respond to certain stimuli with growth phenomena; these growth phenomena differ quantitatively according to the intensity of the stimuli used. If the stimuli are weak we find merely predecidual changes (mentioned under *a*) and when the stimuli are stronger, they lead to the production of the maternal placenta (mentioned under *b*). Qualitatively these changes are of the same kind and the predecidual changes indeed form a part of the maternal placenta and represent the initial phenomena in the formation of this structure.

Recently Bouin and Ancel have confirmed our finding that the corpus luteum without the addition of mechanical stimuli causes predecidual changes in the mucosa of the uterus of the rabbit (amitotic nuclear proliferation) and they add that these changes are preceded by mitoses and swelling of the mucosa. Inasmuch as the ephithelial mitoses are not a characteristic feature of the placenta, we have not yet given especial attention to their occurrence, leaving a more detailed description of the predecidual changes in the uterine mucosa of the rabbit to a later study.

2. The results of our experiments leave no doubt whatever that the corpus luteum is indispensible for the formation of the maternal placenta, inasmuch as in only one exceptional case did we find a very small area of decidual tissue after an early extirpation of the corpora lutea. Thus far, however, our experiments had not enabled us to state definitely by what mechanism the corpus luteum exerts this influence. We could readily conceive that the corpus luteum might act upon the uterine mucosa with the aid of a nervous mechanism. A so-called internal secretion might also be suggested. But, without actual experiments proving either, such explanations must be considered as purely hypothetical. Several years ago I showed that it is possible to obtain the formation of maternal placenta (deciduomata) even in the uterus transplanted into the subcutaneous tissue, provided the transplantation has been carried out approximately five to seven days after ovulation. At first I was inclined to consider this experiment as a proof that the corpus luteum acts through an internal secretion. But very soon I recognized that it merely proved that the formation of the maternal placenta takes place independently of a nervous mechanism, after the stimulus for its formation has been transmitted to the mucosa. Such a transmission might have already occurred at the time of the transplantation of the uterus. For reasons which I cannot go into at this time, it is impossible to obtain the formation of maternal placenta in the transplanted uterus, if the transplantation has been carried out immediately after ovulation. Nevertheless, it is possible to prove directly that the influence of the corpora lutea is exerted by means of an internal secretion, in the following way. If we excise the ovaries six days after ovulation and at the same time apply the mechanical stimuli to the not transplanted uterine mucosa, we still obtain, usually, the formation of maternal placenta, as I stated in some previous communications; but the quantitative examination of such newly formed tissue shows the quantity of maternal placenta thus formed to be much smaller than in the control experiments, in which the ovaries had been left intact. There is, therefore, even later than six days after ovulation an influence exerted through the ovaries acting upon the uterine mucosa, and it can be shown that this influence is not of a nervous character, but is exerted by means of a certain substance which is given off to the body fluids, and is thus transmitted to the uterine mucosa. If we transplant the uterus of that period, namely, six days after ovulation, and extirpate the ovaries at the same time, the maternal placenta in the transplanted uterus, if produced under such conditions, is likewise much smaller than that in the transplanted uterus when the ovaries are left intact. This proves without doubt that in this case the internal secretion of the ovaries is responsible for the production of the maternal placenta. That this influence of the ovaries is dependent upon the presence of the corpora lutea and not of other parts of the ovaries we conclude from experiments in which we proved that at early periods after ovulation the only parts of the ovaries of importance for the formation of the maternal placenta are the corpora lutea.

3. The experiments just recorded prove still another point, namely, that for the production of the maternal placenta it is not sufficient that the mechanical stimulus merely act upon the mucosa after a certain amount of the corpus luteum substance has been secreted for a short period; but, in order to obtain from a quantitative point of view the full development of a maternal placenta, it is necessary that the corpus luteum continue to secrete the substance even at later periods. We need, therefore, a

continuous cooperation between the mechanical local stimulus and the chemical influence exerted through the corpus luteum. We may assume that the latter has continuously to sensitize the uterine mucosa, in order to make the cells of the mucosa responsive to the mechanical stimuli. Nothwithstanding this relationship of the two sets of stimuli, six days after ovulation the mucosa of the uterus is sufficiently sensitized in the majority of cases to respond to mechanical stimuli with the production of the maternal placenta, although, as stated above, the full quantitative response can not be obtained without a continued cooperation of the ovaries.

4. Our further experiments, carried out under still more favorable conditions, again demonstrated that the corpus luteum substance acts merely upon the uterine mucosa, the mucosa of the Fallopian tubes for instance being at no time sensitized to mechanical stimuli, and this is, as we pointed out before, probably one of the reasons, why in the guinea pig it is impossible to obtain a tubal pregnancy experimentally.

5. At a very early stage of our experiments we had planned to prove the existence of the substance given off by the corpus luteum by injection of blood of a suitable animal in which ovulation had taken place, into a guinea pig previously castrated. Cuts into the uterus of the castrated guinea pig should then lead to the production of maternal placenta, if the substance had been transmitted with the blood of the first guinea pig to the castrated animal. A few such experiments which I carried out several years ago proved negative, although we had ascertained through special investigations that at an early stage after castration the uterus is not changed to any marked degree. Soon after ovulation the uterus of the guinea pig becomes succulent, and as we described before, predecidual changes take place in the uterine mucosa within five to six days.

In animals which have been castrated the uterus looses its succulence and the predecidual changes do not take place. The uterine mucosa returns to its resting stage. Fibrous changes in the uterus, which have been found after castration, must follow at a later period. It cannot, therefore, be due to such secondary structural changes in the uterine mucosa after castration if the injection of blood of an animal that has recently ovulated into a castrated animal remains without effect.

In the meantime our experiments taught us that a constant cooperation between the action of the corpus luteum and the mechanical stimuli exerted upon the mucosa is necessary in order to obtain the full development of the maternal placenta. It was, therefore, not probable that even a periodically repeated subcutaneous injection of the fresh corpus luteum substance could act as a substitute for the constant physiological activity of the corpus luteum. These considerations induced us to defer experiments in which corpus luteum substance was administered to castrated guinea pigs.

Last winter we carried out three experiments, in which previously castrated guinea pigs were injected usually every day, sometimes every second day with fresh corpora lutea of other guinea pigs. In two series the corpora lutea were six to eight, in one series two to four days old. Cuts made in the uterus of such animals did not lead to the production of maternal placenta. In two cases, however, I found several mitoses in the connective tissue of the mucosa, before the cuts had been made, and after the corpora lutea had been injected for several days. We can, therefore, positively state that intermittent injection of the corpora lutea of the guinea pig cannot to any great extent act as a substitute for the action of the living corpus luteum. We cannot deny, however, the possibility that a very slight influence might be exerted by the corpus luteum substance injected subcutaneously.

Our previous experiments proved without doubt that the corpus luteum acts by means of a substance given off to the body fluids. If, notwithstanding this fact, the subcutaneous injection of corpus luteum substance does not act as a substitute for the living organ this must in the light of our other experiments in all probability be interpreted in the following way: The living organ discharges continuously a small amount of the specific substance. The latter is carried through the body fluids to the mucosa of the uterus, and it does not, therefore, accumulate to any great extent in the blood or in the corpus luteum itself; a periodical injection of very small quantities of this substance cannot take the place of a continuous discharge of the substance which occurs probably in the living organ.

I may here mention that recently Dr. Robert T. Frank, of New York, tested the effect of extracts of the corpus luteum of the pig on the production of deciduomata in the guinea pig and rabbit, and he also obtained negative results.

6. In our previous work the mechanical stimuli which we applied consisted in deep incisions into the uterine wall. Further experiments proved that such cuts do not act through the wound as such, but indirectly through a complete or partial eversion of the uterine mucosa, which they cause. If such an eversion is prevented by the application of a circular ligature near the cut end of the uterus, the maternal placenta is only formed in that small remnant of the uterus which is left between the ligature and the cut end, while on the other side of the ligature no decidual changes take place. The stimulus exerted upon the connective tissue of the mucosa affects, therefore, at first the uterine epithelium, producing some changes therein and only secondarily is the connective tisue affected. This can be proven in the following more direct way: We found that it is possible to imitate the action of the ovum directly by introducing a foreign body (thin glass rod, platinum wire, paraffin) into the uterine cavity at the proper period, the action of the ovum being excluded in the usual way. Within a few days the uterus increases in volume to a surprising extent, this increase in volume being caused by the new formation of the maternal placenta, wherever the foreign body came in contact with the mucosa. Here again the foreign body acts first upon the epithelium, causing a necrosis of the epithelial surface layer at some places and thus initiating the enormous tissue proliferation. A preceding necrosis of the epithelium, however, is not necessary, as has been proved by our experiments, mentioned above, in which a mere eversion of the epithelium was followed by the same changes. The ovum also injures the surface epithelium at the point of fixation, and we thus see *that it is possible to imitate the action of the ovum by an inert foreign body;* both foreign body and ovum, however, need the co-operation of the corpus luteum. The *mechanical* effect of the attachment and of the growth of the ovum is, therefore, sufficient to explain, in the main, the influence which the ovum exerts in the production of the maternal placenta.

7. In our previous investigations we had found that extirpation of the corpora lutea soon after ovulation prevents the formation of the maternal placenta, which takes place under the influence of a mechanical stimulus. If the corpora lutea have been extirpated on the second or fourth day after ovulation frequently small deciduomata form. Later extirpation of the ovaries does not prevent the production of the maternal placenta, but it diminishes its size, as we have already pointed out. We now tested the effect of the extirpation of the corpora lutea upon the development of pregnancy. In the guinea pig, after removal of the corpora lutea on the first, second and third day after copulation, no trace of pregnancy is found, if we examine the uterus on the nineteenth day after copulation. If, however, the corpora lutea are removed six or seven days after copulation, in the large majority of cases pregnancy has progressed normally on the nineteenth or twentieth day after copulation.

On the basis of our former work we are now in a position to understand such an outcome. The normal course of pregnancy is interfered with, if the corpora lutea are excised at such an early stage, because under such conditions mechanical stimuli are unable to produce a sufficient quantity of maternal placenta, as we have already pointed out; if, on the other hand, the corpora lutea are extirpated six days after copulation, a certain quantity of placental tissue can be formed, and the ovum is able to develop under such conditions. Thus the influence of the corpora lutea on the development of pregnancy has been satisfactorily explained through our experiments. Those experiments allow one more conclusion: We saw that a maternal placenta can develop around the dividing ovum, if the corpora lutea have been extirpated six days after copulation. On the other hand we have definitely proven that even six days after copulation the internal secretion of the ovaries is still of importance for the full development of the maternal placenta, and that their extirpation at that time diminishes the amount of placental tissue formed. From these facts it follows that the embryo does not need for its development the maximum quantity of placental tissue which a certain part of the uterine mucosa could furnish. This is another instance of the existence of a certain reserve power that is not made use of under natural conditions.

On former occasions I emphasized the fact that the uterus has a much greater capacity for producing maternal placenta than is ever made use of during normal pregnancy. Especially after the introduction of foreign bodies into the uterine cavity the newly formed decidual tissue far exceeds the quantity of maternal placenta produced in pregnancy.

8. So far I was concerned with one function of the corpus luteum, namely, that of enabling the uterine mucosa to proliferate, I was, however, able to establish securely another function of the corpus luteum, which is perhaps of no less importance: *The corpus luteum changes the periodicity of the sexual cycle, it prolongs the sexual period, the interval between two successive ovulations, by preventing the rupture of the follicles.* This function is exerted by the corpus luteum in the non-pregnant animal as well as in the pregnant animal, the corpus luteum in the latter case preventing interference with the progress of pregnancy by preventing a new follicle to rupture.

In a large series of experiments I could prove that, while the sexual cycle in the guinea pig has usually a duration of approximately nineteen (rarely eighteen) to twenty-four days, after extirpation of the corpora lutea, the sexual cycle usually has only a duration of twelve to fifteen days. After extirpation of the corpora lutea, approximately six days after copulation (or earlier) new follicles usually rupture spontaneously without the presence of a male on the twelfth to the fifteenth day after the previous copulation. This rupture of follicles takes place even, if a pregnancy is proceeding at the same time; *the growth of the embryo does not prevent a new rupture of follicles; it is merely the influence of the corpus luteum that has such an effect.* Even during pregnancy a new rupture of follicles usually takes place on the twelfth to fifteenth days after the fertilizing copulation, if the corpora lutea have been removed approximately six days after the last ovulation. This effect of the corpora lutea is not of a mechanical but evidently of a chemical nature; it affects also the second ovary, even if corpua lutea had been present and removed only in the first ovary; and in such a case the ovary in which no cut had been made also reacts.

Under the normal conditions the corpus luteum of the non-pregnant animal lives approximately eighteen to twenty days, when degenerative processes set in; and the beginning degeneration of the corpora lutea acts in a similar manner as their extirpation. A new rupture of the follicles can now take place. During pregnancy, which in the guinea pig lasts approximately sixty-six days, factors are at work (presumably some direct or indirect action of the embryo—this is a point which we still intend to test experimentally) that prolong the life of the corpora lutea, and correspondingly the follicles are prevented from rupturing until the corpora lutea begin to degenerate at the conclusion of the pregnancy.

Thus far we had progressed in our work, when we found in the literature a communication by T. Beard,* in which this author gave expression to the hypothesis that the corpus luteum might have the function of preventing the rupture of the follicles during pregnancy. He did not undertake to prove this suggestion, and his hypothesis does not absolutely correspond to reality. The corpus luteum has a wider function than he conceived of; it not only prevents ovulation during pregnancy, but it delays ovulation also in non-pregnant animals. It changes the sexual cycle, a conception rather contrary to what Beard assumed. But, notwithstanding these imperfections in his hypothetical conclusions, we cannot but express our admiration for the scientific imagination of Beard. He has not received his due recognition, and what now has proved to be correct in his hypothesis we find in the literature without justification attributed to others—a mistake transmitted from one writer to another and a marked example of a not uncommon occurrence.

Concerning Fraenkel's hypothesis, it attributes on the one hand functions to the corpus luteum which it does not possess; the corpus luteum does not cause heat in the guinea pig, but, it has the opposite function; it prevents heat by preventing the rupture of the follicles. On the other hand, L. Fraenkel underestimates the function of the corpus luteum, in as much as the latter does not only induce hyperemia and softening of the mucosa, but is one of

*Anatom. Anzeiger 1897, XIV p. 97.

the principal factors that build up the maternal placenta. As we saw above, the experimental means at the disposal of L. Fraenkel and of his successors did not make it possible for them to get a clear insight into the functions of the corpus luteum.

9. In the guinea pig the various stages in the sexual cycle are accompanied by definite changes in the ovarian follicles, which to a certain extent enable us to diagnose in what period of the sexual cycle the animal stood. Soon after ovulation all follicles, with the exception of the smallest ones, show more or less pronounced degeneration of the granulosa. In the case of the larger follicles this stage of granulosa degeneration is soon followed by atresia (connective-tissue organization). The smaller follicles, in which only a few cells degenerated, may recover.

Gradually the small follicles begin to grow, and as soon as they reach their full size they also begin to degenerate; in the meantime other maturing follicles take their place. This process continues as long as a corpus luteum is present. As soon as in the corpus luteum degeneration has set in a certain change takes place, in a few mature follicles the granulosa remains preserved, these follicles enlarge and rupture and their granulosa and theca interna become transformed into new corpora lutea. At this time again an almost general degeneration of the other follicles sets in in the ovary and a new cycle begins.

10. We may now briefly recapitulate the principal features in the sexual cycle. At a certain period the animal enters the period of heat; a few ovarian follicles rupture and become transformed into corpora lutea. In the early stage of their life the corpora lutea are one of the factors initiating growth processes in the uterine mucosa by means of an internal secretion. If no pregnancy takes place, these proliferative phenomena are slight. If pregnancy does take place, the ovum adds a mechanical stimulus to the sensitizing action of the corpus luteum and a maternal placenta is produced. The ovum can be substituted by an indifferent foreign body. Within a few days this receptive period of the uterine mucosa is followed by a refractory period, in which the uterus no longer reacts to mechanical stimuli, notwithstanding the functioning of the corpus luteum. In this period the corpus luteum exerts a new function, it prevents the rupture of new follicles and prolongs artificially the period of the sexual cycle. During pregnancy some factor extends the life of the corpus luteum, and the period of the non-rupture of follicles is thus prolonged. At the end of the pregnancy the corpus luteum degenerates, new follicles rupture, and a new cycle begins, the pregnancy as such, does, however, not prevent a new rupture of follicles. If no pregnancy is present the factor that prolongs the life of the corpus luteum is absent. The corpus luteum degenerates much earlier and permits new follicles to rupture. The changes in the corpus luteum and in the uterus are accompanied by rhythmic changes in the ovarian follicles.

In conclusion, I wish to emphasize that the conception of this mechanism is not hypothetical, but rests on a secure foundation of experimentally established facts.

ON THE AFFECTIONS CLINICALLY SIMULATING TYPHOID FEVER, WITH ESPECIAL REFERENCE TO AND REPORTS OF CASES OF BRILL'S DISEASE.

By H. FRED LANGE ZIEGEL, B.S., M.D.,

NEW YORK,

ADJUNCT ATTENDING PHYSICIAN TO THE BETH ISRAEL HOSPITAL.

Attesting to the evolution in clinical observation which our present knowledge of the differentiation of the exanthemata represents are the historical facts[1] that from Sydenham's time up to the beginning of the eighteenth century the term scarlet fever was applied to no less than four distinct diseases and that only about seventy-five years ago was the distinction recognized between typhus and typhoid fever. Owing largely to important bacteriological investigations in which Gärtner[2] in 1888 was the pioneer, the terminology of the older writers as to exceptional cases of typhoid fever began to undergo changes. Thus the appellation "abortive typhoid" was often replaced by "food poisoning" and some of the outbreaks previously regarded as "mild typhoid" were differentiated as epidemics of "paratyphoid fever." Based on interpretations of distinctive clinical and negative bacteriological evidences a further advance is the relegation into a separate though unclassifiable group of a fairly common condition which has previously been regarded as atypical typhoid fever.

Some of the acute infectious diseases which occasionally assume a temporary clinical picture of typhoid fever are miliary tuberculosis, septic endocarditis, malaria, influenza and the meningitides. Let us disregard this casual simulation in a *tentative classification* of the conditions which frequently bear more or less clinical resemblance to typhoid fever: (1) Intestinal Sapremia. (2) Coli Infections. (3) Meat Poisoning. (4) Paratyphoid Fever. (5) Brill's Disease.

1. *Intestinal Sapremia.*—In conditions of marked constipation, headache, apathy, a dry furred tongue, anorexia, prostration, abdominal pain, sustained temperature elevation, palpable spleen and an eruption may all be present to suggest the possible existence of typhoid fever. The eruption is, however, profuse and blotchy, macular and erythematous, and is not likely to be mistaken for a roseola nor for the eruption peculiar to Brill's disease (*vide infra*). Moreover, the administration of a brisk saline purge causes prompt defervescence and rapid disappearance of the rash. If, however, the duration of symptoms is not definitely ascertainable, or if they have been of longer duration than usual, the suspicion of typhoid fever may make active catharsis inadvisable. Such circumstances have been known by the writer to prolong for a week or more the ultimate exclusion of typhoid fever by means of the clinial course and the diagnostic aids of the laboratory.

2. *Coli Infections.*—Cases of aggravated constipation exhibiting typhoidal symptoms are occasion-

ally met with in which isolation from the urine and blood of the *Bacillus coli communis* or positive and exclusive agglutination of the patient's serum against most strains of this organism prove these exceptional cases to be a general coli infection rather than an intestinal sapremia.[3] An epidemic of this nature has been reported in Bavaria.[4]

Sanarelli has shown that the bacillus coli in the intestine increases in number and virulence in typhoid fever.[5] Moreover, the serum of typhoid patients frequently gives an agglutinative reaction with races of *Bacillus coli*, and a bacteriuria in typhoid fever shows the presence of this organism in the urine.[1] The clarification of the exact relationship of the *Bacillus coli* to typhoid fever is a problem for future solution.

3. *Meat Poisoning.*—In the outbreaks of meat poisoning which occur from time to time the clinical course of the disease varies considerably. In many of the cases the symptoms suggest a simple gastroenteritis; some of the severer cases resemble cholera nostras; while still other cases bear clinical as well as pathological resemblances to typhoid fever.[6] In the last type differentiation from typhoid fever has been made practicable by the discovery of the efficient cause, which is either Gärtner's enteritidis bacillus, or the *Bacillus paratyphosus B.* Both of these organisms can be distinguished biologically from the colon bacillus and the *Bacillus typhosus*: and recent studies have conclusively shown that the serum of patients ill with meat poisoning regularly agglutinates known cultures of the causative organism.[7]

Poisoning caused by the proteus or colon bacillus in decayed meat and certain other forms of bacterial food poisoning have not been touched upon for the reason that the symptoms produced are not likely to be mistaken for those of typhoid fever.

4. *Paratyphoid Fever.*—That there exists at least one infectious disease not caused by the Eberth bacillus though materially componental of the previously so-called typhoid fever was firmly established nearly a decade ago by the studies of Achard and Bensuade, Widal, Gwyn, Durham, Cushing, Schottmüller, Coleman and Buxton, Meltzer, and others.[8] An important and more recent contribution to the literature of this subject is that of Herbert Fox.[9]

Indistinguishable clinically from typhoid fever, and occurring both sporadically and in epidemics, paratyphoid fever can be diagnosed only with the aid of the bacteriologist, who must isolate from the blood, urine or feces the paratyphoid bacillus, or else obtain properly controlled positive agglutination reactions against this organism either (preferably) with the serum of a highly immunized animal or with the patient's serum. In bacteriological investigations of epidemics abroad the *Bacillus paratyphosus B.*, is recovered much more frequently than the *Bacillus paratyphosus A.*, while in America the reverse seems to hold true.[9] Thus Proescher and Roddy have reported forty-eight cases of type A paratyphoid occurring in Allegheny.[10] Recently, however, in an epidemic in Virginia, agglutination tests were positive exclusively against the *Bacillus paratyphosus B.*[11] In another recent epidemic in a barracks in France similar results were obtained after the *Bacillus paratyphosus B.* had been isolated from the blood in seven of the eight cases in which cultures were made.[12] There is still some uncertainty, however, as to the diagnostic adequacy of such serum reactions without other definite bacteriological proof as to etiology. Occasionally, as in Libman's celebrated case,[13] the serum of a patient from whose blood a paratyphoid bacillus has been isolated will agglutinate, not only this organism, but also the *Bacillus typhosus* in low dilutions. Interesting are the facts that immunity from paratyphoid is not conferred by a previous attack of typhoid and that there is a paratyphoid cholecystitis similar to that complicating typhoid fever.[14]

Because of the etiological relationship of the *Bacillus paratyphosus B.* to certain forms of bacterial food poisoning, the question arises whether there is a common infectious disease assuming an acute form as meat poisoning and a subacute form as paratyphoid fever. Some of these problems will probably be solved by the continued studies of competent bacteriologists such as the recent painstaking investigations of Proescher and Roddy.[7]

5. *Brill's Disease.*—Because of the complex symtomatology and protean typology of typhoid fever caution should be exercised before stating that an affection bearing clinical resemblance to atypical typhoid fever is not the same disease, especially if the condition has hitherto remained unrecognized by all internists except N. E. Brill and by all pathologists except E. Libman. In no spirit of disapprobation be it said that both of these observers have taken advantage of and have been able to evolve a new disease from the criteria born of scientific exactness and bacteriological scrutiny which now limit the scope of the term typhoid fever. Fortunately all authorities are now agreed as to certain criteria based upon the following facts: (*a*) the Widal reaction is present in about 95 per cent of all cases: (*b*) the Eberth bacillus can be isolated from the blood in over 90 per cent of all cases; and (*c*) the roseola is an almost constant sign. If, therefore, in a large number of cases the true roseolar eruption is regularly absent and the blood culture and Widal are regularly negative, we are justified in concluding that the great majority of these cases, to say the least, are not typhoid fever. Similar negative evidence with reference to the paratyphoid roseola and the paratyphoid organisms and agglutination reaction also establishes the exclusion of paratyphoid fever. Furthermore, if there are definite and constant clinical characteristics in the cases referred to distinguishing them from typhoid and paratyphoid fever, such a deduction is indisputably warrantable.

Every practical clinician of to-day, provided that he has fair training, experience and acumen, must recollect having at one time or another treated what passed for atypical typhoid fever—not, however, without the conviction that he was not actually dealing with typhoid. That this is true is shown by the following incident. The house physician at Beth Israel Hospital had suggested influenza as a discharge diagnosis, and on being questioned as to the propriety of this designation, Dr. S. Horwitt replied that he knew the case was not really influenza, but that the system of nomenclature in vogue at this hospital (the Bellevue system) excluded vague terms like autointoxication; and furthermore that though the condition resembled typhoid or paratyphoid somewhat, neither of these appellations would be justifiable. The interne's response demonstrated his recognition of an unclassifiable condition, which in fact was a typical case of the disease which we have called Brill's disease in spite of the undesirability of eponymic nomenclature.

For a detailed description of this affection the reader is referred to Brill's convincing and comprehensive presentation of the subject in the *American Journal of the Medical Sciences* for April, 1910,[15] and for a critical survey to an editorial in the Medical Record for April 30, 1910.[16] In this communication we shall limit ourselves to: (*a*) a justification of the proposed admittance into medical nosography of this affection; (*b*) remarks on the facility and practical importance of differentiating it from typhoid fever; and (*c*) reports of three cases.

As early as 1896 Brill had "noticed a type of disease somewhat similar, but characteristized by many features irreconcilable to the picture of typhoid fever;"[15] and two years later Brill published "A Study of Seventeen Cases of a Disease Clinically Resembling Typhoid Fever, but Without the Widal Reaction."[17] These studies have been continued ever since with the best obtainable laboratory facilities for agglutination tests and blood, stool and urine cultures, all of which were most systematically carried out with the last fifty cases of Brill's series, and have proven that "the affection has nothing in common with typhoid, paratyphoid and typhoid-colon or intermediate group infections."[15] In 1906, speaking before the Johns Hopkins Hospital Medical Society, E. Libman stated that "in the group of cases described by Dr. Brill, which resemble typhoid fever somewhat, and which have been considered to have been possibly cases of paratyphoid fever, we could not succeed in isolating any organisms from the blood. There is no proof as yet that they are cases of paratyphoid, and should, therefore, be classed for the present as a *separate group*."[18]

The discussion following Dr. Brill's original presentation of this subject before the Section on Medicine of the New York Academy of Medicine evinced a hesitancy to accept as a newly discovered disease a condition for which there existed only negative bacteriological and pathological evidence. Some of the participants in this criticism seemed to be oblivious of the fact that medical nosology was well established before the advent of the bacteriologist. Were his services required to distinguish measles from scarlet fever, typhoid fever from typhus, and infantile scurvy from rheumatism?

It is no exaggeration to state that the clinical differences between Brill's disease and typhoid fever are so pronounced and easy of recognition that the practical differentiation is less difficult than that between German measles and measles or that between German measles and scarlet fever. Let us now consider these differences seriatim.

The most striking mark of differentiation is the *eruption*, which appears as a single crop usually before the seventh day of the disease. There are no new crops. Appearing first on the abdomen and back, the rash spreads rapidly to the chest wall and extremities, is sometimes seen on the neck, palms and soles, and is often more profuse on the upper extremities than on the trunk. The rash is a profuse one and sometimes a number of the lesions run together to form small patches. The spots are maculopapular in character and usually have an oval, indistinct outline. On stretching the skin or making pressure over the spots, the latter fade somewhat but do not disappear entirely. Sometimes hemorrhagic spots are seen interspersed with the other lesions and frequently there are present in addition suspicious but not typical roseolæ. The eruption fades rapidly at the time of defervescence, but its remains are seen for some days in the form of brownish stains.

The febrile invasion is usually abrupt and is ushered in with a chill or chilly sensations followed by very severe headache and high fever. For a variable period previous to the invasion there is general malaise. The temperature curve reaches its acme in about three days and then remains sustained till the time of crisis or rapid lysis (see temperature charts of illustrative cases). While the fever lasts the headache persists severe and in a small proportion of cases there is also meningismus. Apathy and prostration develop very early, and the patient ill with Brill's disease looks as poisoned and as sick in the first week as does the typhoid patient in the second or third week.

Just as distinctive as the eruption is the *prompt recovery of the patient at the time of defervescence*. After the temperature has remained continuously high for a period varying from one to two weeks, there is a fall to normal in from ten to sixty hours; thereafter, in the great majority of cases, the temperature never again rises above normal. No case has been observed with a relapse or with serious sequelæ, and the mortality is nil. At the time of crisis or rapid lysis, the mental condition becomes bright, the headache disappears and the patient says that he is entirely well. It is usually difficult and apparently unnecessary to keep the patient in bed for as long as a week after the temperature has fallen. Characteristic is this rapid convalescence to complete recovery.

A leucopenia in this disease is exceptional. Usually the absolute and differential leucocyte count is normal.

The negative agglutination reactions and negative blood, stool, and urine cultures have already been dwelt upon.

The uniformity of the symptoms, the distinctive features mentioned above and their unlikeness to comparable manifestations in typhoid and paratyphoid fever make the diagnosis comparatively easy. Moreover, with the help of the characteristic eruption the diagnosis can be made early in the course of the disease, a fact which from a prognostic standpoint is of great practical significance to the practitioner. Is it not a boon when a patient is apparently seriously ill with a febrile disease to be able to predict with a fair measure of certainty that the patient will be up and about in between two and three weeks and that recovery will be complete?

Speculations will not be indulged in as to the pathogenesis, about which practically nothing is known. Clinically the disease bears more resemblance to mild typhus fever than it does to typhoid. Brill states that during an epidemic of typhus differentiation from mild cases would probably be impossible. Yet Brill is firmly of the opinion that the disease is *not* typhus. Against the view that Brill's disease is typhus modified and attenuated by importation, new environment or other changed conditions are its nonepidemic occurrence, its usual noncommunicability, its uniform clinical picture, and the absence of grave and fatal cases. Immunity from Brill's disease is not conferred by a previous attack of typhoid fever. Since there are apparently periods of incubation, invasion, continued fever, and decline, by analogy the designation "infectious" is justifiable. There is little evidence to indicate that the disease is communicable. In Brill's 221 cases members of the same

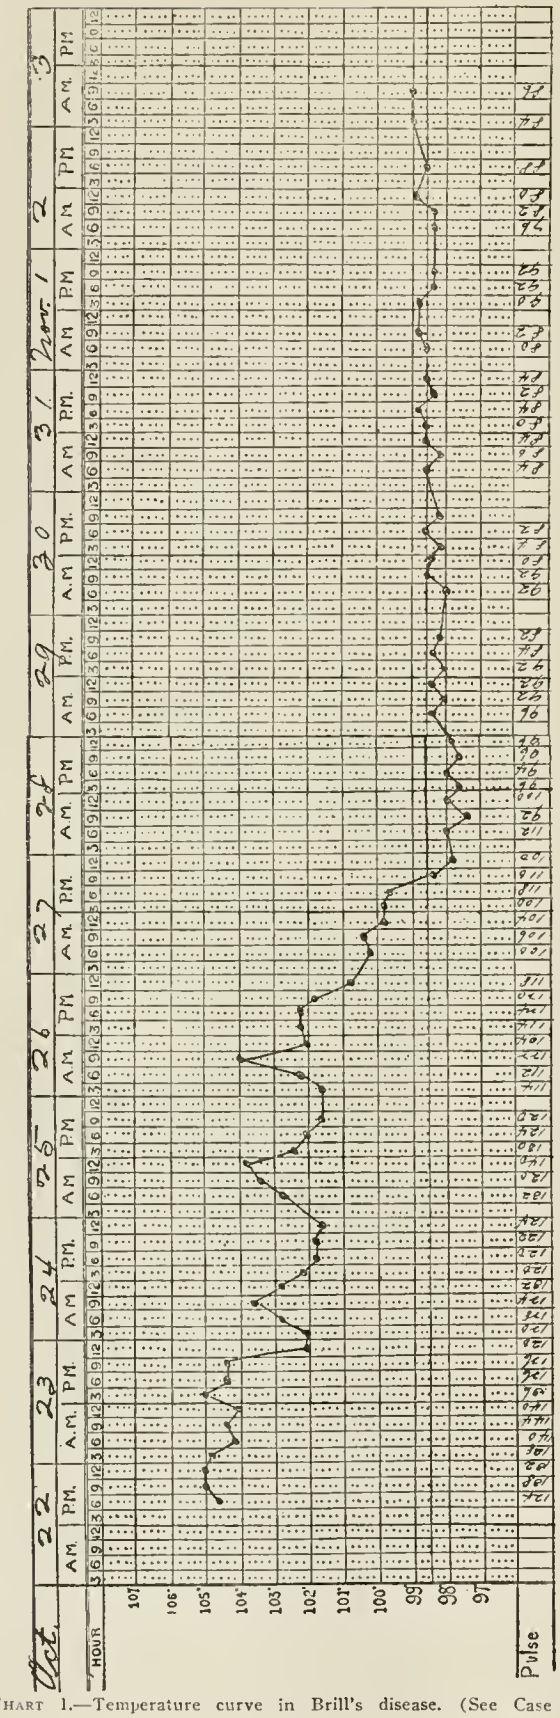

CHART I.—Temperature curve in Brill's disease. (See Case I.)

family or occupants of the same house were never attacked. Warren Coleman has, however, observed four cases from the same family and same household—cases in which Dr. Brill concurred in the diagnosis.

The following case reports are submitted with the hope of aiding in the general recognition of this interesting affection, for which we know no better name than Brill's disease:

CASE I.—A woman 29 years of age, born in Russia, was admitted on October 22, 1909, to the service of Dr. J. E. Reinthaler at Beth Israel Hospital. Married when 16 years old, she had had five children who were alive and well. The present illness began suddenly five days before admission with a chill followed by high fever. Since the onset there were severe headache, anorexia, prostration, fever and diarrhea (about six bowel movements a day). On admission the temperature was 104.6°. There was a profuse maculopapular eruption spread over the trunk and extremities with suspicious roseolæ interspersed amongst the other lesions. The patient was well nourished and well developed but greatly prostrated. The skin was hot and dry. The pharynx was congested. The pulse was not dicrotic. The spleen was not palpable. The course of the temperature curve is shown in Chart I. Five leucocyte counts averaged 10,200 with an average polymorphonuclear count of 70 per cent. The diazo reaction was positive; otherwise the urine was negative. On the 10th and 11th days of the illness the temperature dropped within 30 hours to subnormal, was subnormal for 24 hours, and then remained normal. Repeated Widal reactions were negative and a blood culture performed on the ninth day of the disease by Dr. J. J. Hertz was negative. Recovery was rapid and the patient was out of bed one week after defervescence.

CASE II.—A man 25 years of age, unmarried, a native of Russia, was admitted on May 12, 1910, to the service of Dr. A. H. Friedenberg at Beth Israel Hospital. Twelve days before admission there developed general malaise, anorexia, and constipation; these symptoms continued for nine days and then the patient took to his bed because of the development of chilliness, fever, headache, and prostration. The temperature on admission was 103.6°. The pulse was dicrotic. Though well nourished and robust, the patient was markedly apathetic and prostrated. The tongue was moist and uniformly coated. The skin was hot and dry. A profuse maculopapular eruption, hemorrhagic in areas, was scattered over the abdomen, back, chest wall and extremities. The spots were of a dull red color and not completely effaced on stretching or making pressure over the skin. In certain areas a number of spots ran together to form small patches. There were numerous lesions on the forearms and a small number on both soles. Otherwise physical examination was negative. The spleen was not palpable. The temperature remained sustained (see Chart II), never more than one degree above or below 103, until the ninth day, when it fell to normal within 36 hours and remained so. The symptoms during the febrile period were severe headache, apathy, prostration, anorexia and constipation. No new lesions appeared on the skin during the time of observation and the original crops faded rapidly at the time of defervescence. On the seventh and eighth days of the disease the headache was extreme, and there developed moderate rigidity of the neck and slight Kernig's sign. The meningismus disappeared at the time of crisis. The absolute and differential leucocyte counts were normal. The urine was negative. Repeated Widals during and after the febrile course were negative. A blood culture performed on May 16th, by Dr. J. J. Hertz, was negative. Recovery was rapid and uninterrupted.

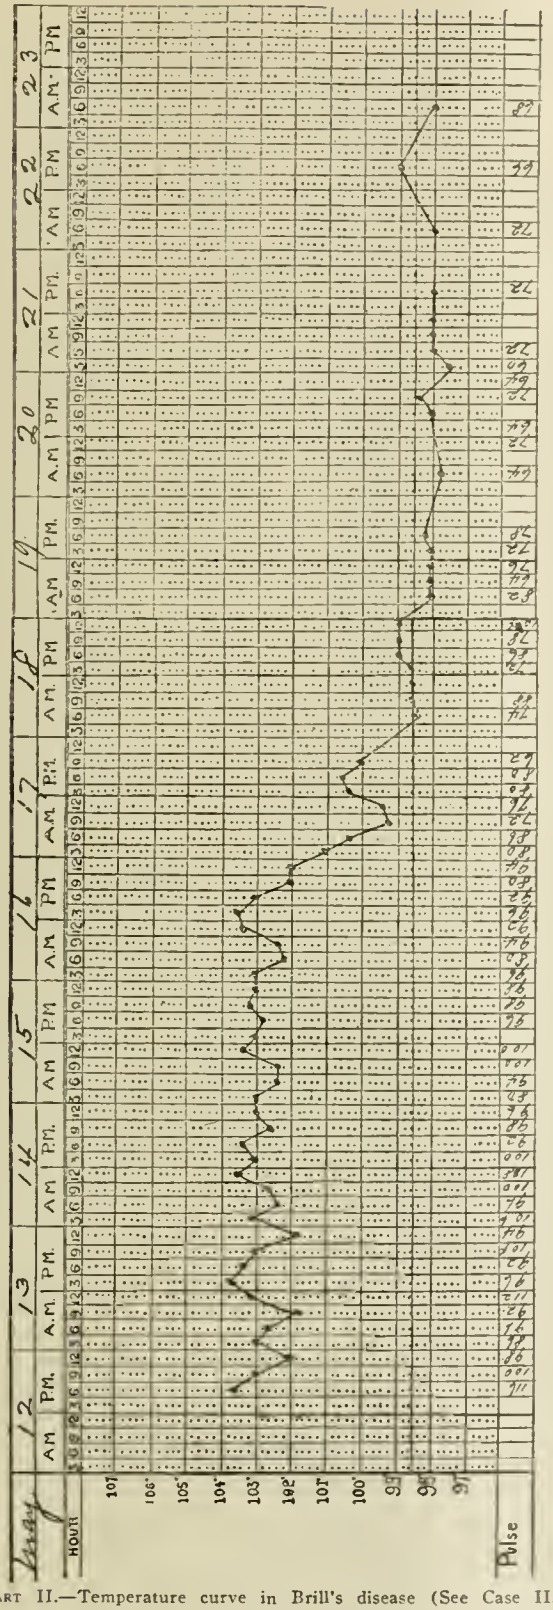

Chart II.—Temperature curve in Brill's disease (See Case II.).

Case III.—A married Russian woman 41 years of age, with six living children, was admitted on March 29, 1909, to the service of Dr. A. H. Friedenberg at Beth Israel Hospital. Having had no serious illness previously, the present one began ten days before admission with chilliness, fever, severe headache, general pains and prostration. There had been general malaise for some days previous to this onset. On admission the temperature was 105°, the pulse 110. The tongue was dry and red, the throat was congested. There was slight rigidity of the neck, no Kernig's sign. A profuse maculopapular eruption was scattered over the trunk, neck and extremities. The spleen was palpably enlarged. The patient was somnolent, markedly prostrated and complained of severe headache. Otherwise physical examination was negative. The temperature remained elevated above 102° till the thirteenth day of the illness, when it dropped to normal within 60 hours and thereafter remained normal. A blood culture performed on the thirteenth day of the disease was negative. Frequently repeated Widals continued after defervescence were negative. As the temperature dropped the headache disappeared, the mental condition became brighter, the appetite returned and the patient was up and about six days after defervescence.

Relation Between Alcoholism and the Ability to Nurse, Tuberculosis, and Caries.—J. H. Greeff has investigated a large number of families in respect to this subject and he says that the prospect of a nursing daughter is best if the mother has been able to nurse. Whether the father has been an occasional hard drinker or a steady drinker seems to make but little difference. The fact that he drinks at all, however, seems to have a slight influence in preventing the daughters ability to nurse. There is also apparently a relation between alcoholism on the part of the father and grandfather in causing pulmonary tuberculosis and caries in the descendants.—*Deutsche medizinische Wochenschrift.*

STUDIES IN AMEBIASIS, WITH A REPORT OF FORTY-TWO CASES.*

By WILLIAM ALLEN, A.B., M.D.,

PROFESSOR OF PARASITOLOGY, NORTH CAROLINA MEDICAL COLLEGE, CHARLOTTE, N. C.

I WISH to discuss, briefly, some of the points in the problem of amebiasis, on which there is urgent need for more light. Some idea of the importance of this problem may be gained from the fact that out of sixty-five cases of intestinal parasitism, encountered by the writer within the last two years, forty-two have been cases of amebiasis.

In the first place, do the amebæ found in the soil and instanding fresh water supplies become pathogenic when taken into the body? From the occurrence of an outbreak of nine cases within two weeks in five families, all using the same ameba-infested well, which, recently, came under our observation,[1] and from the work of Captains Nichols and Siler[2] of the U. S. Army Medical Corps, in relation to pellagra at the Peoria State Hospital, it would seem that the amebæ commonly found in water can, and do, produce amebiasis.

Is the same thing true of the amebæ found in the soil? Out of five specimens of earth, taken from vegetable gardens in different parts of Charlotte, two showed amebæ. These were easily grown out in a 1 per cent. alkaline bouillon, although, so far, we have not been able to grow amebæ from infested stools or water. If amebæ from the soil can cause amebiasis, would it not be well to lay more stress on the washing or cooking of raw vegetables in the South, in view of the prevalence of this parasite? Why should tropical fruit be looked on with suspicion? Fruit is acid and amebæ have refused to grow for us on fruit or on any other acid medium. Is there a specific pathogenic ameba, the *Entamœba histolytica*, as Schaudinn[3] claimed? If so, what becomes of it outside of the body? Aside from the cases due to water, or soil, or contact infestion,[4] it would seem that, if the pathogenic ameba lies encysted and does not multiply outside the body, then we must assume an enormous amount of pollution of our food or drink with human excrement to account for the large per cent. of remaining cases. Even in the Carolinas, where soil pollution is all but universal, it seems improbable that most of our cases have become infested from food or drink contaminated with human feces. If the *Entamœba histolytica* does multiply and thrive outside of the human body, where and under what conditions, and how can it be differentiated from other amebæ occurring in nature? We are sorely in need of further knowledge concerning the ameba family, as without such knowledge prophylaxis is impossible. In the second place, it has also been stated by Schaudinn,[5] that amebæ occur in normal stools—meaning normal individuals. Admitting that this condition may exist temporarily at times, it has never been our good fortune to find that those people who constantly harbor amebæ unknowingly and without symptoms, are normal. In a recent series of differential blood counts on 100 supposedly normal individuals, a certain number (about 3 per cent.) were found to be harboring amebæ unsuspectingly. After careful investigation, we could not consider either these individuals or their stools normal. They were not able to produce a formed stool except during the day or so following a purge or following three or four spontaneous movements in a single day, which were invariably attributed to some error in diet. Their stools are alkaline, and they generally have a moderate esinophilia and are to some degree neurasthenic. From our present limited experience we are obliged to hold to the opinion of Musgrave and Clegg,[6] as against that of Schaudinn, that all amebæ constantly found in the stools are pathogenic and that everyone constantly harboring amebæ will sooner or later show unmistakable signs of amebiasis.

In reviewing the forty-two cases seen by us since April, 1908, we are struck by the following facts: First, that 12 have died, a fatality of 28 per cent. Second, that 16 of the 42 cases gave no history of frequency of bowel movements. This point was long ago brought out by Futcher,[7] but has not been sufficiently emphasized. These are the cases that are particularly liable to be passed on with a blanket diagnosis of neurasthenia.[8] Third, that 10 out of 16 cases had bald tongue, which we believe to be indistinguishable from that of pellagra. Fourth, that of 25 cases in which the hemoglobin was estimated, in 6 it was about 80 per cent., and in 19 below 80 per cent.; in 1 case the hemoglobin was below 10 per cent. Anemia seems to be as constant and as a rule as severe in amebiasis as in ankylostomiasis. Fifth, that in making a routine blood examination the presence of a moderate eosinophilia has repeatedly directed our attention to the intestinal tract, with the result that amebæ were found in the stools. At present we cannot agree with the best authorities, who, without exception, we believe, state that uncomplicated amebiasis does not show eosinophilia. Out of 29 cases in which differential counts were made, 14 showed eosinophilia of 5 per cent. or over, 2 between 4 per cent and 5 per cent., and 11 below 4 per cent.; one case complicated by *Ascaris lumbricoides* showed 17 per cent., and 1 case complicated by hook worms showed 5.2 per cent. In 1 case of combined amebiasis and ankylostomiasis the removal of the hook worms caused the eosinophilia to drop from 10 per cent. to 5 per cent. in 8 months. This leads us to believe that a moderate increase in the eosinophiles will be found in over 50 per cent. of cases, if not less than 500 white cells be counted. Sixth, that since amebæ can be grown in alkaline bouillon, the reaction of amebic stools may prove of interest. In 14 cases in which this point was noted, litmus paper showed 10 alkaline, 2 neutral, and 2 acid; unfortunately these acid stools were not tested with phenolphthalein. In this connection it is interesting to note that out of 35 cases, *Trichomonas vaginalis* was present in 19; this observation leads us to disagree with the statement of Broun,[9] that this organism "lives—not in normal mucous, but in mucous of acid reaction." The presence of monads in such a large per cent. of cases of amebiasis, we believe, calls for further investigation as we have not found them in anything like so large a per cent. in any other class of cases.

In three cases a diagnosis of abscess of the liver was made; two of these cases left the hospital within twenty-four hours and were lost sight of; the third case showed abscess at autopsy.[10]

Because of the wide variance in character of the many substances recommended for the destruction of amebæ, when applied as colonic irrigations, we determined to try out their effects as observed under the microscope, on amebæ in stools and from

*Read at twelfth annual session of the Tri-State Medical Association of the Carolinas and Virginia at Richmond, Va., Feb. 15-17, 1910.

cultures. Only some preliminary work in this line can be reported at this time. Reagents causing at least a temporary loss of motion in amebæ may be classified under three heads—protoplasmic poisons, acids, and dessicating agents. The action of quinine sulphate up to 1 to 1000 and that of powdered ipecac in solution with sodium bicarbonate, was slow and uncertain. After treatment with ipecac, locomotion reappeared in forty-five minutes. The action of citric acid (lemon juice and lime juice) was also slow and uncertain. The action of coal oil (recommended by Hanes of Louisville [11] last year) we were unable to determine, as it will not mix either with stools or with bouillon. Rochelle salts in 5 per cent. solution stopped motility sooner than any of the preceding reagents, due partly to its acidity, and partly to its dessicating effect. Magnesium sulphate in strong solution not only instantly stops all motion on the part of the amebæ, but dessicates and shrivels it beyond recognition; whether or not it can be resuscitated again with normal salt solution, we have been unable to determine. We irrigated a number of cases daily with a gallon of 8 per cent. magnesium sulphate, but were unable to see that this was of any special advantage. On bathing amebæ in accurately prepared solutions of this reagent, it was found that motility finally ceased only in about 25 per cent. to 30 per cent. solutions, and that even considerably stronger solutions were required for instantaneous dessication. Magnesium sulphate does not irritate the bowel, but whether or not strong enough solutions can be introduced to destroy the ameba without injuring the mucous membrane, remains to be seen. We are unable to say that a heavy solution is superior to normal salt solution as a mechanical remover of the organism. But whatever the effect produced on the amebæ in the lumen of the bowel, it has been only too evident that those within the intestinal wall have not been permanently damaged.

We have not been entirely successful in using magnesium sulphate to produce stools for the purpose of diagnosis, as recommended to us by Dr. Walter A. Glines of Colon Hospital. At times the amebæ are rendered sluggish or even motionless. It would seem that a watery purge with some drug that has no direct action on the organism would be better.

In consideration of the high praise given ipecac in the treatment of amebiasis by Sir Patrick Manson,[12] we gave from 30 to 60 grains daily for two weeks in 8 cases. Ipecac may be given rubbed up with mutton suet, in capsules, in lemon juice an hour after meals, generally without difficulty, or it may be given coated with salol. Except that it sometimes sets up diarrhea, it has not seemed to influence the clinical course of these cases. If given in larger doses, less frequently, over a longer period of time, possibly its action may be more beneficial.

Of the 12 fatal cases, 7 died within 10 days after first being seen by us; 3 refused treatment and died in from 3 weeks to 4 months; of the 2 fatal cases that took treatment, 1 was complicated by an infected ovarian dermoid cyst and died in 3 weeks; the other improved sufficiently to later pass through an attack of pellagra, but after 9 months died of nephritis. Of the 30 cases still living, we had an opportunity in 20 to give a fair trial to medical measures as we understand them—that is, rest in bed for two weeks at least, on liquid or light diet without residue, with daily colonic irrigations, with or without cathartics or ipecac by mouth. In every case there was prompt relief from distressing symptoms. In two cases diarrhea returned within two weeks; in 18 cases the relief continued for from 3 to 15 months. Not a single case has gained materially in weight, and we are confident that not a single permanent cure has been effected. Hence, we are forced to conclude either, that our treatment has been radically defective, or that medical treatment of amebiasis is only palliative and can hold out no hope of a permanent cure.

THE CARE OF THE MAMMARY GLANDS, BEFORE, DURING, AND AFTER THE PUERPERIUM.

BY J. H. TEBBETTS, M.D.

HOLLISTER, CAL.

IT has seemed to the writer that the method of compression and moderately tight bandaging is of very great value in all forms of irritation or inflammation of the mammary gland occurring before and after labor. It has been our custom for several years to avoid massage, the use of the breast-pump, and even the pressure of the patient's clothing, whenever the breasts are sore and tender, from distention or inflammation. Before labor, we avoid all applications to the nipple, and all so-called drawing out of the depressed or flat nipple if in the least degree painful to the patient.

After labor, as soon as the second day, the entire mammary glands are covered with a rather thick layer of clean, choice cotton batting from the dry-goods store. This is preferable to absorbent cotton, being more elastic and compressible. The night-dress is then smoothed and arranged neatly, then a broad bandage is passed around the chest, outside of everything, and pinned moderately tight, which, being on the outside, can be kept free from wrinkles and in its proper position. When the babe is to be applied to the breast, but one side is uncovered, the nipple bathed with boric acid solution after nursing, and the cotton and bandage rearranged as before. As a result, we almost never see a caked breast, fissured nipples, or mastitis in its various forms, possibly ending in prolonged suppuration. In a normal case, the cotton is applied in gradually decreasing thickness after the fifth day, until by the eighth day none is applied. The bandage, however, is continued until the patient is dressed in her usual clothing.

Should we be called on to advise treatment for any of the several pathological conditions of the mammary glands, our advice is as follows:

Sore nipples.—Examine for erosions, fissures, and probable infection. Apply sterilized castor oil, or an ointment of bismuth subcarbonate, 5i to 5i of sterilized petrolatum, after cleansing well with 2 per cent. lysol solution, or a saturated solution of boric acid, then do up both glands in cotton batting, and bandage. Nursing from a sore breast is forbidden for twenty-four hours, then it is allowed if painless. If still painful, cover as before for another twenty-four hours, or longer, until all soreness has ceased, and nursing is painless. The other breast is given to the babe at regular two-hour intervals, until empty, when, if still hungry, the babe is given a small bottle of modified cow's milk, and fed until satisfied, always, however, giving the breast first.

No breast under compression and bandage, will ever become over-distended under any circumstances, but will drain itself constantly of all overplus. Moreover the gland, if thus let alone, will not secrete milk over freely.

Sore nipples most frequently occur during the very early days of lactation, when the breast is seemingly full of milk, but is really swollen and congested instead, the milk content being often small, or even absent. A strong babe, tugging and suckling under such circumstances, will often cause eroded and chafed nipples. As in other forms of active and chronic inflammation, absolute rest and temporary loss of function are demanded, and secured, readily and painlessly by our compression and snug bandage.

Congestion and engorgement,"caked breast," so-called.—This condition is often seen on the third day after labor, and was formerly treated by us with hot stupes, gentle digittal massage, etc. We now know that this condition is practically a normal one, and is caused by the hyperemia of the lobules and lactiferous ducts, nearly closing the ampullæ, so as to leave but little space for the secreted milk. This hyperemic condition demands rest, compression, and the bandage, instead of massage, heat, or the breast pump, and if rightly treated, the swelling will subside in a few hours, the milk begin to collect in the ampullæ, and soon will flow out, if there is distention, escaping gradually into the cotton, just rapidly enough to keep the breast soft and painless, allowing the patient a quiet, restful night.

Mastitis.—We have never seen this occur where proper preventive treatment by our compression and bandage has been employed. Should we see a case in its early stages, we examine for infection and try to find its source, which is nearly always external. If pus be present, it should at once be evacuated, the breast washed in lysol 2 per cent. solution, the incision covered with loose gauze, then covered with cotton batting 6 inches thick, and 24 by 12 inches in size, and a tight bandage applied. Change dressings twice daily. A rapid and uneventful recovery will almost invariably result. Nursing will of course be absolutely prohibited while the breast is inflamed. Even if a week or more out of commission, the breast will again secrete milk abundantly as soon as normal. Meanwhile, the child may be nursed from the sound breast, supplemented by a bottle of modified cow's milk, always given immediately after the nursed breast is nearly empty. It may possibly be necessary to feed the child for several days entirely on the bottle, letting both the breasts rest, but they will nearly always resume their function as soon as again normal.

In drying up the breasts, in weaning, no other method is now employed by us except the same compression with cotton and bandaging. Once a day this may be removed, and new cotton applied. No rubbing, massage, breast pump, belladonna, or camphor is ever required. The breasts take care of themselves, and in two or three days have become flaccid and free from milk secretion, and that, too, without distention, or pain. In a week the cotton may be removed, and the function of the glands will have ceased.

We claim for this method simplicity, and practically a perfect result, in nearly every complication or pathological condition of the mammary glands when present, and a perfect prophylaxis in normal cases, when carried out as a routine treatment. It has been many years since we have used the breast pump, prescribed liniments, or employed massage in any of these cases, and we believe their use may become practically obsolete in all cases seen early, and under intelligent nursing.

PROCTITIS AS A CAUSE OF HEMORRHOIDS,

WITH SUGGESTIONS FOR MEDICAL TREATMENT.*

By MARTIN L. BODKIN, M.D.,

BROOKLYN, NEW YORK.

LECTURER ON RECTAL DISEASES, BROOKLYN POST-GRADUATE MEDICAL SCHOOL; RECTAL SURGEON, WILLIAMSBURGH HOSPITAL; ASSOCIATE SURGEON, ST. MARY'S HOSPITAL.

In my early experience attention was drawn to the coexistence of a proctitis when examining hemorrhoidal patients. Curiosity prompted me to examine all of the hemorrhoidal subjects presented to me in private as well as in dispensary and hospital practice, and to my surprise I found that a catarrhal inflammation existed in every instance.

Cases of acute catarrhal proctitis have demonstrated that as the inflammation subsides the edematous hemorrhoids also become reduced and finally completely disappear. When acute catarrhal proctitis persists in the form of a low grade or subacute inflammation, then the hemorrhoids exist until the inflammation entirely disappears. Hemorrhoids due to this cause are most satisfactorily treated.

Should this most common course of the disease take place, or if the beginning was not so acute as to justify its being classified as an attack of proctitis, but sufficient irritability exists to inflame the membrane, then according to the following theory a gradual hypertrophy of the mucous membrane takes place with a separation and sliding down of a small portion inside of the loose cuff of mucous membrane at some point within the grasp of the sphincter muscles. The mere weight of the redundant membrane is sufficient to initiate the loosening and the subsequent formation of a hemorrhoid. This small hemorrhoid is quickly filled by the serous exudate from the vessels lying within its submucous tissue. The upright superficial vessels of the lower rectum are acted upon by the descending fecal mass in a reverse direction to the normal current and tend to swell up. These vessels, temporarily distorted from their engorged condition, tear more of the mucosa and submucosa from the surrounding tissue, and they are lifted gradually by the accumulating serum away from the muscular layer.

*Read before Long Island Medical Society, March 1, 1910.

This condition existing for months or years occasionally becomes edematous from irritation or traumatism in the form of hard fecal movements. The parts are constantly in a state of hyperemia. This increased blood supply causes hypertrophy of the blood vessels and connective tissue; finally a well-organized hypertrophic mass becomes a recognized hemorrhoid.

Hemorrhoids existing in the presence of an atrophic cartarrhal proctitis are in my judgment secondary to this hypertrophic inflammation, and their presence is due simply to the serum forced within the meshes of the connective tissue of the submucosa, which, with the blood vessels, remains hypertrophied, the atrophy only affecting the mucous membrane.

The primary etiological factor in the causation of hemorrhoids from this point of view is most probably a digestive disturbance, either in the stomach or intestine with the fermentative excreta acting as an irritant, which brings about the inflammation of the mucous membrane. Indigestion in one or another form seems always associated with hemorrhoids.

We may find other well-known and positive causes of hemorrhoids, such as glandular disturbances, meaning the liver, kidneys, or pancreas; or heart lesions, traumatisms, pressure due to pregnancy and to tumors, malignant disease of the rectum or adjacent organs and to specific forms of catarrhal proctitis, as tuberculosis, syphilis, etc. These causes are not common. The large number of cases presented for treatment positively refute the assertion that every one suffering from hemorrhoids also suffers from one of these serious diseases.

The treatment of this form of hemorrhoids due to simple catarrhal proctitis by medicines or local applications begins with correction of the digestive disturbance, arresting fermentation and overacidity with the alkalies and intestinal antiseptics, relieving the liver by restricting the carbohydrates, contraindicating the use of alcohol, tobacco, coffee, and tea if possible, guarding against the overindulgence in rich food, and encouraging exercise or rest as indicated. Constipation should be treated with cascara, olive oil, or the injection of a pint of cold water before breakfast; diarrhea with castor oil and bismuth.

Locally, in the acute form wash out the rectum each day for a week with a gallon or more of plain warm water at a temperature of 110° F., or with any of the mild solutions used for the nose or throat. The irrigation should extend over a period of not less than fifteen minutes.

In the subacute and chronic forms begin with the irrigations for a week, then instead inject an ounce or two of a weak solution of one of the silver salts every second or third day, or instead of the silver salts an application of some combination of the following remedies, either in the form of a suppository or as an ointment by means of the hard rubber pile-pipe; ichthyol and iodoform for their alterative and stimulating action, tannic acid, adrenalin, and hamamelis for their astringency, and as sedatives belladonna or stramonium. There is no doubt that these drugs do aid in the relief or cure of hemorrhoids by their action upon the inflamed mucous membrane.

In very weak subjects apparently exhausted from the effects of the catarrhal disease existing also in the upper bowel, associated with profound digestive disturbances, autointoxication and its concomitant symptoms of depression, every effort should be made to improve the general tone of the body and of the eliminating organs, in addition to the above suggestions.

290 Clinton Avenue.

A CASE OF DEXTROCARDIA.*

By GEO. RICHTER, M.D.,

AND

CHAS. H. WEINSBERG, M.D.,

ST. LOUIS.

The following history of a case of dextrocardia (situs viscerum inversus partialis), incomplete as it is, may prove interesting on account of the great rarity of the condition and the remarkable course of the terminal illness.

Miss L. E. C., fourteen and a half years old, had always been an apparently healthy, though a very sensitive and retiring, child. Let us mention right here that the girl, as well as her parents, knew of her anomaly—dextrocardia—but up to now she had not been examined by any physician.

On November 3, 1909 she became ill rather suddenly, as also a younger brother, with typical symptoms of influenza, cough, fever, and pains in all the muscles of limbs and trunk which rendered her practically motionless. About November 9 she, as well as her brother (who, however exhibited no symptoms from part of the locomotor apparatus), had recovered from the catarrhal affection, were free from fever, and enjoyed returning health. Her appetite and sleep were excellent. But the pulse remained high, 120 per minute, and the muscular pains persisted. She could not sit up nor even turn over in bed. The condition reminded one somewhat of trichinosis, but there was no edema. The girl had not menstruated yet, but she suffered from a profuse leucorrhea. Iron preparations were given and menses established the first days of December. No untoward symptoms supervened, the pulse became less frequent, there was no cough, the apices of the lungs seemed to be free from disease.

January 4, 1910 she again became ill with a persistent cough, labored respiration, high pulse rate, great prostration, and sharp pains in the right side of the thorax. Examination of her body was rendered very difficult because it was impossible to change her position owing to the pains she suffered. She lay flat on her back, settled deep in the cushions. Respiration 60, pulse 130 per minute, temperature 99.8°. Her chest exhibited a typical pectus carinatum, it was symmetrical with no other local bulging. A very much pronounced apex-beat was visible about ½ inch to the right of and above the right nipple in the third intercostal space. Auscultation evidenced normal heart sounds there. The whole of the left side of the chest on percussion and auscultation proved to contain nothing but normal lung tissue; there was no dullness whatever over the usual site of the heart, but from here downward resonance due to the stomach was found. On the right side of the chest, at the apex of the lung and down to the third rib, we heard on percussion a tympanitic somewhat muffled sound. Here began a dullness corresponding to the plainly visible impetus of the heart. This dullness continued to the lower border of the chest, where we could outline a

*Read before the Verein Deutscher Aerzte of St. Louis, January 21, 1910.

dullness due to the liver, which we found at its normal place and of normal size, not palpable. Palpation and percussion of the abdomen showed normal conditions. To the right of the heart in the right half of the thorax there was complete dullness and also pain on touch. An almost incessant hacking cough produced but little frothy sputum. This contained few leucocytes, no eosinophiles, very few erythrocytes, some epithelial cells, an abundance of staphylococci and streptococci, no pneumococci, and a small number of tubercle bacilli.

January 6, A. M., temperature 101° in the axilla. A dose of whiskey stimulated the heart action and lowered the pulse rate. With local anesthesia (cocain) an aspirator needle was inserted in the right middle axillary line, between the seventh and eighth ribs, and about 4 ounces of a bloody serum withdrawn, which clotted quickly. The patient, who felt no pain from the aspiration, was at once greatly relieved in every respect. Dr. J. P. Nemours, who kindly assisted in the operation, also satisfied himself of the presence of dextrocardia with partial situs inversus.

At 9 P. M. the same day the temperature was 103° in the axilla, the pulse 150, and the breathing labored. The succeeding night she became delirious and restless. The eyes were half open in her sleep.

On January 7 the pulse was 120, the temperature 101°. The patient was much weaker. Stool and urine were discharged involuntarily. She took nothing but an occasional sip of champagne. The apex beat was 2 inches to the right of the right border of the sternum, and felt in the fourth and fifth intercostal spaces. The left lung was normal. There was no expectoration. The abdomen was normal. The stomach was in the left, the liver in the right hypogastric region. Arrangements were being made to have a skiagraph taken, but on the same afternoon, while the nurse changed the bed sheeting, the patient died suddenly. Permission for autopsy was not granted, and the *x*-ray specialist stated that skiagraphs taken of dead bodies are never satisfactory.

This was without doubt a case of dextrocardia with normal situs of the abdominal viscera. The fact that the pleuritic effusion appeared on the same —right—side and did not displace or crowd the heart toward the left, but rather upward, seems to indicate that there must have been further anomalies within the mediastinum, possibly a persisting enlarged thymus which would also account for the bulging of the sternum (pectus carinatum) and the sudden death. At any rate there had been no rhachitis nor any symptom of aneurysm. The diagnosis of a pleuritic and not a pericarditic effusion was verified by the aspiration. The healthy condition of the abdomen and the qualities of the left side of the chest exclude all other disturbances as possible causes of the dextro-position of the heart. This condition was congenital. We should add that there was no marked cyanosis at any time, nor anything else to indicate the existence of a diseased heart. The girl was right-handed. None of the other members of the family exhibit any congenital anomalies.

The last disease was apparently a relapse of influenza with an acute tuberculosis and a persisting polymyositis universalis, due to the influenza. Polymyositis partialis accompanying influenza, though of a milder type, is not infrequent here at present. It is often mistaken for either rheumatism, cellulitis, or erysipelas. Usually, it is characterized by a pronounced edema setting in immediately after the acute stage and the fever begins to subside. No edema, however, occurred in this case.

We have searched the literature in vain for parallel cases. Those reported* by Lochte in *Ziegler's Beitrœgen* 16, 1894, by Koller in *Virchow's Archive* 156, 1899, and by Kurt Schelenz, Inaug. Diss. 1909, differ from ours in many essential points. Dextrocardia is generally accompanied by other malformations which we could not discover in this case. Though no autopsy was held, we believe that our findings are conclusive proof, being based on repeated careful physical examination by three physicians of many years' experience, and also upon the personal observation of the patient and her parents.

*By George Jackson Fisher in the "Reference Handbook of the Medical Sciences," VII, 241, 1889.

The Thoracic Index in Pulmonary Tuberculosis.—Washburn says that the normal male thoracic index is about 70, and that an index very much above that is an abnormality, either inherited or acquired; that the normal female thoracic index is slightly lower than that of the male, and is therefore an evidence of a higher stage of physical development, tending to lessen susceptibility to pulmonary disease; that the great majority of patients suffering from pulmonary tuberculosis present a thoracic index in excess of the normal, instead of the contrary, and this is a mark of degeneracy, increasing liability to tuberculous infection; and that patients in eleemosynary institutions, in general, have thoracic indices higher than patients in private practice, a finding which might be expected from the fact that degenerates of all kinds are found in such institutions.—*The Wisconsin Medical Journal.*

Double Infection with Measles and Scarlatina.—Brudzinski says that a perfect knowledge of the true picture of a double infection with measles and scarlatina is of the greatest importance in hospitals for children, at the beginning of the eruption as well as during the desquamation. The diagnosis of the infection will permit of isolation from the rest of the patients before infection has occurred. It is of equal importance in the schools. Children who have measles remain under observation but a short time, while scarlatina is infectious for a much greater period of time. Koplik's sign is of value when scarlatina appears first, and is complicated with a measles occurring during desquamation. Cases of late infection are most frequent. When the two eruptions appear at the same time the effect is the most severe, and complication most frequent. The two eruptions appear in different parts of the body, the measles coming out on the face and thorax and the scarlatina on the trunk and limbs. The measles eruption may disappear before that of scarlatina. The desquamation is more intense than when the diseases are separate. On the face is seen a typical measles desquamation, while the hands and feet show the large plaques of scarlatina. The desquamation of measles is prolonged beyond the usual time. —*Archives de Médecine des Enfants.*

Cardiovascular Apparatus in Nephritis of Childhood.—P. Nobécourt and Roger Voisin give results of observations of twelve children, from three to fifteen years of age, from the *Hôpital des Enfants Malades*, Paris. Of these nine had acute nephritis, in several cases after scarlatina. In five cases cure resulted; one died of pneumococcic nephritis; three cases became subacute or chronic. The histories are given. The points of especial interest have reference to the cardiovascular changes observed. The most important changes in arterial pressure are seen in acute attacks of nephritis. There is often an increase in arterial tension, more or less enduring. This disappears when the nephritis is cured. In long cases, and when the disease becomes chronic, the pressure falls to normal again. In fatal acute nephritis dilatation of the heart may occur; when the disease lasts some time the heart remains large or returns to normal. In chronic nephritis the heart is large only in old cases or acute attacks; here enlargement is due to dilatation. Galop rhythm is rare and passing. The size of the liver is often increased. The mechanism is explained by the increase of water retained, which increases weight by edema, and thus causes increased arterial pressure; the increased work of the heart causes dilatation; the liver enlarges in its turn. Increase of pressure and dilatation are not necessarily of bad prognosis; a more insidious form is often more tenacious. —*Archives de Médecine des Enfants.*

MEDICAL RECORD.

New York, June 25, 1910.

THE REPORT OF THE CARNEGIE FOUNDATION ON MEDICAL EDUCATION.

THE most recent publication, entitled "Bulletin Number Four," of the Carnegie Foundation for the Advancement of Teaching, treating of medical education in the United States, makes what Horace Greeley used to call "mighty interestin' readin'." Whether it is also entertaining depends largely upon the direction of the reader's sympathies and college associations. Very naturally, those who are connected directly or indirectly with the schools so fiercely and contemptuously flayed by Mr. Flexner, the writer of the report, resent his attack bitterly; while those connected with the institutions receiving his faint praise—there is but one perfect school in the eyes of this investigator—whatever they think, say little.

The report professes to be based on a thorough and most painstaking personal investigation of every medical school in this country and Canada, made by Mr. Abraham Flexner, a professional critic of educators, or student of systems of education. In order to correct a very current misconception, we may say, in parenthesis, that this is not Dr. Simon Flexner of the Rockefeller Institute, but his brother. The doctor has troubles of his own with the antis of various ilks, and should not lose professional support through being made to answer for the sins of his brother. Neither, may we add, should the brother be judged by the essay which the president of the Foundation contributes by way of introduction to the report.

As a result of this investigation Mr. Flexner concludes that the country is suffering from a great plethora of medical schools—a fact which medical men have well known and deplored these many years; that many of the medical schools have not a sufficiently high standard either of admission or of graduation—another fact long well known; and that the facilities for teaching, in the way of apparatus, subjects for dissection, etc., are lacking in a number of schools—likewise a matter of common knowledge. What the writer of the report does not seem to have discovered is that all these schools, with the exception of a very small and practically negligible number, are in process of betterment, and that several associations of medical men and medical educators are working constantly to encourage and force the poorer schools to raise their standards and improve their teaching methods. When one realizes what the best of the medical schools were twenty-five or thirty years ago, and what tremendous progress has been made during the past twenty, and especially the past ten years, and when one remembers that all this uplift has come from within, without the help of any outside "Foundation," the work of Mr. Flexner seems somewhat a waste of effort and a needless expenditure of Mr. Carnegie's hard-earned money. All reforms, worthy of the name and lasting, come from within, and the interference of outsiders serves only to bewilder and irritate. The facts gathered and tabulated in this Bulletin of the Carnegie Foundation will perhaps be useful for reference by the real reformers, and had nothing yet been attempted or accomplished in the way of raising standards, the comments and admonitions of these self-appointed critics might have been useful as a goad. As it is, they will be very properly resented as uncalled for. The writers of the Bulletin are unfair in that they ignore what has already been accomplished and are silent as to the agencies at work in raising the standard of medical education. Whether this omission of a fact which, if properly presented, would prove the work of the Foundation to have been one of supererogation, was intentional or whether it is only evidence of a superficial and one-sided investigation, we do not know.

ANTISTREPTOCOCCUS THERAPY IN SCARLET FEVER.

THOUGH the etiology of scarlet fever is still an unsolved problem, there is but little doubt that in the course and prognosis of the disease the *Streptococcus pyogenes* plays a part of no mean proportions. Eight years ago Baginski called attention to the fact that this organism could be isolated from the blood at autopsy in a large proportion of all fatal cases of scarlet fever. The hope at first expressed that this would lead to the demonstration of the etiology of the disease, has unfortunately not been fulfilled, and in consequence, the antistreptococcus treatment has not been received with especial enthusiasm.

During the past year or two, however, Jochmann and Michaelis have made a careful study of a large number of cases of the disease and the effects of various forms of specific antistreptococcic treatment upon its course and outcome, the report of their work being published in the *Berliner klinische Wochenschrift* for May 16, 1910. While admitting that the streptococcus is not the cause of the disease, and that in the malignant rapidly fatal cases, it plays no part whatever, they contend that in the severe anginose forms of scarlatina it is practically constantly present as a secondary infection, and in such cases is more responsible for the fatal outcome than is the scarlatina virus itself. Having picked from 400 cases of scarlet fever, 62 in which the prognosis appeared to be especially bad owing to the severity of the infection, the authors began early with the specific treatment. In a few cases a vaccine, made according to Wright's technique, was used alone in

the hope of increasing the opsonic index sufficiently to protect against the secondary infection when it should occur. In a few others an antistreptococcus serum, prepared by inoculating horses with bouillon cultures, was used. In the majority of the cases, however, the two methods were combined, both the vaccine and the serum being administered.

From this procedure results were obtained which the authors considered more than justified the experiment. Of the sixty-two cases treated, in all of which the prognosis was considered to be very bad or hopeless at the time of inoculation, but twenty-four died. In ten of them the death was not due to the streptococcus, as at autopsy staphylococcemia, pneumococcemia, or diphtheria was demonstrated. Of the other fourteen, most of them first came under observation when late in the disease. Of the cases which recovered, in 28 the temperature fell by lysis, in 4 by crisis, and in 6 it was not influenced by the injection. In nearly all of the cases marked improvement in the general condition was noted immediately or shortly after the inoculation. The sensorium cleared; the appetite improved; the pulse and respiration strengthened; and the throat became more clean. Even more striking was the freedom from complication in the cases which received the specific treatment. In the entire series there developed not a case of nephritis among the cases which recovered, and in the fatal cases but faint traces of albumin were found, so slight as to be ascribable to the general septic condition of the patient.

The goal to be sought in the fight against scarlet fever, a specific serum against the scarlatina virus, has not yet been gained, and probably will not until more is known of the etiology of the disease. If, however, this theory of Jochmann and Michealis that the fatalities are due to a secondary infection with the streptococcus, is correct, and their observations point strongly to this being the case, their suggestions of fighting against the streptococcus even before it has made its appearance is thoroughly rational. The results of their careful study would suggest that it is as valuable in practice as it is logical in theory.

Alcoholism and Offspring.

An exceedingly interesting and, so far as it goes, valuable report has just been issued in England. The report is the result of an investigation which has been conducted as to the effects of the alcoholic habits of parents upon their progeny, by Miss E. M. Elderton, Galton research scholar in the University of London, and Prof. Karl Rearson. More than three thousand children were examined in Edinburgh and Manchester, half of whom were the offspring of drunkards. The conclusions reached were as follows: 1. The death rate is somewhat higher among the children of alcoholic than among the children of sober parents; more marked in the case of the mother being a drunkard than in that of the father. 2. The weight is slightly greater among the children of the sober. 3. Parental alcoholism has no marked effect upon filial health. 4. Parental alcoholism is not the source of mental defect in the offspring. 5. The relationship, if any, between parental alcoholism and filial intelligence is very slight. 6. Vision is somewhat better among children of alcoholic parents. To sum up, no marked relation was found between the intelligence, physique, or disease of offspring and parental alcoholism in any of the categories investigated. In regard to the question as to whether the children of drunkards inherit a predisposition to alcoholism no conclusion was come to. However, the investigations seemed to show in a decided manner that children do not inherit marked disabilities in consequence of the drinking habits of their parents. Of course the outcome of these investigations cannot be regarded as by any means decisive. The examination of three thousand children is on a too limited scale to warrant the passing of a final judgment, but the results of the investigation appear to point to the view that the harmfulness of alcoholism, so far as it directly affects the physical and mental health of the offspring, has been greatly exaggerated. If the children of drunken parents are brought up in the same way as the offspring of sober parents, they will be in no way inferior to them by reason of their parents' intemperance.

Operation in Pyloric Stenosis in Infants.

While probably the majority of pediatrists are still inclined to trust to medical treatment rather than surgery as a routine in cases of pyloric stenosis in infants, basing their preference upon lower mortality statistics than the operator is able to present, there is some justice in the plaint of the latter that he is rarely given a fair trial, that usually the cases have been kept from him so long that the condition is hopeless before the operation is begun, and that if all cases were referred to him at the onset of the disease, or at least as soon as the diagnosis became established, the results would be far more favorable. It takes no small courage, however, for the internist to advise an extensive, and too often fatal, abdominal operation in a child during the first few weeks of its life so long as he has a reasonable amount of hope of curing the baby by less heroic means. An infant at that time of life, in the greatly debilitated condition usually found in the disease, will stand no great amount of intra-abdominal insult, and the surgeons who are most enthusiastic over the early operation argue that the procedure should be such as can be completed in the briefest possible time. Various operations have been performed for the relief of the condition, including jejunostomy, pyloropexy, gastroenterostomy, and most common of all, stretching of the pylorus, the quickest and least dangerous, but also the least certain in the final results. In the *Berliner klinische Wochenschrift* for April 25, 1910, Weber of Dresden reports a procedure from which he has obtained favorable results. Intending, in his first case, to do the classical pyloropexy, he made his longitudinal cut in the pylorus through serosa and muscularis, but then, instead of going through the mucosa, he left this intact, completing the operation by sewing up the longitudinal cut transversely as in the classical operation. The advantages of this procedure are twofold: the lumen of the gut not being opened, there is no danger of soiling the peritoneum, and as a result of this the two layers of sutures usually required may be replaced by one only, thus valuable time being saved and a permanent cure ensured. The two cases treated by Weber by this method, as well as two of three reported

in 1908 by Dufour and Fredit, have made good recoveries. Though the number is far too small to justify conclusions, the mortality of 20 per cent. is certainly sufficiently low to warrant the operation being given further trial.

Congenital Family Cholemia, or Recurrent Family Jaundice.

Bile-pigment is a modification or a derivative of blood-pigment, accordingly, it is conceivable that yellowish or greenish discoloration of the tissues and body-fluids may result from the presence in a free state of one or the other of these pigments in the circulating blood—in other words, that jaundice may be either hepatogenous or hematogenous. It seems, further, not impossible that there may be mixed forms of the disorder. There has been described a condition of recurrent cholemia or jaundice appearing early in life, in more than one member of a family, and characterized by alterations in the blood, the spleen and the liver. Three illustrative cases were reported some time ago by F. J. Poynton in the *Lancet*, who discussed the nature of the disorder, as well as its relation to cognate affections. The patients may be yellow or merely pallid. The spleen is enlarged, the liver less constantly so. Examination of the blood discloses the existence of anemia, with a good color-index, pecilocytosis, anisocytosis with polychromatophilia, a predominance of macrocytes over microcytes, nucleated red cells, leucocytosis involving especially the uninuclear cells, myelocytes. The red corpuscles are unusually fragile, but not affected by phagocytosis. The serum exhibits no hemolytic power; in some instances specific agglutinating power, in others not; in some instances it contains bile-pigment, in others not. Poynton is inclined to the belief that the primary change in the disease resides in the blood-forming rather than in the biliary system, and that the affection represents a congenital familial defect rather than an acquired disease. He indicates certain points of relationship between the affection and paroxysmal hemoglobinuria and splenic anemia of infancy.

News of the Week.

New York State Appropriations.—The New York State appropriation bills, as signed recently by Governor Hughes, after much pruning, allow for an increase in appropriation for maintenance of hospitals for the insane for the ensuing year over the past year of $699,754. An appropriation of $175,000 for the deficiency in the maintenance of the State hospitals, which was passed by the Legislature, was rejected by the Governor. Insane hospital construction items also eliminated by Governor Hughes were as follows: Utica State Hospital, $27,500; Willard State Hospital, $55,670; Hudson River State Hospital, $155,200; Middletown State Homeopathic Hospital, $67,000; Buffalo State Hospital, $44,500; Binghamton State Hospital, $70,600; St. Lawrence State Hospital, $55,000; Rochester State Hospital, $32,400; Gowanda State Hospital, $14,000; King's Park State Hospital, $38,000; Manhattan State Hospital, $12,800; Central Islip State Hospital, $9,000. The Letchworth Village appropriation of $186,250 was accepted.

Health in the Canal Zone.—The report of the Department of Sanitation of the Isthmian Canal Commission for April shows an annual death rate per 1,000 of 13.04 as compared to 8.91 for March, 1910, and 8.57 for April, 1909. The annual average sick rate for malaria in hospitals per thousand among employees for the month was: White 220, black 56, all 97, as against white 253, black 83, all 125 for last month. No cases of smallpox, plague, or yellow fever originated on or were brought to the Isthmus during the month.

Rabies in Paris.—Reports from Paris state that that city is practically free of rabies. In 1909 there were only 13 cases reported with a registration of 185,000 dogs, whereas in 1902 there were 846 cases among 140,000 dogs. In 1900, 637 persons bitten by dogs suspected of being rabid were treated at the Pasteur Institute, whereas in 1909 only 105 were admitted. The last authentic case of human rabies in the Pasteur Institute in Paris occurred in 1905.

English Radium.—The first output of radium from the Trenwith mine, St. Ives, Cornwall, has been obtained. It consists of about 24 grains of radium and is valued at $150,000.

The Government Laboratory for the Study of Cancer.—The U. S. Senate has passed the bill recommended by President Taft appropriating $50,000 to establish a biological laboratory for the study of diseases of fish, especially cancer. The station is to be established by the United States Fish Commission.

Smallpox on Ocean Liners.—The steamships *Uranium* from Rotterdam and *Graf Waldersee* from Hamburg and Boulogne were detained at Quarantine in New York Harbor recently owing to smallpox among steerage passengers.

Health Officer Contracts Smallpox.—The health officer of Walden, Orange County, N. Y., is suffering from variola, supposed to have been contracted while on a visit recently to the immigrant quarantine station in New York City.

Mine Casualties.—The calender of the Geological Survey for 1909 gives records of 2,412 deaths in coal mines in the United States during the year, as compared to 2,450 in 1908, and 3,125 in 1907. The 1909 record does not include the toll of the Cherry mine in which 393 lost their lives. The list of nonfatal injuries for 1909 reports 7,979 such cases, an increase of 1,200 over 1908. This apparent increase is partially due to improvement in the records.

Body Weight in Cancer.—Having observed that the body weight of women suffering from cancer appears to be greatest just prior to or coincident with the first stages of the disease, Dr. E. Atlee, 4105 Spruce street, Philadelphia, is endeavoring to gather statistics upon this subject, and will be glad to receive records from physicians as to the date in relation to the diagnosis of the disease at which their cancer patients attained their maximum body weight.

The New York Academy of Medicine.—The Anniversary Meeting, to be held Thursday, November 17, 1910, will be devoted to the subject of Animal Experimentation in Medicine, with the following program: I. "The Influence of Antivivisection on the Character of its Advocates." By Dr. William W. Keen of Philadelphia. II. "Objections to Proposals of Further Legislation to Regulate Animal Experimentation." By Dr. Wm. H. Welch of Baltimore. III. "The Character of Antivivisection Literature." By Dr. W. B. Cannon of Boston.

Privacy of Hospital Records.—Supreme Court Justice Erlanger of New York in a decision recently stated that hospital employees had no right to withhold information in regard to patients taken to hospitals as the result of accidents. Such information was considered to be a public record and therefore must be open to any one wishing to see it.

Overcrowding in New York Hospitals.—A special commission of the New York State Board of Charities has investigated sixty private hospitals in the City of New York. In twelve of the institutions visited overcrowding and inadequate sanitation, ventilation, and fire-escapes were reported. The State Board of Charities has adopted resolutions which provide that no patient shall be retained at public expense in any ward of any hospital wholly or partly under private control, unless the building is fireproof or its fire protection facilities have been approved by the State Board in writing; unless the building is sanitary, and unless the wards provide at least 1,200 cubic feet of air space for each bed. In extraordinary cases the air space may be cut down to 800 feet, but only on written permission of the board.

Princeton University, at its commencement exercises held June 14, conferred the degree of Doctor of Laws upon Dr. William H. Welch, professor of pathology at Johns Hopkins University, and president of the American Medical Association.

The Cornell University Medical College held its annual commencement exercises in New York, June 15, 1910. The degree of Doctor of Medicine was conferred upon sixty-one men and seven women. The names of four of the seven women appeared on the honor rôle of the ten highest rank students for the graduating class.

Yale Medical School.—As a further step toward raising the standard of the Yale Medical School, a movement which has been going on for several years past, thirty students were "failed" in the recent examinations, and permission to take the examination over again was refused. The school is also endeavoring to raise an endowment of $2,000,000.

Hospital Terrorized.—A crowd of twenty rowdies, who had been turned out of Central Park on the evening of June 19, after attacking a number of people in the street, broke into Mount Sinai Hospital, fought in the halls, and badly frightened many of the patients.

Reorganization of the American Medical College of St. Louis.—The trustees of the American Medical College of St. Louis, at a meeting held on June 6, 1910, unanimously decided that, in the future, the college shall be conducted as a regular college of medicine. New officers were elected as follows: *Dean*, James Moores Ball, M.D.; *Treasurer*, J. J. Link, M.D.; *Secretary*, W. T. Burdick, M.D.

Died at 108.—The death occurred recently in Cincinnati of a man who was supposed to have reached the age of 108 years. He was head gardener in the estate of Congressman Nicholas Longworth and had been in the employ of the family for 90 years.

Unlicensed Physician Arrested.—Through the agency of the Medical Society of the County of New York, an illegal practitioner was arrested lately in his office in East Eighty-second street. He claimed to be "an osteopath and a phytologist," but was unable to produce any license to practise or evidence of registration.

The Connecticut State Tuberculosis Commission announces the appointment of Dr. Harry C. Clifton of Hartford as surgeon-in-chief of all the sanatoria in the State and medical director of the Hartford County institution. Dr. Richard W. Moriarty has been appointed resident physician of the latter institution.

The New Jersey State Pediatric Society will hold its first annual meeting at the Hotel Chalfonte, Atlantic City, Monday, June 27, 1910. The *President* of the society is Dr. Henry L. Coit of Newark, and the *Secretary* is Dr. Martin J. Synnott of Montclair, N. J.

The Fifth International Congress of Medical Electrology and Radiology will be held at Barcelona, Spain, September 13-18, 1910, in the amphitheatre of the Faculty of Medicine. The *President* of the congress is Dr. L. Cirera Salse, and the *General Secretary* is Dr. C. Comas Llaberia, Calle Cortes, 613, pral Barcelona.

The American Association of Medical Journal Advertisers held its fourth annual meeting in the parlors of the Jefferson Hotel, St. Louis, on June 9. The following resolution was unanimously adopted: *Resolved* that, where the business of an institution has been built up by newspaper advertising or other irregular methods, the owners or managers thereof shall not be accepted as members of this association or their advertisements permitted to appear or remain in journals containing the advertisements of members of this association until such institution has purged itself of irregularity to the satisfaction of the County Medical Society of the county in which it is located. The following officers were elected for the ensuing year: *President*, Dr. S. Grover Burnett of Kansas City, Mo.; *Vice-President*, Dr. Geo. H. Moody of San Antonio, Tex.; *Secretary*, Dr. Geo. E. Pettey of Memphis, Tenn.; *Executive Committeemen*, Dr. J. Jos. Kindred of Astoria, L. I., N. Y., and Dr. F. H. Barnes of Stamford, Conn.

Obituary Notes.—Dr. Randall Doyle Bibber of Bath, Me., died at his home, June 9, 1910, aged 64 years. He was a graduate of the Bowdoin Medical School in 1871. He was a member of the Sagadahoc County Medical Society, the Maine Medical Association, the American Medical Association, and the Bath Medical Club. Dr. Bibber has served as acting assistant surgeon in the Marine Hospital Service, as overseer of the poor, city physician, and Mayor of Bath. He was the president of the Home for Aged Couples and Old Men.

Dr. Carl August A. Bruck of Milwaukee died at his home, recently, aged 55 years. He was a graduate of the Wisconsin College of Physicians and Surgeons in 1896 and was a member of the Milwaukee County Medical Society and the State Medical Society of Wisconsin.

Dr. Charles A. Burleigh of Forest Hill, Cal., died at his home, June 3, 1910, aged 47 years. He was a graduate of the California Eclectic Medical College in 1889.

Dr. A. D. James of Penrod, Ky., died at his home June 7, 1910. He was a graduate of the medical department of the University of Louisville in 1873, and had served at various times as member of the State Legislature and Senate, United States Mar-

shall, Member of Congress, and member of the World's Fair Commission.

Dr. CHARLES S. STROUD of Montreal died at his home on June 5, 1910. He was a graduate of McGill University in 1876.

Dr. L. D. TEBO of Bordentown, N. J., died recently, aged 65 years. He was a graduate of the Hahnemann Medical College of Philadelphia in 1873.

Dr. WILLIAM EUGENE TRAUTWEIN of New York died at his home, June 19, 1910, aged 43 years. He was a graduate of the Bellevue Hospital Medical College and was chief surgeon to the Delaware, Lackawanna, and Western Railroad.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

BIRTHDAY HONORS—YELLOW FEVER EXPEDITION SAILED—MALARIA—ROYAL SOCIETY'S COMMISSION ON SLEEPING SICKNESS—PANCREATIC REACTION (CAMMIDGE)—ASYLUM BOARD'S EXCESSIVE STAFF—A NEW DANGER OF MEAT—OBITUARY (THREE NONOGENARIANS AND OTHERS).

LONDON, June 3, 1910.

THIS being the King's birthday, a number of appointments have been conferred upon officers of His Majesty's household and the household of the late King. Among these Sir Francis H. Laking, Bart., M. D., G. C. V. O., receives a K. C. B. These honors, it is stated, are not in the place of the customary list of birthday honors, which will, as formerly, be published this year on the 24th inst., the day on which the late King's birthday was officially celebrated.

The outbreak of yellow fever at Sekondi, West Africa, has stirred the Colonial Office into prompt acceptance of the offer of Sir Robert Boyce, dean of the Liverpool School of Tropical Medicine, to go out with a staff of assistants to direct the organization of measures to stamp out the disease. At the meeting of the African section of the Liverpool Chamber of Commerce on Monday a letter from the Colonial Office stated that there had been eleven cases at Sekondi, ten of them fatal, eight of the victims being Europeans. Two cases at Freetown were both fatal. All the other places on the coast were reported free from infection. As soon as the outbreak was known, Lord Crewe summoned the Advisory Medical and Sanitary Committee for Tropical Africa and was acting on their advice in the emergency.

Sir Robert offered to go if the Liverpool University and the Corporation would consent to his absence. These bodies, as you might be sure, gladly gave permission, and Sir Robert actually sailed yesterday in the steamship "Dakar." Eight members of the London Tropical School accompanied him, but two of these, Drs. Nicholson and Wood, are for a supplementary mission at Sierra Leone. The other six, for Sekondi, are Drs. Mugliston, Duff, Goodbrand, Fraser, Crowly, and Moffatt.

The prompt devotion of all these gentlemen is eliciting the hearty commendation of the public and a recognition of the readiness of the profession at all times to step into the front.

It happens that at this same time tropical medicine is brought under public notice by one of its experts, Major Ronald Ross, who won a Nobel laureateship for his investigations on malaria. Yesterday he gave the first of two lectures on this subject at the Royal Institution. As to its history, there was no mention of it in the Homeric period and he found none in Hesiod, who lived in a valley which is now highly malarious. Supposing malaria entered Greece about 500 B.C., it must have spread from valley to valley and have been one factor in the downfall of the Greek nation. Major Ross did not think the carrier mosquito was then present in the swamps and marshes, and suggested that Greek warriors returning from Asia and Africa brought back the actual germs. The rise of temperature in malaria was known to the early Greeks, although they had no thermometers. They differentiated between quotidien, tertian, and quarten fevers, though they erroneously connected the last with dysentery. Further, the ancients recognized not only that malaria was prevalent in or caused by marshy districts, but they also connected it with insects. Passing to the dark ages, nothing was done, said the lecturer, in the study of the disease. In 1530 A.D. cinchona was sent to Spain and Louis XIV. was cured with it by a quack. This gave great prominence to the discovery of the bark and marked a new epoch in the history of the disease.

The Royal Society's Commission on Sleeping Sickness, in a report on the development of trypanosomes in the tsetse, remarks that up to the end of 1908 these flies were believed to act only as mechanical carriers and the limit of time of infectivity of the flies was considered forty-eight hours, so that if an infected district could be cleared of all sufferers from the disease it would be safe for healthy persons to enter it after two days from the complete clearance. But at the close of 1908 Kleine found a fly could convey the parasite fifty days after feeding on an infected animal. Experimenting on these lines in Uganda, the commissioners found the flies on the lake shore were infected with two species of pathogenic trypanosomes, so they used flies bred in their laboratory from pupæ gathered on the shore. At first there was some trouble to obtain them, but when the natives found out what was needed they provided ample supplies. Their experiments show a late development of trypanosomes in about 5 per cent. of the flies which become infective to the animals they feed on. The shortest time after feeding on an infected animal before the fly became infected was eighteen days, the longest fifty-three days, the average thirty-four days. It is not known how long the infected fly may live on the shore. One was kept alive in the laboratory for 75 days and was infective all the time. Experiments made as to the period an infected area remains infective after the removal of the whole native population seem to point to two years as the least.

The results of the pancreatic (Cammidge) reaction in 1,475 cases were brought before the Medical Section (Royal Society of Medicine) on May 24 by Dr. P. J. Cammidge, who also submitted a separate paper on the diagnostic value of an analysis of the excreta in disease of the pancreas. He did not assert that the reaction was pathognomonic, but experience proved that it strongly suggested active degenerative changes in the pancreas and in conjunction with the history, symptoms, and analysis of the feces, was of no little clinical value. No reaction was obtained in most affections where the pancreas was not involved, nor even in quiescent cirrhosis, in some cases of calculi and cysts, nor in 67 per cent. of cancer of the pancreas unless there was pressure or obstruction. The reason being that in these exceptions there was not active degeneration of the gland substance to set free the glyconucleoprotein of the cells to which is attributed the reaction, inasmuch as the pancreas contains nearly five times as much pentose as any other organ, calculated as dry weight, and that, too, more loosely combined than anywhere else. It was therefore to be expected that the reaction would be obtained more constantly in lesions which involved degenerative changes of the pancreas and the experience of many observers tend to confirm Dr. Cammidge's conclusions.

London ratepayers are very patient burden-bearers, but they have sometimes grumbled at the Asylums' Board as inclined to extravagance. The charge is considered deserving by many and their opinion will be enforced by some remarks of the retiring chairman respecting the number of the staffs exceeding the number of patients in the board's fever hospitals. At the Eastern Hospital the staff was 157 for 130 patients. At the Northern Hospital for 276 patients the staff numbered 309. Other cases were more disproportionate, Park Hospital having nine patients and a staff of 116. Altogether in the fever hospitals the staff employed was 2,526 for 2,281 patients. In the smallpox hospitals, where there were no patients at all, a staff of ninety-seven was kept up. The matter was one which the retiring chairman commended to the attention of the managers. It does not appear why he did not bring forward the matter during his own year of office.

An unsuspected danger of contracting tuberculosis has lately been pointed out. The meat of healthy animals may become contaminated in the slaughter house. It is stated that the bacilli may frequently be found on the floor and the walls of abattoirs. Moreover, the knives used by the butchers, as well as their hands,

have been found contaminated. From these the bacilli may easily be transferred to the surface of joints during the cutting up. It is true that they would be on the surface only, and that cooking would destroy them. But underdone, and even raw, meat is often consumed, and sometimes prescribed. No wonder the disease is so prevalent, seeing that fresh foci of infection seem to be found wherever they are looked for.

The week has been very fatal to our seniors. Among the deaths that have occurred are those of three nonogenarians. The oldest had reached the age of ninety-eight. This was Dr. John Cooper, whose first diploma was dated 1838. He practised for many years in Clapham and was chief medical officer to the dispensary.

The next oldest was Sir F. Seymour Haden, M.D., who died on Wednesday at the age of ninety-two. He was for years honorary surgeon to the science and art department at South Kensington, was founder of the Royal Society of Painter Etchers, and author of several works on art, and especially etching. His reputation as an artist tended to overshadow his position as a physician. He was made K.C.B. in 1894.

The third nonogenarian also died on Wednesday at the age of ninety. This was Elizabeth Blackwell, who claimed to be the first woman doctor in modern times. She certainly led the fight for the sex on this side. I think she practised in New York in the early fifties, and was concerned in founding a hospital, but you will know. Later she practised here and greatly assisted in establishing the London Medical School for Women. Later she retired to Hastings, where she died.

Prof. William Rose, F.R.C.S., author of the "Manual of Surgery" jointly with Mr. Carless, which has for years been so much esteemed, has died after a prolonged illness in his sixty-third year. He was Emeritus Professor of King's College and Consulting Surgeon to the hospital. He graduated at the London University in 1875, taking M.B. and B.S. with first-class honors, and in the same year the Fellowship of the Royal College of Surgeons.

Dr. Robert Smith, late Medical Superintendent of Durham County Asylum, died in his seventy-eighth year. He was an Aberdeen graduate, taking the M.B. there in 1854, and the L.R.C.S.Ed. about the same time. He proceeded to M.D. four years afterward. Before being appointed to Durham he had served in the junior appointment at Dumfries Southern Asylum, and also at Newcastle-on-Tyne.

The death was lately announced of Dr. Alexander Menzies Brown, Medical Officer of Health of Sydney, New South Wales, who will be remembered as the author of "Molière and His Medical Associations" and other literary essays on Molière's period.

OUR VIENNA LETTER.

(From Our Regular Correspondent.)

MIND READING—THE ELECTRICAL ACTIVITIES OF THE HUMAN BODY—OPERATIONS UPON THE PENDANT BRAIN—THE SIGNIFICANCE OF THE FACIAL PHENOMENON—BONE TRANSPLANTATION—ETIOLOGY OF GONOCOCCUS-FREE URETHRITIS.

VIENNA, May 1, 1910.

With wide participation on the part of the scientific circles, the fourth congress of the Society of Experimental Psychology has been held in Innsbruck. Professor K. Marbe of Würzburg spoke upon "Mind-Reading and the Uniformity of Psychic Processes." The speaker first discussed the various known methods of mind-reading and completed them by the method which he has called the egomorphic method. This, which is the method of mind-reading usually used in ordinary life, consists in assigning to another the thoughts which the "reader" himself would have were he placed in the position of the other. Marbe emphasized, however, that this method does not always succeed, as the thoughts of men are substantially dependent upon their individuality, and the egomorphic method must always be completed by observation of the individuality of the man whose thoughts one is guessing. It was possible in certain researches which he had made by means of the egomorphic method, in a great majority of instances, to point out the playing card which the subject had picked out of three lying on the table. That in this manner one can guess the chosen card in a greater proportion of cases than would be expected, according to the laws of probabilities, was proved by Marbe by numerical researches, which showed that with several exposed cards certain ones were definitely preferred. The results of these researches can also be taken as evidence that the psychic processes by different individuals show a greater uniformity than *a priori* would have been expected. Marbe now reported a number of researches in other spheres in which various individuals under similar circumstances showed remarkable uniformity of psychic processes. A study of 469 persons who were asked to note a number between one and ten, then one between eleven and twenty, and one between twenty-one and thirty demonstrated that the digit five was the last figure in most of the cases. The further the last digit varied from five, either above or below, the less frequently it was given. If one asked a large number of persons to write down any color, red was noted much more frequently than any other. Of 350 school girls who were told to write an entirely optional word, 199 words were noted which were given by at least one other scholar and only fifty-two occurred singly. Marbe then spoke of the increased uniformity of psychic processes in different individuals under the influence of suggestion, and drew examples of the unity of phychic activity from history. The relatively great uniformity of psychic activity under similar conditions and influenced by suggestion gives us, according to the view of Marbe, the keynote of popular will and popular thought.

Professor Albrecht of Graz reported a new method of examining the electrical processes of the human body. Under the name of the psychogalvanic reflex phenomenon, Varaguth has pointed out an occurrence of which the physical and psychological basis was unknown. If a man took electrodes in the hands, a sufficiently delicate galvanometer included in the circuit would indicate a current which would show regular typical variations according to the sensory stimulation or mental activity of the subject. The same phenomenon appeared if one passed a current from a weak battery through the body. In recent years a number of authors have busied themselves in trying to explain the facts which underlie those phenomena. The speaker spoke of various methods of study which could lead to no satisfactory results, and then presented a series of demonstrations and tables of the experiments he had carried on for this purpose. Concerning the relations of the variations of the current, it was necessary to establish whether these occurred from changes in the resistance or in the electromotive force. The answer to this question depended upon the use of certain apparatus whose purpose was to produce the same electromotive force simultaneously in two circuits. The author described its construction, demonstrated several curves, showed the results calculated therefrom, and finally reported an improvement recently made in his method, which gave expectations that, with necessary modifications, it would be useful in measuring other electrobiological phemonena.

J. P. Karplus and Alois Kreidl have described operations on the dependent brain. In the course of some experiments on brain physiology the observation of certain points in the middle of the base of the brain was desired. In order to make the desired parts more accessible, the experimenters placed the heads of the animals in such a position that, after opening the skull and the dura mater the weight of the brain came into play. In this position of the head the hemispheres at once fell outward and drew away from the base of the skull. In order to make this separation more satisfactory, cotton was packed between the brain and the base of the skull. In this manner a thorough inspection of the base of the brain was possible, extending from the pons to the frontal pole, a field of observation such as has not been obtained by any other operative procedure. By it a whole series of investigations, which otherwise would scarcely have been possible, have been carried out under the control of the eyes. Karplus and Kreidl by this method have discovered a sympathetic center in the hypothalamus which in carnivora lies almost entirely in the base of the midbrain, and is now accessible for stimulation and destruction experiments. In the course of the experiments the method was used for exposing the base of the brain of monkeys. It was astonishing how well the animals bore the operation without any appreciable injury to the brain. The tolerance of the monkey brain to this procedure suggested the thought as to whether this method of raising the brain from the base of the skull might not be available in surgical procedures on man. In a study on the cadaver investigation showed that with unilateral wide opening of the skull and careful traction of the brain from the base of the skull, by the brain sinking outward, the same wide accessibility

of the skull cavity and inspection of the base of the brain as far the mid-line were obtained as in the monkeys.

Berthold Sperk has made a study of the significance of the facial phenomenon. He has investigated the occurrence in children between three and twelve years of age. This showed that it usually appeared in weak, anemic children with vague symptoms and nervousness. In the marked cases there were also increased knee jerks and decrease of the corneal and pharyngeal reactions. Sperk believes that these cases could be considered as a rudimentary form of tetany. He was also able to find a considerable number of cases which showed direct or family signs of tetany. The question arose as to whether there was not some relation between this nervousness and tetany, and whether the complex did not make up an entity. Sperk considers it justifiable in the development of this theory to think of a congenital or acquired relative insufficiency of the parathyroids. If the parathyroids are not able to detoxify the poisons produced by metabolism, deficiencies develop with the symptoms of manifest or latent tetany. It is theoretically conceivable that the function of the parathyroids is more important in infancy than in later life, and that in consequence infants show more readily the symptoms of manifest tetany. From this point of view the before mentioned symptom complex may be considered as a tetanoid condition, according to Escherich's idea. This would make tetany a disease produced by direct injury, or inborn or acquired, absolute or relative insufficiency, producing different clinical manifestations, according to the amount of the lesion and the age of the patient. By this theory the conception of puerile tetany receives some illumination, and an etiological insight into at least some cases of nervousness is offered.

Ludwig Moszkowicz, in the case of a patient twenty-seven years of age, with a spindle cell sarcoma of the lower end of the femur, resected a portion of bone 18 cm. long, extending into the knee joint. In order to fill up the great defect in the continuity of the femur, he used a correspondingly long piece of the fibula from the same extremity, which, carefully dissected from the muscles, was implanted with its adherent periosteum between the femur and the tibia, so that the lower pole of the piece of fibula was impacted into the medulary cavity of the femur and the head of the fibula, partly freshened, was placed in the groove between the two condyles of the tibia. Considering that the patient is able to get about with the help of a brace, the case may be accepted as a successful free bone transplantation. The *x*-ray showed some not uninteresting features. About five weeks after the operation the transplanted bone showed some changes in its contour, being here and there narrowed at the borders, and the medullary cavity widened (signs of resorption). From the femur there developed an ever-stronger periosteal callus, which surrounded the transplanted piece of bone and knitted the two together. The union of the bone was close and strong. On the other hand, at the transplantation point into the tibia, no callus appeared, which is explainable in that the transplanted bone here was not covered with periosteum—and it touched on both sides the cartilagenous articular surface of the tibia, and the callus of the freshened tibia did not reach up to produce the close union of the bones. There remained at this point a motility which, however, continually decreased. This, therefore, teaches that in the next case one should take a longer piece of bone for transplantation and imbed it well into the adjoining bones. Furthermore, it would be possible where the transplanted bone is not covered with periosteum, as in the surface of a joint, to cover the end of the bone with a periosteal flap.

Johann Fritsch has read a paper on the etiology of nongonorrheal urethritis. Lindner and Fritsch have succeeded in transferring the so-called inclusion blennorrhea of the newborn into monkeys. With equal success, Lindner and Hofstätter have inoculated the vaginal material from the mother of one of the children into the same species of monkey. It is, therefore, requisite to take steps with a gonococcus-free urethritis in man, of which Waelsch has written and Gross has studied and established. This disease of the urinary tract demonstrates itself as a rule clinically by a mucous, dull gray secretion, by a chronic course, and by the ineffectualness of all local therapeutic measures. Fritsch succeeded four weeks ago in infecting the conjunctiva of a monkey from a fourteen-day-old gonococcus-free urethritis. A few days before, Lindner had demonstrated the cell inclusion in the secretion from the patient. At the time of the inoculation a smear from the secretion failed to show the bodies. On the third day the inoculated animal showed a conjunctivitis, with intense injection, reddening, and a little secretion. On the eighth day the disease reached its high point. At this time the swelling of the conjunctiva narrowed the opening; injection, reddening, and secretion were much more marked. This condition persisted for two or three days, and then gradually subsided, but injection, redness, and a slight secretion remain to-day in the animals. Besides this, at the base of the lower lid granules are beginning to appear. Smears taken on the fifth day were negative, but those taken on the tenth day at the height of the disease showed the typical cell inclusions, which were exactly like those seen in the urethral secretion of the patient, and previously found in trachoma and blennorrhea. There were also found many free initial forms. Clinically as well as morphologically, therefore, the same picture occurs in the monkey, whether we inoculate from the vaginal secretion of the mother of a child with this form of blennorrhea, from the blennorrhea itself, from trachoma, or from a nongonorrheal urethritis in man. The results of this research justify the statement that there exists in a group of genitourinary diseases in men a virus which, inoculated into monkeys, produces in these animals a conjunctivitis which clinically and morphologically is indistinguishable from the affection which we have observed after inoculation from trachoma, inclusion blennorrhea, and the vaginal secretions of the mother of a blennorrhea infant. By these researches it is experimentally proven that there exists in men and in women a nongonorrheal genital disease which may infect the child and produce the so-called inclusion blennorrhea.

Progress of Medical Science.

Boston Medical and Surgical Journal, June 9, 1910.

Cancer of the Uterus; a Clinical Study.—S. Rushmore studies a series of 25 cases admitted to one of the Boston hospitals for uterine cancer. The series illustrates two points. First, the time suffered to elapse by the patients before a positive diagnosis was made. That a patient should suffer for two years without medical care from symptoms which suggested one of the most hopeless and fearful diseases is a sad commentary, says the author, on the present state of civilization. This condition is due primarily to ignorance or carelessness on the part of the patient. In two of the cases there was evident neglect on the part of the physician. Second, the author says that radical intervention increases the percentage of operable cases thus giving hope to a larger number of patients. In the series of cases operated on, one patient died on the twenty-fourth day from starvation. There had been some infection after operation in the pelvis where a small abscess had been opened. The temperature had never been high and for the last ten days the course had been afebrile. The patient was not able to retain food, the cause of which fact it was impossible to discover. Without the more extensive operation these cases could have been treated by palliative means only. To judge of the value of the operation years of observation and long series of cases are necessary, but the author quotes Wertheim as saying that even those patients in whom there is a cancerous involvement of the glands removed at operation may be free from recurrence at the expiration of five years.

Bier's Vein Anesthesia.—F. H. Lahey reports one case of operation upon a brachial aneurysm treated by Bier's vein anesthesia in which local anesthesia is produced by the introduction of the anesthetic into the area to be anesthetized by allowing it to filter out through the veins in this region. The method of preparing the region to be operated on is described. The case of the author was that of a man of 31 years who seemed to have an aneurysm of the lower end of the brachial artery and one that might well lend itself to the reconstructive operation of Matas. The indications for the operation were an inability to flex the arm, marked pain, and tenderness in front and just above the elbow. The cardiac conditions contraindicated the employment of a general anesthetic. In this case the anesthesia was perfectly satisfactory and the wound healed by first intention but the patient died one month later from his cardiac lesion. In Bier's own experience in 134 cases, anesthesia was perfect in 115, satisfactory in 14, while in 5 the patients suffered pain. The author gives several rules on technique which his experience has convinced him it is advisable to follow carefully in order to insure the best results.

New York Medical Journal, June 11, 1910.

Primary Tuberculosis of the Nose.—S. Oppenheimer reports the case of a man of 34 years without antecedent history. Five years ago he had a nasal obstruction and in the course of two years no less than ten intranasal operations were done for its relief. Microscopical evidence as to the nature of the recurring mass were indefinite in result but there had never been a suspicion of tuberculosis. Examination when the patient first came under the author's observation revealed a septal perforation about one inch in diameter while in the defect was crowded a mass which completely blocked it and prevented a view of the nares farther back. Apparently the growth was attached to the septum which was thickened. Smaller masses were attached to the anterior segment of the septum. In appearance the growth resembled a papilloma while the septal enlargement were indicative of an enchondroma. Microscopical examination of a fragment at this time revealed giant cells and tubercle bacilli. The operation consisted in the incision of the gingivolabial fold from the first molar tooth on the one side to a corresponding point on the other. The lip and face were then dissected from the bone until the anterior nares were exposed to view and the septum reached which was cut through below to a sufficient extent to allow the nose being turned up upon the face. The hemorrhage was considerable but easily controlled. The entire tumor was then removed as well as most of the cartilaginous septum, extending well back into the bony septum. Anteriorly he was compelled to remove tissue which appeared thickened and suspiciously diseased, so that he feared he was encroaching on the supporting nasal frame, but fortunately no deformity resulted. The lip was sutured back in position and the nares packed with gauze. Recovery was uneventful, the wound healing with considerable rapidity.

Pathology, Treatment, and Prophylaxis of Gastric and Duodenal Ulcers.—W. H. Thomson refers to a recent observation of Haliburton to the effect that just as poisons from without stimulate the cells to produce antitoxins, so harmful substances produced within the body are provided with antisubstances capable of neutralizing their effects; for this reason the blood does not clot within the blood vessels and Weissland has shown that the gastric epithelium forms an antipepsin, the intestinal epithelium an antitripsin and so on. Consequently a gastric ulcer is not a disease *sui generis*, but merely the local expression of a general dyscrasia caused by the presence in the blood of cytolites for the gastric epithelium. Hence arises the modern treatment of injecting rabbit's serum hypodermically and this has been done successfully. Injections have been used to supplement autogenous vacciues. Prophylaxis involves the consideration of dietetics, for the general dyscrasia referred to cannot begin without some disturbance of nutrition. If there are signs of local stomach inflammation resorcin has been in the author's hands the main stay, to be given in case of hemorrhage as soon as that is stopped. Similarly he has found it useful in the stomach disorders consequent upon gallstones. The only other drug he uses for such conditions is bichromate of potash. Both these agents are powerful antacids, arresting local fermentation. He also uses the bichromate in the strength of half a grain to the ounce of ordinary boric acid solution for washing out the bladder in chronic cystitis from which many of these cases suffer. The resorcin is given in doses of from five to six grains in tincture of nux vomica syrup of ginger, and peppermint water half an hour after meals and the bichromate in one-twentieth grain doses in pill form with bismuth half an hour before meals.

The Injection of the Salts of Mercury and Arsenic During the Reaction Period Following Tuberculin Injections as a Treatment for Tuberculosis.—C. A. Penrose says that his hope in making these antecedent injections was that such antiseptics would enable us to use larger does of tuberculin without risk and that the larger doses of this latter remedy by their action on tuberculous areas would insure better penetration of these antiseptics into such places. The method he first adopted was as follows: He gave his patients from one-fifth to one-third of a grain of succinimide of mercury, hypodermically, every other day until thirty injections had been taken, and then started them in with small doses of tuberculin (old tuberculin) hypodermically until a good tolerance dosage was obtained, and then gave this usually every other day, alternating with mercury injections for fifteen days. After a variable period of rest from treatment, from fifteen to thirty days, he gave another course of the mercury alone, etc. He now finds it best to get the tolerance dose of tuberculin first in the untreated case and then he has a gauge as to the amount of tuberculin best to use after the mercurial course. This, he has usually found, is three to four times as large as the initial dose of tuberculin used before the administration of the mercury. He has been surprised to find, in one case especially, that such a dose every other day gave no general reaction, although one-fourth of this dose every four or five days before the mercury was started shot the temperature persistently up to 102° F. and more. He hopes to confirm this observation later or have it confirmed by others on more numerous cases, as this was a result which seemed to him most significant.

Journal of the American Medical Association, June 11, 1910.

Vaccine Therapy.—The basal principles of vaccine therapy are laid down by J. G. Adami as follows: First, the main basal principle is that bacterial infection is primarily local, and that, even when the microbes spread from the primary focus or even when bacteriemia is set up, there still persist tissues of election in which alone those bacteria find conditions for active growth. He illustrates this by the course of a malignant streptococcus endocarditis, in which it is clear that the streptococci have been circulating in the blood, and there is no question about the bacteremia. Yet how rarely do we find a true abscess in the spleen, and the only conclusion we can reach from this and other cases is that the spleen destroys the bacteria. What is true of the spleen is true also of some of the most widespread and important tissues of the body. The germs undergo little or no destruction in the blood. The amount of phagocytosis is minimal, nor do the specific cells of the various tissues destroy the bacteria to any marked extent, with the exception of the hemolymph system. The fact that bacterial infection is primarily local indicates that there is a natural indifference or nonspecific immunity toward most bacteria existing in most of the tissues of the organism. This has its limits, but it is too little thought of, and it is this that renders vaccine therapy possible. The second great underlying principle is that once bacteria have established themselves in a given tissue and have undergone proliferation, that is a sign that that particular tissue is not immune, and any subsequent check to their growth is not due to any increase of its bactericidal power, but is due to aid contributed by the organism from elsewhere. This is generally accepted. There are certain subsidiary principles, however, of vaccine therapy that must be heeded. First as to dosage. Adami thinks that Wright's demonstration of the possibility of gauging the extent of the reaction following heteroinoculation has been of service, not so much in affording an accurate index as in showing that the best results are apt to follow doses so small that they need not induce general reaction during the next few hours, obvious to ordinary clinical observation. It is a general principle that minute rather than massive doses of vaccine are to be employed. As to the qualities of vaccine it would seem that the surer results follow the employment of minute, nonlethal doses of the specific bacteria rather than the use of dead cultures, and by the latter rather than by injecting the products of bacterial growth. Since, however, we cannot consider the resistance of the organism as normal, it is, in general, unwise to employ inoculations of the living bacteria. More constant and safer results are to be gained by the use of the dead cultures of the particular strain of pathogenic bacteria causing the infection, obtained from the patient himself rather than from stock laboratory cultures. Considering the cases suitable for vaccine treatment, we must recognize the difference in the virulence of the strains employed, and also those in the grade of resistance of the patient. If the bacteria are especially virulent and the patient extremely depressed, we have the most hopeless condition, and in neither case is vaccine therapy applicable. In the intermediate cases, however, those in which the reaction is slight might be at first thought unsuitable, the resistance of the organism having isolated or encapsulated the toxic germs. They are latent, however, and not destroyed, and may yet create mischief, and vaccine therapy may excite a stimulation of the tissues to their destruction. When a reaction exists, Adami inclines to think that a fatal outcome in severe infections is due to action of the toxin on medullary nerve centers rather than exhaustion in general, and, to guard against such excessive action on the nerve centers, vaccination should always be subcutaneous and never into the blood stream. A sinking temperature with increasing weakness of pulse and respiration is clear evidence of the overcoming of the reacting powers of the patient and here

vaccine therapy is contraindicated. On the other hand, if the fever is somewhat high and there are no signs of cardiac weakness, it may be safely undertaken. He does not consider Wright's method, valuable as it has been, as altogether perfect, and would have more hopes of educated clinical experience in this particular work. Vaccine therapy is for trained specialists, not for the general practitioner.

Poliomyelitis.—Irving M. Snow notices the scantiness of the literature of neck and diaphragmatic paralysis in poliomyelitis, and reports a case in which paralysis of both regions was observed. He also reproduces the accounts of other cases of the kind which he has collected, and draws the following conclusions: "1. Cervical poliomyelitis affecting only the origin of the phrenic and spinal accessory nerves is rare, but in the two recorded cases recovery occurred. 2. Paralysis of the neck muscles occasionally occurs in poliomyelitis and, save in Landry's paralysis, the prognosis is favorable as to restoration of function; some improvement always takes place. 3. Paralysis of the diaphragm is exceptionally seen in poliomyelitis and, although dangerous, recovery is possible."

False Metaplasia.—Peyton Rous has investigated the question whether the gradual transition of cancerous tissue into normal tissue, frequently observed on the borders of the growth, is primary or secondary. Many pathologists hold that the transition here noted is evidence at once of the primary seat of the growth and of its manner of origin. Ribbert has long held that a secondary union really explains such findings, but experimental evidence of this has been lacking. Rous has examined many grafts in which mixed tissue and embryonic tissue have grown intimately together in the new host. Mouse tumor and hashed mouse embryos have been used. In some cases there is such an intermingling of cells at the meeting point that it is impossible to determine microscopically where normal tissue ends and carcinomatous tissue begins. On histological evidence alone it would be said that the metaplasia exists. This probably explains, he says, only a part of the recorded cases in which such a continuity has been observed, but, while admitting that such may be primary, it should lead to caution in assuming that it necessarily implies the point of origin of its growth. If such a secondary appearance can be produced experimentally we may assume that there must occur many opportunities for such a secondary phenomenon in carcinoma or epithelioma.

The Lancet, June 4, 1910.

The Fatty Degeneration of Arterial Hypertension.—L. T. Thorne says that the two most common forms of tissue degeneration, the result of hypertension, are those of atheromatous and fatty degenerations accompanied in the latter by infiltration. It is not possible to distinguish clinically between fatty degeneration and fatty infiltration. In a typical case of fatty degeneration due to overtension the patient is overfat, has cold extremities, a urine of low specific gravity, but with no albumin, has an increased area of cardiac dulness, very feeble cardiac sounds, and sometimes edema of the legs and feet. These cases may be mistaken for ones of chronic nephritis but are distinguished from them by the fact that the impulse at the apex is often absent or very slight, that the heart sounds are often very feebly heard at the apex and are often too feeble to be audible over the aortic and pulmonary areas. This condition combined with increased cardiac dulness indicates a dilated and fatty heart in contradistinction to the hypertrophied and over-vigorous heart of nephritis. In the former the health can be restored, arterial tension lowered, cardiac dilatation cured, fatty degeneration arrested, and the weight greatly reduced without resort to any strictly limited dietary or vasodilator drugs. Treatment follows along the lines suggested. Nauheim baths and regulated exercises meet all indications. Drugs are unsatisfactory. If the digitalis group is used the benefit is only temporary. If the vasodilators are used the general vitality is lowered and the heart is depressed. In the plan suggested the tension is lowered but there is no depression of vitality. We get a better nutrition and consequently a more perfect heart action, the function of this organ being to nourish both itself and the system at large.

Pulmonary Tuberculosis in Children.—M. H. Williams says that the time has come to alter our conception of tuberculosis. It is generally a non-fatal disease. Tubercle bacilli are present in a large number of people but do harm only in a small percentage of cases. Tuberculous infection begins in many cases in early childhood and its frequency increases as the child approaches puberty. The author analyzes collections of statistics taken by various English authorities and makes a plea for abandonment in common use of the term "phthisis." In examining children it is often impossible to make a positive diagnosis at the first examination. Some require several examinations before a positive conclusion can be arrived at. In children it is notoriously difficult to get enough sputum for examination and hence the tubercle bacilli can rarely be found. Speaking from the standpoint of school inspection the author says that if it is to be more than a farce and a farce disgraceful to the medical profession, we must insist on taking such time as we, each one, consider necessary for diagnosis. We cannot advise either our education authority or the parents, of the many steps necessary if we cannot diagnose what diseases are present. And the fact that examination of the lungs takes time is no reason for omitting it.

The Pathology of Rheumatic Fever.—F. J. Poynton and A. Paine review their work on this subject during the last ten years and repeat their two main conclusions. First, that a diplococcus, streptococcus, or micrococcus is a cause and most probably the only exciting cause of acute rheumatism and secondly that acute rheumatism may be a cause of simple and of malignant endocarditis. They answer various objections to this theory which from time to time have been brought forward. The microorganism they believe to be the one in fault has not been found in every case examined but there is no proof that it may not be present; with regard to its specificity they are led to believe that no other germ can be found in the rheumatic lesions of man which will produce similar lesions in animals. Undoubtedly various organisms produce experimental endocarditis as they may also produce endocarditis in man but various organisms are not found in human rheumatic endocarditis which will reproduce the disease. They do not pretend that a pure culture is a constant result but they have invariably found that the streptodiplococci predominate. In general they assert that no explanation of acute rheumatism can compare with that which attributes it to an infection with a diplococcus of the streptococcus group. The paper is most interesting and well worthy of being read by all who wish the latest discussion on the cause of acute rheumatism.

British Medical Journal, June 4, 1910.

The Rightward Edge of Cardiac Dulness.—W. Gordon says that any statement in regard to the transverse measurement of the heart made without mention of the patient's attitude or posture at the moment is utterly worthless. In the recumbent position we get, in many cardiac cases, a misleading idea of the condition of the right heart which is then percussionably almost invisible while in the upright position we usually have the great advantage of having much more of the right heart percussionally in view. The author has previously pointed out how in cases of cardiac disease the variation in dullness in change of position is even more considerable than in the case of the normal heart and how necessary it is to bear these facts in mind before making a final opinion. If we examine transverse frozen sections of the body taken at the levels of the fifth intercostal cartilages and the third intercostal space respectively we see that the right auricle does not lie nearly so close to the chest wall as does the right ventricle and that a considerable part of the right ventricle falls back from the chest wall toward the right. Thus a great deal of the right heart is seen to be removed from contact with the chest wall. When the erect posture is assumed gravity no longer tends to pull the heart from the chest wall, while the heart as a whole comes more fully into contact with the sternum and the rib cartilages. Under these circumstances the right ward region of the heart which in recumbency is percussionally invisible might be reasonably expected to come more fully into view. It becomes clear that the width of the cardiac dullness in the erect position is a much more reliable measure of the heart's true width than in the dullness in the recumbent posture. Illustrative diagrams support the author's contention.

Gastrotaxis.—W. Hale White reviews Bolton's article on this subject in the *Journal* of May 21 and in the main supports the latter's views. He himself has seen only three cases out of 7,500 post mortems. We do not know the cause of it any more than we do that of nose bleed in young boys and of menstruation in girls. There is reason to believe that a similar oozing may take place from the vessels of the kidney and give rise to blood in the urine. Probably some cases of suspected stone in which no stone is found are examples of the lesion now considered. Several cases of bleeding from the stomach have lately been recorded in connection with appendix disease. Although

this is difficult to explain it is easier to imagine that some toxin from the appendix acting as an endothelial poison would cause gastrotaxis or oozing of blood rather than cause gastric ulcer for we know that in toxemia associated with liver disease (apart from portal congestion), hematemesis may occur without any ulceration of the stomach and rupture of minute gastric vessels is not rare in acute infective processes, for out of 172 post mortems on patients with gastric ecchymoses seen at Guy's Hospital, in 68 the cause of death was an acute infective process.

Sterilization of the Skin in Operative Areas.—J. L. Stretton gives the results of 348 cases. He is an advocate of iodine in disinfecting surgical fields. He believes that it is absolutely unnecessary to shave the skin and this is an important advantage. He finds that staining does not persist and that by the time most operations are finished the staining has already gone. If the stain persists it vanishes on washing with a 3 per cent. solution of carbolic acid. Towels are cleaned by soaking in the same solution. As a rule there is no desquamation. The solution should be kept tightly corked and used from a wide-mouthed bottle. Personally the author has never seen a case of dermatitis from the remedy though several have been reported. The only disadvantage he has discovered is lacrymation, to which some assistants are more susceptible than are others. The tincture made from the rectified spirit is far less irritating than that made from the methylated spirit and can be tolerated by most people. The author still uses the methylated preparation for the primary painting immediately before operation. The second painting is done when the anesthesia is complete and this is done with the rectified preparation. The final painting when the operation is finished is done with the methylated. The matter is merely one of expense.

A Case of Prolonged Abstinence.—B. Hall reports the case of a woman of 66 years who had a cancerous mass in the rectum but who declined all operation. There was complete stoppage of the bowels throughout the duration of the case, nothing passing but a little foul discharge. Vomiting took place even after a mouthful of water. The abdomen become distended but caused little distress. Occasional back pains were relieved by hypodermics of morphine and toward the close these were given every six hours. A bed sore developed over the sacrum. For fifty-one days she was absolutely without food and practically without drink. This period seems to be about the limit to which life may be prolonged during complete abstinence. Considering the cancer and the bed sore one must regard this case as unusual and remarkable.

Berliner klinische Wochenschrift, May 23, 1910.

Intratracheal Insufflation (Meltzer) on Man.—Lilienthal and Elsberg report three cases in which the Meltzer method of intratracheal insufflation was used in human beings. The first case was that of a patient dying of myasthenia gravis. When the disease had progressed until respiration stopped, she was unconscious, and pulseless; the tube was inserted into the trachea and insufflation was begun under 20 mm. pressure. Within a minute the patient's appearance changed. The face became light rose colored, the lips red, and the pulse could be felt, at first very slow, 32 per minute, but soon 110 to 120. The insufflation was kept up for five hours, during which time there were no respiratory movements, but the color remained good and the pulse 120. At the end of this time the patient's condition being hopeless, the insufflation was discontinued. The second case was of a man, aged 55, who gave signs of a pulmonary abscess. After painting the throat with a 10 per cent. solution of cocaine the tube was inserted easily to the bifurcation of the trachea. Insufflation was begun with ether and air under 15 mm. pressure. This caused a cough, which was stopped by slightly withdrawing the tube. An incision four inches long was made through the left pleura, and the lungs thoroughly explored, and an aspiration needle inserted in several places. The abscess was not found. During the closing of the wound the pressure was raised to 25 mm. in order to fill the thorax completely with lung and drive out all air. When the last stitch was taken the pressure was raised to 30 mm. Respiration instantly ceased, but soon began again at a rate of 32 per minute. The pleural cavity was open for twenty-five minutes. The insufflation lasted fifty-five minutes. There was no cyanosis at any time. The pulse at first was 120, but soon dropped to 108, and remained between 96 and 108 throughout the operation. The respiration varied from 32 to 48. The patient made a rapid recovery, and has remained well since. The third case was a simple rib resection and drainage for empyema. This operation was uneventful. The disappearance of râles as soon as the insufflation began was noteworthy.

Morbus Ceruleus in Four Generations.—Burwinkel reports the case of a man of 55 years of age who had been blue since birth. Though his color was very dark, and there was a loud systolic murmur, best heard at the left border of the sternum at the third interspace, he had no subjective symptoms, the heart was not enlarged, and he had served two years in the army. The point of interest was that several other members of his family had also suffered from morbus ceruleus. His grandmother died of old age at 76, having been blue from birth. His mother also was affected, having died at 44. A younger brother was normal. His sister and her only child were both congenital cardiac cases, as were two of his own three children. In none were there any symptoms of cardiac insufficiency.

Münchener medizinische Wochenschrift, May 17, 1910.

The Nature and Mode of Infection of the Poliomyelitis Virus.—Römer and Joseph state that virus of poliomyelitis, which had been preserved for five months in undiluted glycerine, when injected into monkeys was shown not to have lost its virulence, or even to have had its virulence lessened. They then discuss the relation of gastrointestinal symptoms to etiology and show that in monkeys the diarrhea is simultaneous with, not antecedent to, the paralysis. On the theory that the intestinal symptoms, rather than being the cause of the disease, might be the result of the excretion of the virus through the bowel, they injected a monkey intracerebrally. Three days after the simultaneous appearance of general symptoms of illness, onset of paralysis, and occurrence of diarrhea, the animal died. At autopsy the mesenteric glands were found greatly enlarged. These glands injected into a healthy monkey produced paralysis.

Transient Cerebral Hemiplegia.—Riebold says that mild transient cerebral hemiplegia may be caused by the presence of local disease of the cerebral blood vessels, causing temporary mechanical interference with the circulation and consequently momentary anemia of definite portions of the brain, without anatomical lesions. A second cause may be emboli or thrombi in the very small blood vessels and the rapid formation of collateral circulation. His observations suggest that possibly at times large anatomical anastomoses may exist between the branches of the arteriæ fossa Sylvii, which may permit of rapid recovery even from severe cerebral hemiplegias following obstruction of a main trunk of the arteria fossa Sylvii.

Deutsche medizinische Wochenschrift, May 12, 1910.

Scarlet-red and Epithelial Growth.—M. Strauss has made use of 8 per cent. ointments of scarlet-red as a local application to granulating wounds. The first application of 24 hours caused some irritation and a thin gray-white film over the granulations and some increased secretion. The use of antiseptics is not necessary. If the irritation is too great the ointment should be discontinued for from two to twenty-four hours. The results of the use of the ointment is shown not only by the rapidity of cure, but by the thickness of the epithelium produced. The scarlet red ointment is a valuable material for local application to wounds. So far no untoward results have followed its use. The fear that the stimulation of the epithelial proliferation may lead to the formation of cancer is not well grounded. In these cases the drug is applied superficially, while in the animal experiments it was injected subcutaneously. The epithelium produced has the microscopic appearance of normal epidermis.

Costochondral Abscess from the Paratyphoid Bacillus.—John Reenstjerna reports the case of a man 41 years of age. In 1906 he had an indefinite attack of fever which lasted three weeks. After his recovery he had pain and tenderness in the left side. He was observed in a hospital for two weeks, where it was considered that he had a gastric ulcer, or splenic abscess. At the end of 1907 a small swelling was evident over the rib. By Christmas, 1908, this was considerably larger, and in February, 1909, the swelling was opened and a costochondral abscess was discovered, which contained the *Bacillus paratyphosus B.* The patient made a rapid recovery.

Pruritus Ani.—The cause of some obstinate cases of pruritus ani is the presence of a small ulcer on the rectal mucous membrane, between the external and internal sphincters. The best treatment is forcible stretching of the sphincter.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Sixty-first Annual Meeting, Held in St. Louis, June 6, 7, 8, 9, and 10, 1910.

(Special Report to the MEDICAL RECORD.)

(*Continued from page 1033.*)

SECTION ON SURGERY.

Thursday, June 9—Third Day.

THE election of officers for the ensuing year was as follows:

Chairman, George W. Crile of Cleveland, Ohio; *Vice-Chairman,* Emmett Rixford of California; *Secretary,* John T. Bottomley of Boston, Mass.; *Orator,* George E. Brewer of New York; *Delegates,* A. F. Jonas of Omaha, Neb.

Partial Thyroidectomy in Dementia Precox.—Dr. RANDOLPH WINSLOW of Baltimore said that this well-known condition of progressive insanity, which occurred about equally in both sexes and presented clinically many of the signs commonly attributed to hypersecretion of the thyroid, was in at least a few of the cases susceptible to cure by surgical method. He himself was able to report two such cases in one of which at least there had been a certain return to health. It was significant that the operation in these cases was attended with the usual dangers, which accompanied parathyroidectomy in exophthalmic goiter. A further point of suggestive value was that the administration of thyroid preparations usually exaggerated the symptoms.

Diagnosis and Treatment of Esophageal Lesions.—Dr. H. S. PLUMMER of Rochester, Minn., first discussed the important points in the technical usefulness of the well-known methods of conducting esophageal work, namely esophagoscopy, roentgenoscopy, and finally instrumentation. The keynote he said of this new branch of diagnosis and treatment was safety to the patient. All instruments that were used should be patterned in their general make-up as closely as possible after a hypothetical instrument, which gradually emerged in substance from a harmless thread to a firm staff. The recognition of pockets and diverticula was of the greatest importance and in this the well-known shape of the bismuth shadow at its aboral extremity was the most importnt diagnostic feature. In all this work, the use of a silk thread, six yards of which was to be swallowed, proved to be of the utmost value. This length of thread introduced into the intestine afforded a medium upon which sounds and dilators could safely be passed, and in the hands of an experienced operator, the degree of tension upon the thread could easily be so modified as to enable accurate measurements to be made of the depth of any pockets. Outside of the removal of foreign bodies, of course the importance of esophagostomy was chiefly in determining the character of the esophageal wall, and early diagnosis of malignant growth might confidently be looked forward to throughout the country in the near future, as the technic had so far advanced as to place this diagnosis within reach of any painstaking and skillful person. In the Rochester clinics, as a rule, a five-minute examination was possible without an anesthetic, and this usually afforded time to do the necessary work.

Dr. WILLY MEYER of New York, in opening the discussion, said that in certain cases of chronic cardiospasm where the patient had suffered for many years, and in which there must have occurred a degree of muscular stretching around the stricture which would prevent the return of the parts to normal physiological function even after dilatation, operative surgery might be necessary. Such a case had occurred in his service. Under differential pressure, he had entered the seventh intercostal space posteriorly, had without difficulty found the diverticulum, and on account of the bad condition of the patient, he had made a plication of the esophageal wall about two inches long, instead of resecting it, as he had hoped to have been able to do. The wound was closed and the patient did well, but had sudden dyspnea twelve hours later. She was put in a pressure box where she breathed comfortably. After six hours, it was possible to take her out and she made a good recovery.

Dr. Plummer, in closing, said that he had not met a case of cardiospasm in the first sixty-five cases so far treated, which could not be cured by dilatation of the cardia.

Certain Surgical Aspects of Goiter.—Dr. G. W. CRILE of Cleveland said that the work which he had to report was based on the hypothesis that the symptoms of hyperthyroidism were not due to the factors usually submitted, but to ganglionic cellular changes produced by a combination of fear on the part of the patient and tissue maltreatment on the part of the operator. Studies of the brain and cord show that fear could produce chromatolysis in the nerve cells. It was interesting to review the many factors which in time past had been considered as important in causing the fatal postoperative syndrome. Nothing could demonstrate more clearly the condition of flux in which the entire subject was still to be found than the rapid acceptance and rejection of explanatory hypotheses Hemorrage was among the first to be dreaded, but it came about that the fear of it vanished when competent observers found that the ligation of the superior thyroid was as often followed by hyperthyroidism as was the operation of resection. In like manner, the fear of infection had come and gone. Still prominent as a possible causative agent was the hypothesis that the secretions liberated at the time of operation might be responsible. Here again one was confronted by the forbidding fact that severe massage amounting even to the roughest handling of the gland did not produce the symptom complex. A hitherto unrecognized element was fear. It was well known that fear had killed men and women. The exclusion therefore of psychic factors was of the utmost importance. What more was necessary for the complete protection of the patient? Hirst had shown that patients suffering from exophthalmic goiter were hypersensitive to traumata inflicted anywhere on the body and particularly traumata to tissues phylogenetically allied to the thyroid. Obviously the treatment indicated by a consideration of these facts was to eliminate fear entirely. To give a general anesthetic without the patient's knowing it, and in addition to cocainize the parts before operation as thoroughly as one would for operation under local anesthesia. The success attending this mode of treatment was conclusive proof of the soundness of the argument. There was undoubtedly a pathological reciprocal interaction between the brain and the gland and this took place via the nerves. It had long been known that important nerve trunks entered the gland in the region of the superior thyroid. It seemed probable that in ligating this vessel, the benefit which was often amazing in extent came from interruption of the nerve paths rather than in any diminution of the blood supply. For it was well known that the anastomosis would compensate at an early date, and that little, if any, permanent decrease in the blood supply was clinically possible. Finally the speaker emphasized the necessity of removing the patient from the environment which had accompanied the development of the disease.

Dr. A. J. OCHSNER of Chicago, in opening the discussion, said that the author's method of reasoning by exclusion was most valuable. In the normal human body, there existed a balance in the physiological terms which accommodated considerable hyperthyroidism. Any overstrain, whether physical or psychic, might carry a poorly

endowed young person over the balance. It was unquestionable that all harmful causes and conditions should be eliminated both before and after operation.

Dr. A. A. McLaren of St. Paul said that he thought the paper a most important one and agreed that fear was in these cases more than any other a very deciding element.

Dr. Martin Tinker of Ithaca believed that simple manipulation of the gland might cause temperature and other manifestations. He wondered why the free use of drainage was so necessary in all cases of thyroidectomy and suggested the possibility of Dr. Crile's well-known operative skill having more to do with the patient's freedom from symptoms and with the remarkable series shown by the author, than the removal of the elements which Dr. Crile had considered the determining cause. The speaker, in operating upon a hundred cases, had found it very desirable to divide the operation into several stages, and he thought that an estimation of the resisting power of the patient constituted a very importnat surgical factor. He agreed that the local anesthesia was a very important adjunct in eliminating shock.

Dr. W. R. Cubbins of Chicago suggested that the persistence of clinical symptoms in the face of avowed improvement on the part of the patient meant that most of the value from an operative standpoint came from suggestion alone.

Dr. C. W. Mayo of Rochester said that it should be the duty of every surgeon to cause as many "medical deaths" as possible. Thus, particular care had been exercised at the Rochester clinic, not only in the choice of patients, but in the time of operation. Individuals suffering from exophthalmic goiter had well-marked periods of exacerbation and of recession and it was of great importance that the period of greatest inactivity be chosen for operation. He agreed with Dr. Crile and emphasized the value of his work. There were, he believed, unquestionably certain cytolytic changes; a granular breaking up of the tissues of which we as yet knew very little, but which were equally sure of solution in the near future.

Dr. Crile, in closing, thanked the section for the discussion and said that he had wished, particularly, to devise a method of ligation which could be done without danger. He regarded the elimination of the psychic factor and the marooning of the brain as the two essentials in a safe operation. Their employment made possible the ligation of the superior thyroid even when in the most advanced and feeble cases, thus giving a chance to all. The operation broke the pathologic chain and rest cure would prevent its union. This took a year, and no less time should be employed, for it was certain that the cure of a relapse case was far more difficult and hazardous than that of the original disease.

Surgical Management of Suppurative Peritonitis.—Dr. A. D. Bevan of Chicago said that if any man whose chief interests lay in the domain of internal medicine alone, said to the surgeon that medical progress was of late years but little indebted to the art of surgery, no better rebuttal was to be found than in the presentation of the remarkable history of the treatment of peritonitis. This remarkable achievement was to be credited entirely to the clinical surgeon and the development of the work had taken place very largely in the last five years. The surgical treatment might be considered under four heads: (1) saline, (2) rest and starvation, (3) Blake's irrigation, and (4) removal of cause. Considering these in detail, it would be remembered by all that the time was still recent when patients were tortured by the introduction of wholesale doses of concentrated salts in the hope of eliminating the disease factors. Paralytic ilius alone was to be considered the justification for such treatment. Ochsner's treatment was as yet little understood. It favored localization and walling off and prevented generalization. It was therefore not indicated in the class of cases under consideration. As to Blake's irrigation, he regarded the method as excellent if employed after the removal of the cause and if followed by immediate abdominal closure. Enteroclysis, or the so-called drop method of Murphy, held a most important place in the treatment of the disease. All essential was a logical and intelligent employment of the different methods either alone or in combination. An early diagnosis, which meant that it must be made within the first twelve hours, was essential. These, in the very nature of the disorder, must not depend upon distension and other late signs which were evidences of approaching death rather than of the disease; but upon pain, tenderness, and rigidity, which were the real indices of general peritonitis. If a leak existed in one of the hollow viscera it certainly was unsurgical not to close it, and this even at considerable cost of time. A convenient method to determine clinically whether general peritonitis existed or not was to slip gently into the peritoneal fossæ a catheter which might conveniently be used as a pipette. This did no harm, because soft, and with it one could remove for inspection any fluids which might be present. He advocated irrigation, but not by the syphon principle of Blake. The exaggerated Fowler position, he believed, had been responsible for many painful deaths, because of exhausting the patient. In his service, he had as a routine merely elevated the bed. This obtained gravitation for the pelvis and allowed most conveniently of intermittent irrigation, which he considered as good clinically as the drop method and which in his experience was more easily and therefore surely applied by the general average surgical nurse.

Dr. W. L. Rodman of Philadelphia, in opening the discussion, agreed that the essential in this treatment was thorough diagnosis. The saline treatment *per se* had little use in his hands. The Ochsner treatment was in his interpretation of it for the prevention of general peritonitis and was therefore not designed for the treatment of it. As to closure of the causative lesion without subsequent drainage, this did not interest him. Flushing was for the occasional case only. The main stay in the treatment to his mind consisted in bowel irrigation and plenty of it.

Dr. W. H. Wathen of Louisville, Ky., said that the diagnosis and treatment of general peritonitis was not yet agreed upon. He was opposed to irrigation and also saline and cathartics.

Dr. A. J. Ochsner said that the following definite step must be followed, viz., early diagnosis, closure of the opening in the hollow viscus, gastric lavage, rectal irrigation.

Dr. Bevan, in closing, said that the man was a fool who in the presence of threatened peritonitis gave a saline. The one and only condition in which it was indicative was in intestinal paralysis. Blake had shown that many cases might be cured without drainage, and had demonstrated that the dangers of irrigation were theoretical rather than real.

Conservative Surgery of the Pelvic Region and Lower Abdominal Wall.—Dr. F. W. Rae of Atlanta, Georgia, said that surgical victims were as frequent as surgical victories. Neurologists and general practitioners, as well as open-minded gynecologists and surgeons, were agreed that the wave of conservative surgery of the female pelvis, which had swept over the country in the last three years was a most beneficent and timely one. In rebuttal of the falacious teachings of the few remaining radicals in this department the author presented a splendid series of conservative pelvic operations in 16 per cent. of which pregnancy had occurred. This alone, quite aside from the preservation of the woman, which had occurred in 100 per cent. of the conservatively operated cases, was enough to justify the acceptance of the modern treatment. He emphasized the horrible condition of nervous prostration, social ostracism, and absolute uselessness of the women

who in thousands of cases had undergone the easy but destructive operation of total oophorectomy. The author demonstrated a transverse incision for the drainage of pus cases by which the abdomen was entered through the loin very rapidly, satisfactorily, and at a dependent point.

Dr. J. M. Baldy of Philadelphia said that it appeared to him self-evident that the diagnosis of a pelvic lesion, both before operation and at the time of exposure of the parts, was of paramount importance. The operator, therefore, must not only be a good clinician, but must be competent to know what he was looking at when operating. There was no question, be it admitted to his grace of the operating profession, that countless numbers of women were operated upon by improperly qualified persons, whose lesions, whether real or imaginary, properly belonged to the domain of outdoor treatment and rational hygiene.

Dr. McRae, in closing, said that it was aphorismal that the younger the woman, the more necessary and imperative became the saving of ovarian tissue.

Some Further Experience of Drainage of Pelvic Abscess Through the Rectum.—Dr. A. MacLaren of St. Paul, Minn., said that the English had done more work in this important field than we had. Of course the object of the technique was to give the male the same advantages of drainage as was enjoyed by the female through Douglas' cul-de-sac. He had observed that many cases of neglected appendicitis had severe pain in the rectum, and he believed that in opening abscesses at their place of pointing in the rectum we should be only imitating nature and that operation could be done much more safely after relief of pressure than before it.

Dr. J. M. Baldy of Philadelphia said that the cases in which this technique might be indicated, would, it was to be hoped, be exceedingly rare in this day of surgical progress. For the exceedingly small number of cases, which through the neglect or the cupidity of attending physician, got into such condition that this procedure was necessary, the speaker concluded it an excellent one.

Dr. Morris Richardson of Boston said that in the early days of abdominal surgery he had observed many cases of abscess breaking into the intestinal canal. The results were rather uniformly good and it constituted nature's method of healing.

Temporary and Permanent Occlusion of the Large Arteries with Removable Metallic Bands.—Dr. Rudolph Matas in conjunction with Dr. C. W. Allen of New Orleans said that a great many experiments performed under anesthesia on animals by the authors proved conclusively that the blood stream could be interrupted in the arteries as long as 72 hours without damaging the vessels. The occlusion could be obtained with great simplicity and security by approximating the walls of the vessels with an aluminum band. This aluminum band could be removed without difficulty if symptoms or signs of peripheral ischemia and mortification appeared. Advantages of the band over the ligature, especially in dealing with large arteries, were conspicuous. He gave a description of the flat band devised by the authors as a simple substitute for the Halsted rolled band. He also spoke of histological changes in the arteries in various stages of occlusion. The author gave a report of cases in which the bands had been applied in man in carotid, and subclavian arteries, and of the thoracic and abdominal aorta and other arteries in animals.

Dr. Daniel Eisendrath of Chicago said that it was astonishing how long such ischemia as had been discussed by the author would be tolerated by the parenchyma of certain organs. The cortex of a rabbit's kidney will not degenerate until after one hour.

Diagnosis of Mammary Cancer.—William L. Rodman of Philadelphia said that there were many important points to be considered in diagnosing cancer of the breast. As time went on, sarcoma was found to be more scarce even than originally supposed, it amounting to not more than 2 per cent. All growths should be regarded as potentially malignant and retension cysts of all kinds were specifically to be placed in this class. They occurred often in unmarried women between the ages of 40 and 50, were generally diffuse, and were frequently found in the lower and outer quadrant. In the latter, or multilocular cystic stage, they were easily recognized, but in the early stage, it required the microscope to distinguish them. So far as the clinical diagnosis of malignancy went, the older he grew the more he feared to make it, and he was certain that the man did not live who could always be accurate in his conclusions. There was retraction of the nipple in but 52 per cent of cancers, and this sign might easily be present in benign growth. It was therefore valueless and all general practitioners should know this. Surely not more than 75 per cent. of all cases could be safely diagnosed. A microscopic diagnosis could not be made in cystic growths, but was easier in solid growths. Fresh stains and frozen sections in the hands of experienced men gave certain data and could be had in three minutes' time. Removal of any fragments for diagnostic purposes was absolutely faulty technique.

Operative Treatment of Cancer of the Breast.—Dr. Morris Richardson of Boston confidently expressed the cheering belief that we should soon have an effective non-operative cure. At present, however, it could not be too strongly urged upon the general practitioner that operation should be done, even if the suspicion of malignancy was the very slightest, and it was an axiom in his practice to remove all breasts in which there existed any reasonable doubt. The man who says a breast tumor is not malignant assumes a frightful responsibility. As to the extent of the operation it was obvious that the more extensive the better the results, but common sense did not require girdle amputations of the upper extremity. He regarded the value of the statistics as questionable because of the fluctuating conditions under which they were compiled. The three-year limit was of value chiefly in helping to quiet and comfort the patient. For his own part, he had seen recurrences in the spine frequently after the tenth year. Clinically, he regarded diffuse infiltration of the breast rather than the breaking through of the skin as particularly sinister and hopeless. Furthermore, if while operating the glands were found to be at all definitely attached to the vessels or fascia the case might be regarded as hopeless from the standpoint of recurrence.

Dr. Willy Meyer of New York, in opening his discussion, said that the operation was distinctly an American one. The technic was necessarily of two types, either away from the chest or toward it. The latter was gradually coming into vogue.

Dr. Parker Simms of New York said that when one realized that from 80 to 90 per cent. of all breast tumors were cancerous and further when one thought of the tendency of all benign growths to degenerate one was forced to conclude that there were no cases not calling for operation. One sympton he had never seen in print, namely, the elevation of the nipple on the malignant side. This was owing to the shortening in the trabeculae and did not take place in benign growth. It was, of course, an early sign.

Dr. Rodman, in closing, said that upon the general practitioner hung the responsibility of early diagnosis. It was beyond the keen of any surgeon to diagnose involution without the aid of frozen sections.

Physiological Implantations of Severed Ureter or Bile Duct into the Intestine.—Dr. R. C. Coffey of Portland, Oregon, said that an enormous amount of work had been done on this important subject, and that over 250 cases had been published upon it. With the exception of the Matyl operation the results had uniformly been bad.

Because of the character of the intestinal wall in dogs the results in human beings so far as ascending infection went had been more encouraging. He demonstrated an extremely clever adaptation of the natural valve to be found, both in the duodenum and in the bladder, and showed by illustrations how one might easily cut the wall of the viscus down to the mucous membrane and then enter the cavity at the further end of the incision with the ureter or bile duct. Bladders and duodenum distended with water pressure and would not regurgitate after the making of such a valvular anastomosis any more than they would if one used the natural valve. He demonstrated a large number of specimens which showed how admirably this technique had protected the kidneys from infection.

Dr. Arthur Sullivan of Madison, Wis., in opening the discussion, complimented Dr. Coffey on the extraordinary success of his technic and said that the work which he had done at the Columbia Laboratory had taught him the extreme difficulty of accomplishing what Dr. Coffey appeared to have done so easily. His own work, while closely resembling that of the authors, had consisted in an effort to reconstruct the diseased duct and in addition to utilizing a tube in this reconstruction his technic had differed from that just presented in that the valve had consisted of all of the coats of the duct rather than the mucosa alone. He had observed a number of reconstructed bile ducts functionating in dogs for varying periods from several months up to one year.

Dr. J. W. Draper Maury of New York said that he had assisted Dr. Sullivan in his work and took pleasure in corroborating his findings. As to the value of the work presented by these two gentlemen he made no comment, saying it was self-evident. He did make a strong plea, however, for every medical man present—and he hoped every State in the Union was represented—to go home and watch the Legislative proceedings constantly and scrupulously. The antivivisectionists would certainly make an effort this year to force a bill through in some State where the medical work was not active, which bill would be the first fatal step in sealing the progress of this research surgical work. The importance of shelving all such bills could not be overestimated, and the responsibility to the public lay with the medical profession.

Dr. Coffey, in closing, said that he was pleased to hear of Dr. Sullivan's technique and would use it in future in experimental work.

A Further Consideration of Cholecystenterostomy in Certain Cases of Pancreatitis.—Dr. LeGrand Guerry of Columbia, S. C., said that of fifteen cases of chronic appendicitis reported all were confirmed by operation. All were treated by simple drainage. Ten of this number were reopened and permanent drainage instituted. Stone formation was not by any means a constant accompaniment of pancreatitis. Nevertheless, temporary drainage was insufficient if the pancreatic inflammation had progressed to a certain stage. It did not require any very marked obstruction to prevent the outflow of bile. The author had had gratifying results in that all cases treated by permanent drainage had remained well. He regarded the technic as based upon rational foundation and entitled to a larger sphere of usefulness than it at present enjoyed.

Pathology of the Gall-Bladder and Galltract.—Dr. J. P. Runyon of Little Rock, Ark., said that functionally the digestive organs were synergistic. Infection very frequently took place via the portal vein and it was significant that the bile was frequently found infected in pneumonia. He urged the necessity of early diagnosis and operative treatment. He felt certain that gallstones occurred more frequently than usually supposed before middle age and cited in support of this the frequent association of dyspepsia, which at operation was proven to be due to gallstones. The bile salts, of course, were the most toxic constituents of the bile. By the nature of the morphology of the parts occlusion of the common bile duct frequently caused exclusion of pancreatic secretion from the intestine. It was well known by experimental work of Flexner and others that bile was extremely irritating to the pancreas and that its entrance through the gland was frequently followed by acute hemorrhagic inflammation. The function of the bile was well known. Its exclusion from the intestines interfered with the digestion and absorption of fats. The function of the gall-bladder was a double one, viz, to manufacture mucus and to relieve the common bile duct from all pressure.

Inguinal Hernia Following Appendectomy.—Dr. A. M. Pond of Dubuque, Ia., spoke most interestingly on the applied anatomy of the region and discussed the various incisions commonly utilized for the removel of the appendix. It had been proven many times that the integrity of the inguinal canal depended on proper nerve stimulus, and the frequency of inguinal hernia following appendectomy was unquestionably due to the cutting of the nerves supplying the canal.

Teaching the Principles of Surgery; the Ideal and the Practical.—Dr. Martin B. Tinker of Ithaca, N. Y., said that the surgery of the future would be what the man of to-day made it. One predominant fault of present-day teaching was the failure to recognize the relative value of the teachings. The student should be taught the things which all practitioners should know, the simple things, such as the control of hemorrhage, the treatment of nosebleed, of leg ulcer, of minor injuries in general. The ability to do such work and do it properly was the measure of the usefulness of the medical man in his community. His uselessness might equally be measured by his effort to do major surgery before he had attained the necessary qualifications. This in the future should be done only by men who had had proper and long-continued service as hospital internes, as residents, and as assistants to some of the great operators. What was wanted, and the want was a real one, from the Atlantic to the Pacific, was more training in the simple, every-day things, less surgical, technique, and more surgical diagnosis. Nothing could be more erroneous, the author thought, than to teach these young men the newest and, perhaps, as yet, little proved technical surgical procedures. For example, how much more necessary and desirable from the standpoint both of the profession and of the laity that the young graduate should know practical preparation of his hands, of catgut, and of operative field, rather than the size needles which might or might not be employed in the anastomosing of blood vessels. At Cornell the students took great interest in learning the things referred to in the Research Laboratory, and it was indisputable that a man whose hands had been found surgically filthy by himself, after washing in permanganate and surgically clean after the use of Herrington's solution would never forget that lesson. Remembering it would save more human lives than a hypothetical knowledge about aneurysmorrhaphy. Furthermore, the teaching of general anesthesia should be a classroom routine procedure, for every man, no matter what his subsequent predilection and tastes, should have a practical knowledge of this important branch. In conclusion he urged that emphasis should be laid on principles rather than on the presentation of jumbled facts. The teachers should be paid enough to make possible the devotion of the major part of their time to their work rather than to try to practice. The university should control its own hospital where surgical diagnosis rather than treatment should be the keynote of bedside teaching.

Dr. J. C. Stewart of Minnesota, in opening the discussion, spoke of the timeliness of the paper and emphasized

that the glorification of operative surgery had made every student wild to operate. What could be more unfortunate? Every surgeon of large experience knew that to gain this experience he had to sacrifice many human lives. At the time of his novitiate this was unavoidable, but fortunately for all, these times had passed and there was no excuse, either now or in the future, for allowing further sacrifice. There were abundant opportunities throughout the country for all who wished to qualify as practising surgeons, and it was the speaker's hope that the profession would take upon itself the important duty of regulating the matter of surgical practice on its own initiative and before it was forced to do so by leglislative activities. Such legislative activity had been pronounced in at least one State, and at the University of Minnesota arrangements were being made to grant special surgical degrees to qualified students. The degree would be an honorary one; would be based on five years' work and one year's residence in the University Hospital. This, he hoped, would ultimately lead to proper legislation, which should certainly be in the hands of the universities. So far as the teaching went, in his experience, one of the greatest difficulties was the obtaining of proper textbooks.

A Simple Operation for Hemorrhoids without Hemorrhage.—Dr. L. J. Hirschman of Detroit said that in no surgical field was there greater field for the successful operation of quacks and charlatans than that under discussion. It had come to be an accepted dogma with surgeons that internal hemorrhoids could not be operated on except under major anesthesia. He had found that with the double salt of quinine and urea hydrochlorate an anesthesia of the entire region could be easily instituted which permitted of the complete stretching of the sphincter and of the removal of the hemorrhoids, and which lasted from four to five days.

CONNECTICUT STATE MEDICAL SOCIETY.

Annual Meeting, Held in New Haven, May 25 and 26, 1910.

Samuel D. Gilbert, M.D., of New Haven, President.

The Diagnosis of Insanity.—Dr. James M. Keniston of Middletown said that to determine the existence of insanity or a psychosis the examiner should pursue a systematic course, and should get as complete a history as possible. He should find out just what the patient sees and hears, or feels, or smells, and whether things are really what they seem to him. Disturbances of memory should next be noted. Disturbances of the train of thought may be often exhibited and noted during the tests of perception, aperception, and memory. Judgment may be tested in a general way by submitting to the patient various problems concerning proper conduct, morality, business, etc. It is not enough to learn whether he knows right from wrong and the nature of a criminal act. One should ascertain whether he has lost the finer feelings that modern civilization has evolved and society demands. The full fruition of volition depends upon an antecedent idea. Acts performed without a definite idea are not volitional, but reflex. The foregoing details will help the physician to determine the general conduct of the patient and show its deviation not only from his norm, but from the standard imposed to-day by society. After the general practitioner has obtained possession of all these facts, he will be able to demonstrate the existence of insanity. At the Connecticut Hospital for the Insane, up to October 1, 1908, 0.75 per cent. of the patients committed were diagnosed as not insane, a temporary disturbance having been mistaken for a more permanent derangement.

Dr. Max Mailhouse of New Haven said that if the physician would but bear in mind that dementia paralytica often began with neurasthenic symptoms, and would always make his diagnosis by the process of exclusion, he could not go wrong. In those doubtful cases in which one does not know whether to attribute the trouble to insanity or crime, it is of the highest importance to determine whether the conduct and character of the patient deviate from their own norm, as well as from the standard imposed by society. To determine this point, one should question not only his nearest friends, relations, and associates, but also those absolutely disinterested. Dr. Mailhouse considered the large percentage of transitory mental disturbances that had appeared in the State Hospital for the Insane to be a strong argument for the establishment of psychopathic wards in general hospitals.

Dr. William F. Fisher of Middletown said that he had knowledge of only one medical college that afforded instruction in psychiatry, despite the fact that the question of the mental health of a community and its preservation are of vital importance. Were there not abundant evidence of a lack of communion of interests, it would not seem necessary for him to emphasize the necessity of more active cooperation between the alienist and the general practitioner. He considered it no less possible to group the symptoms of the different psychoses so as to afford typical clinical pictures than to group the symptoms of a respiratory or cardiac disease. The study of a mental disease should not be restricted to the minute analysis of the symptoms at some given period, but the entire course of the disease should be studied. One should guard against falling into the habit of seizing upon certain symptoms and ignoring others, and making the clinical picture fit some arbitrary constructed frame.

Dr. George N. Lawson of Middle Haddam said that he had understood Dr. Keniston to say that a man is very often really responsible for his crimes, even though insane. Dr. Lawson thought that the family physician could tell more readily than a stranger whether his patient was insane or not; whether he had passed from his own norm and the recognized standards of the day. In this way the family physician could be of great assistance to the staff of the hospital, particularly if he would send with the certificate of insanity a letter giving minute details of the case.

Instructions to Patients Suffering from Specific Urethritis.—Dr. Percy D. Littlejohn of New Haven stated that in order to overcome the difficulty of not having his instructions accurately followed by such patients, he had prepared some leaflets containing carefully printed directions. He had tried to make the statements therein as terse and clear as possible, to be at the same time emphatic. The following points were particularly emphasized: Gonorrhea is not the slight complaint that many consider it. Alcohol should be strictly avoided by those suffering with this disease. Exercise should be taken, but all forms of violent exertion should be avoided. The nails and hands should be carefully cleansed after handling the gauze dressings. All infected persons should sleep alone, if possible; and all toilet articles should be for the patient's own exclusive use. Particular attention should be given to the alimentary tract, in order to avoid constipation. The drinking of large quantities of water and the free urination produced by this are particularly valuable. Patients in the acute stage must have a milk diet, as far as possible; and all patients should keep reasonably quiet after the day's work is over. The proper technique in the use of the hand injection should be properly explained to the patient. Dr. Littlejohn believed that all cases of anterior infection were curable, and was optimistic regarding the chronic cases, provided his directions were fully followed for as long as necessary. He also believed that such cases would not infect other persons, but he thought that a positive statement to that effect was unjustifiable until all the gonococci could be proved to have disappeared, especially when marriage was contemplated.

Dr. Frank H. Coops of Bridgeport thought Dr. Littlejohn's plan in regard to the printed slips excellent, and said that he would copy them for his own use, making a few changes to suit his individual fancy. For instance, he would put the instruction, "You should drink all the water possible" in bold type. He did not think that when the urethra was washed out every half hour enough discharge would accumulate to require any dressing. He considered it most important from the diagnostic and prognostic standpoint to have the patient come to the office with a plentiful supply of urine in the bladder, and thought that the patient should be instructed as to the meaning of the various urethral shreds, etc. He considered the disease, under the best of conditions, a very difficult one to cure.

Dr. Charles S. Stein of Hartford said that the total elimination of red meat would in some cases retard the patient's recovery by weakening his resistance. He thought that unnecessary handling would increase and continue the local inflammation, and preferred a small piece of cotton as a dressing, rather than a large piece of gauze. He would add as a conclusion to the other instructions, and in heavy type, "Don't stop treatment until you are cured."

Dr. George Blumer of New Haven said that red meats had more extractives than white, and that all meat should be stopped, if any.

Dr. Ralph A. McDonnell of New Haven said that he had been unable to satisfy himself that diet had any influence upon gonorrhea after the acute part of the infection was over. He thought that the drinking of water should be stopped during the latter part of the evening.

Dr. Littlejohn, closing the discussion, said that in telling his patients not to eat red meat he had known that they would not be likely to get any other kind; so they would eat very little meat at all. He considered diet more important in recent cases than in chronic ones.

The Management of Syphilis.—Dr. Alfred G. Nadler of New Haven did not believe that syphilis was on the increase. He said that treatment should be begun as soon as the diagnosis had been made, which would usually be at the first visit or very soon after this. The microscope, he said, would invariably make or confirm the diagnosis of chancre. While the chancre should be excised, if possible, the patient should subsequently be treated just as if this had not been done. The internal administration of mercury should not be resorted to unless conditions prevented the use of inunctions or injections. He considered inhalation one of the best methods. He had had no experience with intravenous injections, but thought that intramuscular and subcutaneous injections had many advantages. They might, however, cause pain, and sometimes left a deposit of mercur·· the sudden absorption of which produced poisonous symptoms. The intramuscular injection of insoluble salts would produce a deposit that was slowly absorbed and slowly eliminated: and would, therefore, have a more profound effect on the deeper manifestations of syphilis. When injected subcutaneously the salts would be absorbed and eliminated more rapidly; and these injections should be used when a prolonged action is required. Dr. Nadler considered the first two years the most important for the patient, but said that active treatment should be pursued for at least five years. He preferred inunctions to injections.

Dr. Ralph A. McDonnell of New Haven had always found it inconvenient to cut the chancre out; and he did not see any advantage in insisting upon this procedure, when he could not promise that it would do any good. He did not find it easy to discover the spirochetæ by means of the microscope, and was not sure that his inability to do so did not work to the advantage of the patient; because he believed that, unassisted, the system would acquire a certain power of opposition to the disease. He preferred to let the patient go untreated for a time, even when he had made the diagnosis. He had given over one thousand injections of an emulsion of metallic murcury without untoward results, and was inclined to prefer this method, by which he had been able to control various late manifestations of syphilis, and even total blindness, after a few injections.

Dr. Thomas M. Bull of Naugatuck said that physicians should be more careful to make a diagnosis of syphilis, because an untold amount of harm might be done by one undiagnosed case. He confessed to a predisposition to giving medicine by the mouth, this being the natural way for anything to enter the blood; and he did not think there was much danger of injuring the digestive tract when the patient was seen frequently and the dose was carefully graded. Although capable of producing the most terrible consequences, he believed syphilis to be the most easily treated of any disease of equal gravity. He would strongly advise anyone who had ever had syphilis to take a month's mixed treatment every year, whether symptoms had developed or not. He considered the best treatment to be prophylactic.

Dr. Charles C. Beach of Hartford said that in treating syphilis successfully it was absolutely necessary to make the diagnosis early. While he admitted injection or inhalation to be the ideal treatment, he said that he never employed either of these. He had obtained sufficiently good results from internal treatment by the mouth, and had found no difficulty in giving the protiodide. He thought that cases of this disease should not be kept as professional secrets, but should be reported with the same care as any other contagious disease.

Dr. Oliver C. Smith of Hartford remarked that the place for such patients was in the hospital, in bed. He thought that they had no right to go around disseminating the disease. Physicians should try to educate the communities in which they practise concerning the importance of these two terrible infections, gonorrhea and syphilis.

Dr. Rienzi Robinson of Danielson asked whether Dr. Nadler would prefer mercurial treatment to the iodide for the tertiary manifestations of syphilis, such as iritis.

Dr. Charles S. Stern of Hartford did not believe that the Wassermann reaction still had the same standing among physicians that it had had a year before. Either positive or negative, it was not to be depended upon.

Dr. Percy D. Littlejohn of New Haven thoroughly concurred in the statement that gonorrheal patients are better off in the hospital, but did not think that syphilitic patients could be kept there.

Dr. Nadler said that the Wasserman reaction was not considered so valuable as formerly, and stated that negative reactions do not indicate a cure of the disease. He would treat the iritis with intramuscular injections of calomel, and give potassuim iodide. He had not considered the sociological question at all in his paper. If the chancre should be located where it could be removed, its removal would eliminate a host of infecting agents. He stated that the spirocheta could be readily discerned under the microscope with the so-called dark-ground illumination.

A Consideration of the Anatomy and Clinical Importance of the Subdeltoid Bursa.—Dr. Paul P. Swett of Hartford stated that lesions of the subdeltoid bursa were more frequent than any other lesions in this region, including fracture and tuberculosis of the shoulder, the exposed position and peculiar function of the bursa rendering it especially liable to inflammation. The vast majority of cases should be treated by excision of the bursa; but in the instances in which limitation of motion did not exist, rest, counterirritation, and massage were usually sufficient. No diagnosis of rheumatism, tuberculosis, paralysis, ankylosis, or neuritis of the shoulder

should be made until the possibility of subdeltoid bursitis had been excluded.

Dr. Ernest W. Arnold of New Haven said that the investigations regarding the subdeltoid bursa were the logical outcome of those regarding the behavior of bursæ in general. In a number of instances in which no great trauma of the knee joint has been received and in which repeated slight trauma from kneeling could not be held responsible for the condition, a chronic inflammation of the patellar bursa had been found. This showed the possibility that these bursæ might partake of the same inflammations that the joint itself was liable to have. All infections leave the bursa permanently thickened, and such a bursa must be not only useless, but a great impediment to the joint. If this impediment is mainly due to the bursa, the latter should be removed. He agreed with the author in thinking that a good many cases of bursitis would clear up under other treatment than operative interference.

Dr. Ansel G. Cook said that all that was true of other bursæ was true of this bursa. He then stated that fixation *per se* had never been proved to cause inflammation of any bursa; but said that if the arm were fixed in such a position as to cause pressure, this pressure would constitute trauma. In giving prominence to this point, his idea was to show that one need not be afraid to fix any of these joints, if necessary. While an inflamed joint would sometimes do better with rest, there were other times when irritation would be desirable.

The Ideal Nose and Pharynx.—Dr. Frederick W. Wilson of Bridgeport stated that the amount of air passing through the nose and pharynx in a year must be reckoned in millions of cubic feet. An obstruction having almost no influence in a single inspiration might have a great influence in a million inspirations. This was also true of nasal cavities that were too large. Expired air has a much lower percentage of microorganisms than has inspired air, most of these organisms having been deposited on the moist mucous membrane of the nose and pharynx, which might almost be called the filtration apparatus of the air. Being subsequently blown onto the handkerchief or expectorated, these organisms rarely breed and do harm if the surface of the nose and pharynx is plane; they must have some hiding places in order to lodge and multiply. The ideal nose and pharynx contain very few of these hiding places, and medical men should be alive to the importance of obliterating any of these that exist by surgical means.

Dr. Dorland Smith of Bridgeport remarked that nasal surgery for the prevention of consumption seemed, at first thought, rather startling. Doctors are used to the correction of large defects in the nose and pharynx, but to make an ordinarily well person perfectly well by paying attention to these small defects constituted a further step in development. The acquisition of a good nose and pharynx would not only give one practical freedom from colds, catarrh, sore throat, and the air-borne diseases generally, but would also give a higher level of health, which almost anyone could get who would take the time and trouble to have done these little bits of surgery that would make the nose and pharynx approach the ideal. He was satisfied that in removing tonsils and adenoids the certainty of permanent cure and ideal end results was to be found, not in thoroughness in extirpating tonsil tissue, but in thoroughness in searching out crypts, pockets, and recesses and converting them into shallow saucers by trimming their edges. In small tonsils it is the pockets and adhesions, and not the smooth tonsil tissue, that make the trouble.

Dr. Wilson said that these small pockets were of importance in influenza, hay fever, asthma, and other minor diseases, but that clinical evidence of their importance in pneumonia, tuberculosis, and other general diseases was needed. This might be obtained with the help of the general practitioner.

The Treatment of Infection Following Abortion.—Dr. Charles A. Monagan of Waterbury stated that the ideal treatment was preventive—the development of a rigid aseptic technique. He considered it unfortunate that the wearing of rubber gloves could not be generally enforced. When the condition was actually present, but before the system had become loaded down with bacteria, the uterus should be curetted with a blunt curette, and intrauterine douches would be of service. He had found the results of the use of antistreptococcic serum disappointing, the same being true of the autogenous vaccine treatment, the application of hyperleukocytosis, and the use of unguentum Crédé. Ergot did good by contracting the uterus and preventing further infection. The supporting treatment used in fighting any toxic condition should be employed. Salt solution in large quantities was the best single means of controlling the sepsis. Opening into Douglas' pouch and packing with iodoform gauze had been advocated; also hysterectomy, for cases that failed to improve after curettage in cases caused by the presence of a suppurating tumor. In septic peritonitis, multiple incisions, thorough drainage, and the constant use of saline rectal infusions offered the best means of treatment. A collection of pus, when located, should be opened and drained.

Dr. Samuel M. Garlick of Bridgeport was far from convinced that every maternity case should have the same preparation and management as an abdominal section would require. He thought that women were often brought to the verge of a nervous breakdown by the anticipation, worry, and fear engendered by such elaborate, detailed, and expensive preparations. His hospital experience had so often shown him the bad effects of indiscriminate and routine curettage that he was sometimes inclined to wish that it had never been introduced. With the different methods of treatment mentioned by the author, Dr. Garlick had either had no experience or a bad one.

Dr. Ralph W. Crane of Stamford remarked that Dr. Monagan and Dr. Garlick had detailed one method of treatment after another and pronounced them all good, and that the fact was that, as Dr. Monagan had said in his opening sentence, the treatment was prevention.

Dr. Thomas G. Sloan of Hartford mentioned the case of a woman who had died of puerperal septicemia, and said that it was impossible to discover any way in which she could have been infected. Her mother and sister had died in the same way. Where the infection came from, unless from the vagina, could not be determined.

Dr. Allen H. Williams of Hartford said that if the patient realized that perfect cleanliness would insure her recovery, he did not think that care of that sort would scare her. The meaning of these precautions should be carefully explained.

The Surgical Treatment of Gastric and Duodenal Ulcer.—Dr. Everett J. McKnight of Hartford stated that the surgical treatment of gastric and duodenal ulcer and their complications showed a higher percentage of permanent cures than could be produced by medical treatment alone. None of the complications or sequelæ, with the exception of hemorrhage, occurred early in the disease. He considered it a question whether a perfectly healed, nonindurated scar following ulcer ever gave rise to further trouble. The healthy stomach, having the same tendency to recover from injuries caused by traumatism as any other healthy organ, some extra factor must be at work in cases that did not recover; and investigation pointed to hypersecretion and hyperchlorhydria as the most important factors in preventing the normal process of repair. He thought that the beneficial effects of a gastroenterostomy were due to a regurgitation of biliary

and pancreatic secretions into the stomach, thus neutralizing to some extent the excess of hydrochloric acid, rather than to better drainage of the stomach. Perforation is more frequent when the ulcer is situated on the anterior wall, and the results of operation performed within a few hours after this accident are exceedingly good. The patients should be watched carefully after the operation until a sufficient time has elapsed to enable the attendant to be absolutely certain that a permanent cure has been effected.

Dr. Oliver C. Smith of Hartford said that it took a reasonable length of time to determine whether medical treatment would be successful or not. After that, the ulcer became a surgical disease. He referred to the fact that conditions lower down sometimes developed symptoms so similar to those of gastric ulcer as to be confused with it, and said that the fact that carcinoma often developed on the basis of a gastric ulcer emphasized the importance of early operation. That it was not possible to tell before operation just what condition one was dealing with argued, Dr. Smith said, for more frequent resection of the portion of the stomach bearing the ulcer. In all operations of this kind, he said, a soluble material should be used for sutures of the inner coat.

Dr. Edward W. Smith of Waterbury said that it was very unusual to find in the same patient a healed ulcer of the stomach and the production of symptoms of pyloric stenosis due to conditions lower down in the intestines. He reported such a case, and said that one should look out for the vermiform appendix also when a gastric ulcer is present.

Dr. William H. Carmalt of New Haven thought that Dr. McKnight had not made so much of the symptomatology of supposedly cured cases as he should have, and stated that the condition of relief obtained from a course of medical treatment was not a cure, but simply a temporary improvement. When several such series of symptoms as those described had occurred in a patient, Dr. Carmalt said, he considered it time to cease medical treatment and look to surgery.

Dr. William F. Verdi of New Haven called attention to the fact that a difference existed between a chronic and a perforating ulcer. The symptoms of the latter, not usually being severe, the patients are able to continue at work, and are usually seized with perforation while at work. They suffer intense pain, which calls for immediate relief. In chronic ulcer, the patients have a long train of symptoms, going on for years, and there is not much danger of perforation, on account of the formation of adhesions.

Dr. Louis M. Gompertz of New Haven stated that ulcers of the stomach and duodenum were much more common than is usually supposed. When patients complain of pain on an empty stomach, relieved by eating, and then coming on again within two to four hours, one should be suspicious of the presence of an ulcer of the pylorus or lower down. When an early diagnosis is made, acute ulcers are sometimes benefited by medical treatment, but not a chronic ulcer.

Dr. McKnight said that all physicians were coming to feel that for ulcer of the stomach resection or partial gastrectomy was the operation of choice, on account of the large number of cancers that develop on the basis of ulcers. He had operated on more cases of appendicitis simulating gastric disease than on gastric ulcers, so that he did not consider these cases so rare as Dr. Edward Smith believed. Regarding Dr. Verdi's distinction between the two classes of ulcers, Dr. McKnight remarked that it would not always hold, for he had seen a case of chronic ulcer with sudden perforation in a man of fifty-five years.

(To be continued.)

INDEX.

A.

Abbe, Robert, radium as a specific in giant cell sarcoma, 1 40.

Abdomen, care in closing wounds of, 249; contusions of and indications for early operation, 293; indications for immediate opening of, in acute cases, 120; position of patients after operation on, 163; surgery of, 716; watersheds of, and their influence on the localization of intraperitoneal infections, 678.

Abdominal viscera, diagnosis of lesions of, 786; reflex pain in diseases of, 635.

Abortion, treatment of infection following, 1113.

Abrams, A., spondylotherapy in pertussis, 588.

Abscess, cerebellar and labyrinthitis, 937; cerebellar, with sinus thrombosis, 535; costochondral, from paratyphoid infection, 1106; pelvic, drainage of, through the rectum, 1109; psoas, 815; tuberculosis of bony origin, treatment by conservative methods, 547; tuboovarian, with interstitial ectopic pregnancy, 123.

Abstinence, a case of prolonged, 1106.

Acetonuria in infectious diseases, 976.

Achondroplasia, 1035; in a twin, 315.

Achylia gastrica and Raynaud's disease, 410.

Acid-fast bacilli in distilled water, 203, 601.

Acne, cultural characteristics of the microbacillus of, 1023.

Acromegaly, operation on the hypophysis in, 322; with mediastinal tumor, 427.

Actinomycosis, of cervicospinal region, 581; of cheek following injury by dental instrument, 954; of cheek, recovery, 556; of lung, 555, 947.

Adenitis, tuberculous, 936.

Adenocarcinoma of the corpus uteri, 123.

Adenoids and tonsils, 975.

Adiposogenital hypophysis syndrome, 548.

Adnexa, appendicitis and diseases of, 109.

Adrenals, total absence of, 288.

Aerophagia, 460.

Aitken, C. S., and Jackson, J. A., report of a case of thrombosis of the left iliac vein, probably due to pressure of distended bladder, 284.

Alabama, Medical Association of, 843.

Albuminuria, constipation, 978; family, 679; frequency and significance of in normal children, 985; postural in a boy subject to chorea, 163; unilateral orthostatic, 977.

Alcohol, effects of in dermatology, 210; effect upon gastric secretion, 112; influence in diseases of the skin, 310; influence on trauma, 1020; in its economic aspects, 1034; injections in trifacial neuralgia, 735; use of, in its moral aspects, 1034.

Alcoholism and offspring, 1098; nondetention in the treatment of, 919; prevention of, 1033.

Alimentary canal, external examination of, 375.

Alkaptonuria, a case of, 877.

Allen, William, contact infection in amebiasis, 63; studies in amebiasis, with a report of forty-two cases, 1092.

Alopecia, two cases with arrest of development localized on the cranial vault, 681.

Aluminum, phosphate, antidote for, 620; silicate, in diseases of the stomach, 334.

Amebæ, at Baguio, 846; in the stools of pellagrins, 72.

Amebiasis, contact infection in, 63; study of, with report of 42 cases, 1092.

American Association of Medical Journal Advertisers, 1100.

American Climatological Association, 931.

American Dermatological Association, 800.

American Gastroenterological Association, 1059.

American Journal of Physiologic Therapeutics, 969.

American Medical Association, address of welcome, 1028; election of officers, 1068; oration in medicine, 1030; President's address, 1025, 1028; reduction of membership dues, 112; report of the board of trustees, 1025; report of the committee on anesthesia, 1027; report of committee on award of medals, 1067; report of the committee on Davis memorial, 1026; report of the committee on medical legislation, 1025; report of the committee on ophthalmia neonatarum, 1026; report of the committee on organization, 1027; report of committee on organization of council on public health, publicity, and legislation, 1027; report of the committee on scientific exhibits, 1027; report of committee on sections and section work, 1027; report of the committee on uniform regulation of membership, 1027; report of the council on defense of medical research, 1026; report of the council on medical education, 1026; report of the general secretary, 1025; report of the judicial council, 1025; report of postgraduate work, 1026; report of the public health education committee, 1067; report of reference committee on insignia, 1067; report of the reference committee on medical education, 1027; report of reference committee on medical legislation, 1067; report of reference committee on officers, 1067; report of reference committee on reports of officers, 1027; resolutions, 1068; resolutions on the death of Dr. Ricketts, 1067; suggested reforms in, 156.

American mortality statistics, 927.

Amputation, for diabetic gangrene, 722.

Amyotrophic lateral sclerosis, 171.

Anaphylaxis, relation to artificial immunization, 854.

Anasarca in an infant, 507.

Anderson, P. V., personal experiences with a few cases of pellagra, 531.

Anemia, aplastic, 640; aplastic pernicious, 409; changes in the central nervous system in, 944; infantile, in relation to the hygiene of the school, 109; of the central nervous system, symptomatology, and pathology of, 398; peculiar sickle-shaped forms of red blood cells in, 985; Momberg's method of artificial, by suprapubic constriction, 945; pernicious, 211, 763, 984; pernicious, improved by large doses of hydrochloric acid, 425; pernicious, pigmentation of the buccal mucosa in, 767.

Anesthesia, a practical method, for the removal of tonsils and adenoids, 795; Bier's vein, 1103; cutaneous, 547; electric, 709; experimental and clinical researches into introus oxide and ether anesthesia, 295; local, 599; local in general surgery, 225, 253; local, in the ear, 632; rectal, 849; report on, in England, 802; spinal, 164, 496, 717; spinal, death from, 679; sudden death from, status lymphaticus, 160; surgeon's responsibility in, 1064.

Aneurysm, rupture at the first symptom of, 367; thoracic, in a boy, 235; thoracic, treated by Abrams' method, 881; wiring of aortic, 471.

Angina pectoris, 116, 763, 802; causation of, 246; certain popular but erroneous notions concerning, 1031; hysterical, 1020; nature and treatment of, 205; Osler's Lumleian lecture on, 675.

Angiomata, treatment of, 599.

Angioneurotic edema, 743.

Animal experimentation, 162.

Ankle, sarcoma of, 39.

Anomalies and some points for the surgeon to bear in mind, 668.

Antibodies, the formation of, 854.

Antiseptic surgery, modern, 677.

Antitoxin, diphtheria, intramuscular and intravenous injections of, 420; tetanus, 375.

Antityphoid inoculations at the Massachusetts General Hospital, 202.

Antivivisection, argumentation, 282; new tactics in, 538; proposed in-

vestigation of laboratories, 541; the first gun of the campaign, 21.
Anuria, lasting five days in a child of three years, 986; nonobstructive, 161; obstructive calculous, 160.
Aorta, thoracic, experimental surgery of, 898.
Appendectomy, inguinal hernia following, 1110.
Appendicitis, 118, 253, 803; advantages of neglect in, 167; and diseases of the adnexa, 109; conditions simulating, 252; congestion at base of right lung as an early sign of, 942; deceptive form in women, 384; dyspeptic type of chronic, 333, 591; four unusual cases of, 256; from the viewpoint of the clinician, 244; in children, 252; in children, with report of 500 cases, 1069; in infants and children, 512; in Malmö, 291; latent, 543; masked, 252; protective, 41; review of 2,000 operations for, 206.
Appendicostomy, for amebic dysentery, 299; some therapuetic adaptations of, 296.
Appendix, analysis of 1,411 operations on, 252; cancer of, 946; latent disease of and its connection with gastric hypersecretion, 634; treatment of localized abscess, 599.
Arkansas Medical Society, 886.
Arm, the carrying angle of, its mechanism and importance, 813.
Army, and navy endurance tests, 625; medical relief units in war, the tactical management of, 408; medical service, 678; physicians in command of, 798; venereal diseases in, 452.
Arterial wall, resistance to compression of, 984.
Arteriosclerosis, climacteric and preclimacteric, a consequence of internal secretory disturbances, 1054; of the uterine vessels, 1032.
Artery, femoral, suture of, 808; temporary and permanent occlusion of, with removable metallic bands, 1109.
Arthritis, 933; acute of doubtful origin, 851; chronic, 506; deformans, 766; deformans following typhoid fever, 419; forms of, 716; of knee drainage by incision behind the condyle, 808; tuberculous, the nonsurgical treatment of, 598.
Association of American Medical Colleges, 542.
Association of American Physicians, election of officers, 983.
Association of French Physicians of North America, 931.
Asteriognosis, 172.
Asthma, pituitary extract in, 933; treatment by adrenalin, 1022; *x*-ray treatment of, 978.
Asylums Board in London, 972.
Ataxia, cerebellar, 923; Friedreich's, 858.
Athetosis, 172.
Athletics and changes in the cardiovascular system, 574.
Atrophy, muscular, and tabes, a case of, 877.
Auscultatory percussion, value and proper method, 590.

C.

Caisson disease, etiology of, 840; prophylaxis and therapy of, 937.
Calcium, abstraction of, from the mother by the fetus the cause of fatty infiltration of the liver, 545; and eclampsia, 196; and magnesium, action of on the animal body, 109; effect upon the blood, 543; in tuberculosis, 417; lactate in the nose and throat, 625; permanganate in gastritis and enteritis, 75; salts in the treatment of epilepsy, 237.
Calculi of kidney, 1070; of kidneys and ureters, 460; of kidneys, surgery of, 381; recurring vesical, 258; salivary, 536; ureteral, 1079; ureteral, complicating prostatic obstruction, 726; vesical, 1063.
Calhoun, J. C., report of a case of acute hemorrhagic pancreatitis, with autopsy, 579.
California Association for the Study and Prevention of Syphilis and Gonorrhea, 502.
Cammidge reaction, 329, 334, 471, 1101; a study of its value, 640; in relation to diseases of the pancreas and ductless glands, 982.
Camphorated oil, in treatment of peritonitis, 938; poisoning, 807.
Canada, cold storage in, 372, 890; letters from, 372, 717, 889, 1016, 1060; medical officers of militia of, 68; rabies in, 372; tuberculosis crusade in, 24.
Canadian Hospital Association, 717.
Canadian Medical Association, 372; official journal of, 1018; milk commission of, 1016; President's address, 1016.
Canadian Society of Superintendents of Training Schools, 1015.
Canal Zone, health in, 712, 929, 1099.
Cancer, bacterial treatment of, 974; Bernato memorial hospital, 933; body weight in, 1099 commission in Harvard, 969; cures in America, 943; duty of medical profession to women with, 251; effect of serum in mice, 766; etiology based on clinical statistics, 943; experimental diminution of resistance to, in mice, 766; frequency of, 170; Hospital Research Institute, 545; in rats and mice, 414; intestinal fermentation and, 1014; is radium a cure for, 76; Massachusetts statistics for, 1905, 974; of alimentary canal, pathological relationship to ulcer, 1072; of appendix, 946; of ascending colon, 298; of breast, diagnosis of, 1109; of breast, operative treatment of, 1109; of gall-bladder and its relation to gallstones, 295; of gastrointestinal tract, 343; of larynx, 601; of liver, with misleading *x*-ray plate, 683; of pylorus, 317; of rectum, diagnosis of, 680; of rectum, review of 120 resections for, 943; of sigmoid, early diagnosis of, 274; of uterus, 123; of uterus, a clinical study, 1103; pelvic transplantation metastases, 552; prophylaxis of, 1068; radium and, 457; recurrence in, 24; sensitization in, 974; specific treatment of, 459, 760; specificity of, and the general principles of its treatment and prophylaxis, 1065; statistics of, 849; treatment of, 992; treatment by radium, 973; treatment with body fluids of a recovered case, 359, 932; urinary findings in, 889.
Carbon dioxide snow, 937, 1019; blotting paper moulds for obtaining crayons of, 855; in treatment of nevi, moles, etc., 332; local application of, 332.
Cardiorenal lesions, experimental, 985.
Cardiospasm, chronic, treatment of, 420.
Cardiovascular apparatus in nephritis in children, 1096.
Card system for recording histories in private practice, 622.
Carnegie Foundation, Report of, 1097.
Carrel, Alexis, experimental intrathoracic surgery by the Meltzer and Auer method of intratracheal insufflation, 491.
Carriers, bacillus, 506; meningococcus, 326.
Carroll, F. J., the uninstructed victims of tuberculosis, 328.
Carter, H. S., diagnosis of lesions of the abdominal viscera, with especial reference to their functional integrity, 789.
Cataract, congenital, is it caused by dystocia, 321; curious arrangement of the capsule of the lens after extraction, 495; operation on the insane, 581; prevention of prolapse of the iris after cataract operation without iridectomy, 508; scleral collapse during operations, 537.
Catgut, iodine, 419; uses of in surgery, 120.
Cavitation, hypertension and, 1023.
Cecostomy, some therapeutic adaptations of, 296.
Cecum, torsion of the movable, 583.
Cellular activity; an epitome of rational medicine, 775.
Central nervous system, anemia of, 398; changes in, in infections, hyperthyroidism, anemia, and shock, 944.
Cerebellar, abscess, and sinus thrombosis, 535; abscess and acute suppurative labyrinthitis, 937; ataxia, 923; dysergia, a method of estimating, 729; tumor, successful operation for removal of, 601.
Cervix, manual dilatation of by Harris's method, 123; rigidity of treatment in obstetrics, 805.
Cesarean section for placenta previa, 971; for puerperal eclampsia, 171; strength of the uterine scar after, 243; technique of the old method of conservative, 709.
Chancre, treated by hot air, 244.
Chancroid, phagadenic, treated by hot air, 244.
Chapin, H. D., the limitations of the caloric method of infant feeding, 910.
Charles Graham medical research fund, 116.
Chauffeur's fracture, 436.
Cheese poisoning, bacterial findings in, 548.
Chemotherapy of infectious diseases, Ehrlich's theory, 416.
Chetwood, C. H., end results following operations for prostatic obstruction, 698.
Childbirth, the aftermath of, 505.
Child welfare exhibition, 454.
Children, circulatory failure in acute infections in, 935; contagion in hospitals for, 197; delinquent, in England, 154; facial hemiatrophy in, 39; fracture of long bones in, 720; intestinal strangulation in, 29; physiology of growth and nutrition in the tropics, 761; position of the apex beat in, 237; pulmonary tuberculosis in, 1105.
Chloral hydrate, the local use of, 67.
Chlorosis, treatment of, 75.
Cholecystenterostomy in certain cases of pancreatis, 168, 1110.
Cholemia, congenital family, 1099.
Cholera, Asiatic, 105; and other similar vibrios encountered in the Philippines, 760; in the Philippines, 201; nitritis, nitrous acid, and nitrous oxide as the poisons in, 120; treatment of, 760.
Chorea, latent, 75; postural albuminuria in a boy subject to, 163.
Chorioepithelioma, 943; of the testis, 634.
Choroiditis, dependent upon appendicitis, 117.
Chyluria, nonparasitic, 978.
Cirrhosis, alcoholic in a boy of four, 459.
City, hygiene of the dweller in, 49.
Clark, C. P., and Tyson, H. H., horizontal oscillation of the eyeball in certain rare types of pontine lesions resulting in seventh nerve palsy, 5.
Claytor, T. H., the more liberal diet in enteric fever, 1051.
Clean hands, the importance of, 66.
Cleaves, M. A., cellular activity, the epitome of rational medicine, 775.
Climacteric arteriosclerosis, 1054.
Coagulation time of the blood, 755.
Coal mines and tanneries, germicidal action of water from, 672.
Cocaine poisoning, ether in, 591.
Cocainism, 744.
Cold storage in Canada, 372, 890.
Colds, nasal douche in, 587; protest against the nasal douche for, 629.
Colic, renal, 289.
Collins, Joseph, letters to a neurolo-

gist, second series, 18, 105, 192, 275, 361, 448.
Colon, affection of, 34, 373; bacillus, infection of the urinary tract, 251, 907; inoperable endothelioma of, 468; medical aspects of affections of, 34; new pathognomonic diagnostic sign in neoplastic stenosis of, 516.
Color blindness, 414; futility of the official tests for, 418.
Columbia University, the medical school of, 156.
Compression, abdominal, effect of in a case of very rapid heart, 635.
Conjunctivitis, a new bacillus of, observed in Singapore, 761.
Connecticut Society of Alienists, 239.
Connecticut Society of Social Hygiene, 931.
Connective tissue, contractive elements in, 374.
Constipation, chronic, 444; in infancy, 1012; in women, embryological and anatomical causes of, operative methods for relief, 1076; treatment of, 973.
Contact, the sense of, and the genesis of pleasure and pain, 517.
Contagion, in hospitals for children, 197.
Contagious diseases, guarded against by preliminary examination of dispensary children, 770.
Convulsions, salaam, 769.
Cook, F. R., the action of intermittent *x*-rays on general metabolism and chronic degenerative diseases of the eye, 779.
Cornell, new infirmary for, 239.
Corpus, cavernosum, plastic induration of, 590; luteum, function of, 1083.
Correspondence, Berlin, 242, 416, 457, 803, 934; Canada, 372, 717, 889, 1016, 1060; London, 28, 70, 116, 159, 200, 241, 285, 328, 371, 414, 456, 503, 543, 588, 630, 675, 716, 763, 802, 847, 887, 933, 971, 1018, 1062, 1101; Paris, 286, 458, 804, 972, 1019; the Philippines, 201, 459, 504, 718, 763, 845, 934; Vienna, 418, 887, 1102.
Coughlin, R. E., the athletic life in its relation to degenerative changes in the cardiovascular system, 574.
Coxa vera, 888.
Craig, H. A., six cases of pneumonia in the aged, treated with pneumococcus vaccine, recovery, 259.
Crandall, F. M., medical practice laws, a review of certain phases of the legal regulation of medical practice, 611.
Cranial flap, 591.
Crepitus, respiratory, 1064.
Cretin, six months of age, 857; unusual manifestations in, 7.
Criminals, juvenile, medical inspection of, 454; sterilization of, 1066; sterilization of in Canada, 890.
Crotalin as a therapeutic agent, 111.
Crothers, T. D., cocainism, 744.
Cyclophoria, a case of, 547.
Cysts, two ovarian dermoid, 85.

D.

Daltonism, 851.
Dana, C. L., the modern views of heredity, with the study of a frequently inherited psychosis, 345.
Davis, E., the importance of correct diagnosis of diseases of the eye, 177.
Davis, E. P., placenta previa, 1037.
Deacon, E. M., a case of puerperal septicemia, treated with diphtheria antitoxin—recovery, 64.
Deaf child and the physician, 74.
Deafmutism, remains of verbal hearing in, 1054; some remarks on, and the methods of treatment, 637.
Deafness, responsibility of the general practitioner and specialist in the prevention of, 589; sudden, during eclampsia, 507.
Delavan, D. B., a report on some of the laryngological work of the British Medical Association and of the XVI International Medical Congress in 1909, 173.
De Lisle, J., serodiagnosis of syphilis, Wassermann test, 233.
Dementia precox, 545; partial thyroidectomy in, 1107; the recognition of, 874.
Dentistry, general therapeutics and surgery in, 417; in schools, 327; school hysteria, 505.
Derelicts, human, 324.
Dermatological manias and phobias, 632.
Dextrocardia, a case of, 1095.
Diabetes, a case remaining cured for 10 years, 681; a sympathetic neurosis rationally treated with electricity, 954; aural, nasal, and throat symptoms in, 633; gangrene, 578; interpretations of the metabolic defects upon the basis of the theory of intracellular ferment action, 982; myelogenous leukemia with, 426; the abstractions of the calcium salts of the lipoids circulating in the blood for the purpose of neutralization of the organic acids, the cause of lipemia in, 795; therapeutic significance of pilocarpine glycosuria in sugar-free, 426; unsuspected, a cause of rapidly fatal coma, 330; urine in, 546; with a favorable course, 419.
Diagnosis, mistaken, based upon an analysis of 1,000 autopsies and comparison with clinical findings, 1030.
Diarrhea, chronic, due to pyloric insufficiency, treated with hydrochloric acid, 288; compensatory, 315; in infants, 795.
Diathermia, operations with, 767.
Dietetic, principles, modern, their practical application, 849; theories in America, 75.
Digestion, essentials of the physiology and pathology of, 649; relation of bacteria to, 320; rôle of lactalbumin in milk, 451.
Digestive functions, correlation of the, 287.
Diphtheria, a simplification of Neisser's stain for, 767; antitoxine, in treatment of puerperal septicemia, 64; antitoxine in the treatment of infective endocarditis, 164; bronchiolitis obliterans following, 420; further experiments on the production of active immunity in guinea-pigs by mixtures of toxine and antitoxine, 983; in children, 687; laryngeal, 331; malignant, in an infant, 926; nasal, 110; presence of toxines circulating in the blood, 851.
Disen, C. F., some anomalies and points for the surgeon to bear in mind, 668.
Disinfection, 847; of skin by iodine vapor, 722.
Disintoxication in treatment, 1020.
Dislocation, congenital, of hip, treatment during infancy, 155; of the os innominatum, 945.
Diver's paralysis, 119.
Diverticula, acquired intestinal, 204; esophageal, surgical treatment of, 897; of alimentary canal, 419.
Douche, nasal, in common colds, 587; protest against, 629.
Dowd, J. H., the Dowd Phosphatometer for taking the phosphatic index or pulse of the nervous system, 1054.
Drainage, extroperitoneal, after ureteral anastomosis, 297.
Dream states, psychoses and, 238.
Dreams, relation to neuroses, 805.
Drennan, J. G., the abstraction of the calcium salts of the lipoids circulating in the blood for the purpose of the neutralization of the organic acids, the cause of lipemia in diabetes mellitus, 795.
Drink habit; non-detention an all-important factor in the treatment of, 919.
Drug habits, bulletin on, 799.
Drugs, standardization of, 112.
Dullness, false, at right apex, 591.
Duodenal tube, 161.
Duodenum, abnormal position of, 942; contents, a practical method of obtaining, 98; contents, examination by means of the Gross duodenal tube, 879; contents in man, 1029; foreign bodies in, 419; ulcer of, 241, 286, 807; ulcer of, perforated, 708; ulcer of, pathology, treatment, and prophylaxis of, 1104; ulcer of, surgical treatment of, 1113.
Dysentery, amebic, 374; amebic, appendicostomy for, 299; amebic, in New York, 835; bacteriology of, in the Philippines, 763; infantile bacteriology, 331; treatment with silver nitrate, 805.
Dyspepsia, appendix, 333; causes and treatment of functional, 635.
Dystocia, as a cause of congenital cataract, 321; due to the cord, 322.
Dystrophy, congenital muscular, 81; muscular, with hemophilia, 773.

E.

Ear, chronic catarrhal otitis media and otosclerosis, 637; intracranial complications of middle ear disease, 1064; local anesthesia in surgery of, 632; non-suppurative affections of the internal, 638; prominent, 415; some interesting cases of foreign bodies removed from the, 72; treatment of chronic catarrhal otitis media and otosclerosis, 638.
Earache, causes of, 1082.
Early case, 325.
Eastern Medical Society of the City of New York, 26.
East Side Physicians Association, 26.
Eccles, R. G., natural selection and our viscera, 993.
Eclampsia, calcium and, 196; cesarean section for, 171; decapsulation of the kidneys in, 281; sudden deafness during, 507.
Edema, acute pulmonary in cardiac disease, 471; angioneurotic, 743; neonatorum, 548.
Effusions, pleural, 850.
Einhorn, Max, a new gastroscope, 1011; a practical method of obtaining the duodenal contents in man, 98.
Eising, E. H., a surgical accident, necessitating intestinal resection, 407.
Elbow, reconstruction of, after fracture of the lower end of the humerus, 814.
Electric spark and diathermia, operations with, 767.
Electrical activities of the human body, 1102.
Electricity, in treatment of diabetes mellitus, 954.
Electrocardiograms, demonstration of, 981; in clinical diagnosis, 980, 1071.
Elsberg, C. A., the value of continuous intratracheal insufflation of air (Meltzer) in thoracic surgery, with description of an apparatus, 493.
Embolism, mesenteric, 461; of pulmonary artery with typhoid fever, 428; pulmonary, some clinical aspects of, 848.
Emigration, transoceanic in 1908, 450.

Empyema, treated by antiseptic plugging, 418.
Endocarditis, acquired at 16 months of age, 858; autogenous vaccine therapy in, 1074; etiology of subacute infective, 940; infective, complicating pregnancy, 246; infective, treated with antidiphtherial serum, 164; of pulmonary valves, 946.
Endometrium, infectious, 1031.
Endothelioma of brain, 601; inoperable, of colon, 469; meningeal, enucleation of, 296; of stomach, effects of *x*-ray treatment, 683; ovarian, 548.
England, general election, 241, 285; the delinquent child in, 154.
Enteritis, calcium permanganate in, 75.
Enteroptosis, cause of, and relation to rheumatoid disease, 1020; symposium on, 1076.
Enterostomy, its technique, 381.
Enuresis, 331.
Environment, heredity and, 1055.
Enzymes, protein digesting, distribution of in the body, and their part in some pathological processes, 982.
Eosinophilia, diagnosic value of, 208.
Epidermidolysis bullosa congenita, 678.
Epilepsy, death in, 49; national association for the study of, 931; periodical vomiting and migraine, 746; surgical treatment of, 296; the rôle of cerebral lesions in infancy and childhood in the causation of, 266; treatment with calcium chloride, 237; unusual aura, 721.
Epithelial proliferation from scarlet red, 894.
Epithelioma of the lip, radical treatment of, 203.
Epstein, S., spondylitis deformans, with a report of several interesting cases, 188.
Ergot, the peculiar province of, 182; the tissue density factor in relation to, 285.
Erysipelas, therapeutic value of hyperemia, 32; two cases of nonfebrile, 507.
Erythema, multiforme gestationis, 595.
Eshner, A. A., and Wood, A. C., actinomycosis (streptothricosis) in man; with the report of a case of pulmonary involvement, 947.
Esophagus, diagnosis and treatment of lesions of, 1107; spasmodic contraction of, in a child, relieved by gastrostomy, 69; surgical treatment of diverticula, 897.
Esperantists, sixth international congress of, 629.
Ethyl dichloride and iodine in sterilization of the skin, 1066.
Eugene Meyer, Jr., Fellowship, 584.
Eugenics and Mendelism, 839.
Evans, W. A., hygienic principles of ventilation, 870.
Exanthemata, throat symptoms of, 466; exercise, correlation of respiration and heart beat during, 676; functional in some nervous diseases, 729.
Exomphalos, 120.
Exostoses accompanying syringomyelia, 505.
Expectoration, serous, 334.
Exudates, differeniation from transudates, 453.
Eye, action of *x*-rays on chronic degenerative diseases of, 779; affections in the insane, 986; growth of, after iridectomy in early life, 1066; importance of correct diagnosis in diseases of, 177; in idiocy, 765; muscle paralysis in exophthalmic goiter, 641; of the newborn, bacteria in, 602; paralysis in tabes, 765; phlyctenular affections of, 806; some conditions of, due to diseases of the upper respiratory tract, 1066; troubles of early life, 101; tuberculosis of, 339, 340, 341, 342, 343.
Eye-ball, horizontal oscillation of, in pontine lesions, 5.

F.

Face, hemiatrophy of, in a child, 39.
Far-Eastern Association of Tropical Medicine, 157; election of officers, 935.
Fat and its uses, 633.
Fats, estimation in milk, 407; in food, effects on mother's milk, 407; rôle of, in treatment of disorder of the stomach, 21, 28, 74.
Fatty, acids in infants' stools, 333; degeneration in arterial hypertension, 1105.
Fear, the use of, in preventive medicine, 545.
Feces, examination of, 249; of infants, clinical significance of curds in, 330; some new tests for examination of, 553.
Fees, medical, 27.
Fellowship, Beit research, 70; Eugene Meyer, Jr., in pathology, at Mt. Sinai Hospital, 584; Mary Putnam Jacobi, 25.
Fernandez, F. M., cataract operation on the insane, 581.
Fernandez, J. S., curious arrangement of the capsule of the lens after the simple extraction of cataract, 495.
Ferris, A. W., the economics of state care of the insane, 911.
Fetus, development of the viscera of, 548.
Fever, from thirst, in infants, 929; hysterical, 735.
Fibroids, myomectomy, complicating pregnancy, 551; submucous, 545; treated by radium, 548.
Fibroid tumor from Gartner's duct, 201.
Fibrolysin, 371.
Fibrosis, generalized, prophylaxis, and cure, 72.
Filaria hematochyluria, 806.
Finger tone, observations regarding, 58.
Fishberg, Maurice, the psychology of the consumptive, 654.
Fistula, biliary, 942; biliary, therapeutic utilization of, 118; cecal, elevation of the pelvis for, 291; intestinouterine, 537; radiological diagnosis of, with bismuth, 804.
Flatulence, 849.
Fletcher, Dr. Robert, a gold medal for, 712, 802.
Flexner, Simon, portrait of, 158.
Flick, L. E., the crux of the tuberculosis problem, 830, 856.
Flies as typhoid carriers, 499; blue color and, 344; control of, and prevention of disease, 677; dissemination of disease by, 677.
Floating heads, 508.
Foot and mouth disease, serum-therapy, prophylaxis, and vaccination for, 32.
Foote, E. M., tapping the pleural cavity, 235.
Foreign bodies in the duodenum, 419; in the intestines, 294.
Fourth International Sanitary Conference of the American Republics, 411.
Fourth of July, a safe and sane, 498.
Fox, H., personal observations on the skin lesions of pellagra, 228.
Fracture, chauffeur's, 250, 436; of extremities, 30; juxtaepiphyseal of the upper ends of the humerus and femur and their treatment, 686; method of overcoming shortening of the old fractures treated by the open method, 944; of humerus, reconstruction of elbow after, 814; of long bones in children, 720; of patella, 181; of ulna, splint for, 245; open treatment of, 1070; Pott's operation for correction of deformities following, 1036.
Fridenberg, Percy, conceptual factors in vertigo and nystagmus; a study of balance reactions, 704.
Friedman, G. A., the early diagnosis of carcinoma of the sigmoid, report of a case, 274.
Friedreich's ataxia, 858.
Fright, brain of a man who died after, 946.
Fulguration, value in gynecology, 938.
Fuller, Eugene, the surgical management of urethral stricture and its complications, 569.

G.

Gallant, A. E., therapeutic drainage in the 185 cases of uterine obstruction, presenting a new fenestrated rubber uterine drain, 661.
Gall-bladder, pathology of, 1110.
Gall-duct, pathology of, 1110; physiological implantation into the intestines, 1109.
Gallstones, formation of, 848; pathology and diagnosis of, 689; with reference to cancer of the gall-bladder, 295.
Gangrene, amputation for diabetic, 722; diabetic, 578.
Gärtner's duct, fibroid tumor from, 201.
Gas bacillus infection treated by proximal injections of hydrogen peroxide, 71.
Gastric juice, digestive or alimentary hypersecretion of, 983.
Gastritis, calcium permanganate in, 75; obliterative, 556.
Gastroenterostomy, clinical results of, for non-malignant disease, 1073; use and abuse of, 1013.
Gastrointestinal surgery, 293.
Gastrojejunostomy, secondary, 294.
Gastroptosis, 933; and enteroptosis, the cause of, and relation to rheumatoid disease, 1021; atonic, 415; treatment of, 976.
Gastroscope, a new, 1011.
Gastrostaxis, 1105; does it exist as an independent disease? 1023.
General Medical Council, 1062.
Genitalia, prolapse of, in primipara, 333.
Germany, medical statistics of, 457; vaccination and smallpox in, 1011.
Gibbs' fund for research in kidney disease, 25.
Gillman, George, the principles and technique of the Wassermann reaction, 958.
Givens, A. J., is insanity increasing? 616.
Glanders, in man, treated with autogenic vaccine, 250.
Glands, ductless, Cammidge reaction in relation to, 982.
Glare, its cause and effects, 290.
Glaucoma, infantile, 547; small flap incision for, 1018.
Globulin reaction in diseases of the nervous system, 938.
Glycosuria, management in elderly persons, 460; surgical treatment of certain cases of, 893.
Goelet, A. H., the significance of leucorrhea, 786.
Goiter, certain surgical aspects of, 1107; exophthalmic, 891, 1063; exophthalmic, blood examination in, 462; exophthalmic, diagnosis of, 295; exophthalmic, in a child, 785; exophthalmic, lymphocytosis in, 1066; exophthalmic, treated with the milk of thyroidless goats, 851; exophthalmic, ophthalmoplegia following, 728; exophthalmic, paralysis of extraocular muscles in, 641;

exophthalmic, symposium on, 1060; intrathoracic, 384.
Goldman, A., cancerous and non-cancerous pyloric obstruction, 317.
Golf as a factor in the public health of a community, 498.
Goodheart, S. P., the recognition of dementia precox, 874.

Perineum, repair of central laceration of levator ani and, 595.
Periostitis of epicondyle of the humerus, 462.
Peritonitis, acute suppurative, from a ruptured pus tube, 295; diffuse secondary, 295; influence of the abdominal watersheds upon localization of, 678; of the upper abdomen, diagnosis and treatment of, 764; originating in pouches of the large intestine, 461; present treatment of, 380; prevention of, and the harm done by cathartics, 373; suppurative, 590; suppurative, surgical management of, 1109; treatment with camphor oil, 938; tuberculous, 528; tuberculous, a case of, 511; tuberculous, a case of a child remaining cured twelve years after operation, 599.
Perry, M. L., the rôle of cerebral lesions in infancy and childhood in the causation of epilepsy, 266.
Pertussis, diagnostic value of the leucocytosis in, 976; precision in treatment of, 23; spondylotherapy in, 588.
Peter, L. C., the use of tuberculin in ophthalmic practice, 14.
Phagocytosis, and Arneth's blood picture, 333; influence of narcotics on, 507.
Pharmacopœal convention, 326.
Pharmacopœia, its present status and coming revision, 208; the father of the, 975; the next, 796.
Pharynx, lesions of, in hemiplegia, 291; the ideal, 1113.
Philadelphia, Academy of the Natural Sciences, 25; bureau of health, 67; College of Physicians of, 114; County Medical Society, 239; Pediatric Society, 240.
Philippines, cholera in, 201; intestinal parasites in, 202, 504, 845, 1020; letters from, 201, 459, 504, 718, 763, 845, 934; unsolved health problems peculiar to the, 846.
Philosophy of a physician, 967.
Phipps' Institute, 24, 199, 842.
Phlyctenular affections of the eye, 806.
Phosphatometer, Dowd's, 1054.
Phosphorus poisoning, 246; hemolytic free fatty acids in the liver in, 1066.
Phrenitis prostatica, 1071.
Phthisiophobia, 832, 856.
Physician, philosophy of a, 967.
Pigmentation of buccal mucosa in pernicious anemia, 767.
Pilocarpine, 447.
Pineapple, therapeutic use of, 924.
Pituitary body and the therapeutic value of infundibular extract in shock, uterine atony, and intestinal paresis, 31; extracts in hay fever, asthma, etc., 932; extract, in treatment of postoperative shock, 76.
Piper methysticum or kava, and its effects in gonorrhea, 417.
Placenta, experimental production of, 1083; previa, 1037; previa, cesarean section in, 971.
Plague, adrenalin in treatment of, 766; eradication and prevention of, 759; infection in wood rats, 237; resolutions on, 935; rôle of cattle in the spread of, 583.
Pleasure, genesis of, and the sense of contact, 517.
Pleural cavity, tapping of, 235; effusions in, 86, 850.
Pleurisy, different forms of mediastinal exudative, 1074; intrapleural injections of sterilized air in effusions, 86; traumatic, 977; tuberculous, 30.
Plumbism, treated by permanganate, 977.
Pneumococcus septicemia with hemoglobinuria, 508.
Pneumonia, atypical, 631; clinical history of, 201; fatal factors in, 663; migrans, 75; of the aged, strychnine in, 921; of the aged, treated with vaccine, 259; postoperative, 213; retention, 332; traumatic, 977; twenty-four, forty-eight, and seventy-two-hour attacks in children, 701.
Pneumoperitoneum, with a means of diagnosis, 633.
Point tying, a case of modern, 72.
Poisoning, bichloride, in the vagina, 235; bismuth, 258; calomel, 1077; cheese, 548; cocaine, ether in, 591; camphorated oil, 807; ergota flora in milk, 677; lead, treated by permanganate, 977; magnesium, 1031; phosphorus, 246.
Polar hygiene, 711.
Polioencephalitis, relation to infantile paralysis, 927.
Polioencephalomyelitis, variability in the lesions of, 418.
Poliomyelitis, 418, 419, 936, 1022, 1105; after treatment of 85; animal pathology of, 980; early stage of, 32; epidemiology of, 980; etiology of, 120, 808; experimental, 209, 376, 462; experimental studies on the etiology of, 161; failure of nerve anastomosis in, 721; immunizing serum for, 710; infectiousness and contagiousness of, 37; nature and mode of infection of the virus of, 1106; of upper extremities, 728; pathology of, 980; prophylaxis of, 978; possible method of infection in, 1063; relation to polioencephalitis, 926; symposium on, 84; symptomatology and diagnosis of, 85; treatment of the early stage of, 120.
Politzer, A. to his American pupils and friends, 370.
Pollock, L. F., and Jewell, E. B., situs viscerum inverus totalis, 152.
Polonium, 456.
Polygraph, a simple and inexpensive portable, 140.
Polyp, nasopharyngeal, diagnosis and treatment of, 1019.
Polyserositis, rheumatic, 507.
Pompholyx, effective treatment of, 505.
Pontine lesions causing horizontal oscillation of the eyeball and seventh nerve palsy, 5.
Poor laws commission in England, 329, 503.
Posture in diagnosis of tricuspid disease, 500.
Potassium permanganate as a local caustic, 419.
Pottenger, F. M., immunity in tuberculosis considered from both the experimental and clinical standpoint, 1042.
Pott's disease, fracture, dislocation accompanying, 422; treatment of, 251.
Pregnancy, and typhoid fever, 374; blood pressure in the toxemia of, 848; convulsive toxemias of, 553; ectopic, 497; ectopic, recognition and treatment of, 133; fibroid tumors in, 891; infective endocarditis complicating, 246; interstitial ectopic, and tuboovarian abscess, 123; lactosuria during, 753; pain sensibility during, 344; rapid development of tumors during, 195; ruptured tubal, time of operation, 598; simulated tubal, 375; unilateral twin tubal, 551.
Preliminary examination of dispensary children, 770.
Preparetic states, 974.
Prevention, an ounce of, 330.
Preventive medicine, some phases of the evolution of, as illustrated by the present campaign against tuberculosis, 391; use of fear in, 545.
Preventorium, 113, 238, 541.
Prevertebral triangle, 1074.
Primipara, prolapse of the genitalia in late, 333.
Prize of the International Dairy Federation, 968; Seaman of the Military Service Institute, 113; Weber-Parkes, 972.
Proctitis as a cause of hemorrhoids, with suggestions for medical treatment, 1094.
Proctoclysis, 678.
Prolapse of genitalia in late primipara, 333.
Prostate, treatment of hypertrophy, 591.
Prostatectomy, end results of, 726; per-

meal, 685; preparation of patients for, 383; suprapubic in two stages, 726; transvesical, 805.
Prostatic obstruction, end results following operation for, 698; ureteral calculus complicating, 726.
Pruritis ani, value of Ball's operation for, 462.
Protein, peculiar, in urine, 806.
Pseudoperitoneum, 289.
Pseudotyphoid fever, 429, 641, 754, 755, 1087.
Psoriasis, treatment of, 678.
Psychiatry and the general practitioner, 665.
Psychoneuroses, 1061.
Psychosis, a frequently inherited, 345; albumin reaction in blood of, 938; and dream states, 238.
Psychotherapy, hypnotism and, 457; in relation to the general practice of medicine and surgery, 597; suggestion in, 373.
Pubiotomy, 675; justifiability of, 634.
Public Health and Marine Hospital Service, 236; report of the Surgeon-General, 671.
Public health, golf as a factor in, 498; increased cost of living and, 279; problems, 1064.
Puerperal sepsis, endowment for the study of, 157; treated with diphtheria antitoxin, 64; treatment of, 334; uselessness of local treatment in 1032.
Purpura, hemorrhagica, serumtherapy in, 642; relation of blood platelets to bleeding in, 1072.
Pus tubes, in the male, 73; ruptured, with acute suppurative peritonitis, 295.
Pyelonephritis, vaccine treatment in, 290.
Pylorospasm, operation for, 1098; rectal instillations for, 291.
Pylorus, benign obstruction of, 1008; cancerous and noncancerous obstruction of, 317.
Pyorrhea alveolaris, vaccine treatment of, 119, 202.

Q

Quarantine, resolution on, 934.
Quinine, malaria and, 893.

R.

Rabies, 506; in Canada, 372; in Indiana, 964; skunks as transmitters of, 711.
Racial deterioration, increased cost of living in relation to, 323.
Radium, 1070; as a specific in giant-cell sarcoma, 1, 40; cabinets, 458; cases treated with, 803; effects and use of, 119; in cancer, 76, 457, 973; injection of solution of, 1022; in treatment of nevi, 508; local applications of, within the body, 74; ultrapenetrating rays in treatment of salpingo-oöphiritis, fibromata, and sclerosis of the uterus, 548.
Raynaud's disease and achylia gastrica, 410.
Rectum, anesthesia per, 849; cancer of, diagnosis of, 680; diseases of, in relation to pelvic disease, 720; drainage of pelvic abscess through, 1109; examination of, as a routine measure, 230; malignant tumors of, 287; modified technique for the combined operation of extirpation of, 460; resection of, for cancer, 943.
Recurrent larvngeal nerve, suture of, 170.
Red Cross Society, New York State Committee for, 198.
Redfield, H. H., pilocarpine, 447.
Remineralization in faulty metabolism, 461.
Research, Beit fellowship for, 70; defense society, 928.
Resistance, sense of, in diagnosis, 966.
Respiration, artificial in new born infant, 1065; correlation to heart beat during exercise, 676; diaphragmatic, in heart disease, 967; graphic studies of disturbances of, 640; intrathoracic insufflation method of Meltzer and Auer, 477, 483, 491, 493, 510, 586, 715, 1106.
Rest in tuberculosis, 66.
Retropharynx, inflammatory and suppurative conditions in infants, 460.
Rhabdomyoma of kidney, 661.
Rheumatism, chronic, the commoner forms and treatment, 634; inoculation of bacterial vaccines for, 203; local injection of sodium salicylate in, 679; pathology of, 1105; tonsillectomy for, 508; tuberculous articular, 798.
Rheumatisms, the, their etiology and prognosis, 210.
Rheumatoid, arthritis, treated by thyroid extract, 547; disease, relation of gastroptosis and enteroptosis to, 1020.
Rhode Island Medical Society, 1059.
Ribs, cervical, operative removal of, 382.
Richter, Geo., examination of urine at the bedside, 275; and Weinsberg, Chas. H., a case of dextrocardia, 1095.
Ringworm, treatment of, 332.
Robinson, Beverley, in memoriam, Dr. Andrew H. Smith, 882; the care of common colds and the nasal douche, 587.
Robinson, Byron, urourcter from neoplasm, 579.
Rockwell, A. D., a case of angioneurotic edema, 743.
Rose, A., necessity for scientific medical nomenclature, 751.
Rosenheck, Charles, cerebellar ataxia, with report of a case, 923.
Rosenwasser, C. A., nondetention an all-important factor in the treatment of the drink habit, 919.
Roth, Henry, the pathology and diagnosis of gallstones and diseases of the biliary system, 689.
Royal Society of Medicine, 159.
Runner's cramp, 247.
Rupture of both quadriceps extensor cruris tendons, 722.
Russell, W. L., the care and commitment of insane persons by health officers, 144.

S

Sacroiliac joint, 598.
Salaam convulsions, 769.
Saline solutions, effect of concentrated on the human body, 985.
Salivary calculi, 536.
Salpingitis, pain in, due to adhesions of sigmoid to tube and broad ligament, 166; treated with gonococcus vaccine, 405.
Salpingo-oöphoritis treated by radium, 548.
Sarcoma, giant cell, radium as a specific in, 1, 40; inoperable, 244; of ankle, 39; of bone, 896; of kidney, case of a woman well 18 years after operation, 600; of long bones, a plea for more conservative treatment, 288; primary of spleen, 331; visceral, 563, 600.
Satterthwaite, T. E., some newer conceptions of myocardial disease, 821.
Scapula, scaphoid, 861.
Scarlatina, and measles, double infection with, 1096; an immunizing subinfection in, 894; antistreptococcus therapy in, 1097; contagion and semiology of, 322; prophylaxis with streptococcus vaccine, 459.
Scarlet-red and epithelial proliferation, 894, 1106.
Schley, W. S., local anesthesia in general surgery, 225.
School dentistry hysteria, 505; hygiene, relation of infantile anemia to, 109; hygienics, third international congress of, 501.
Schools, open air, 815; physical training in, in New York, 24; ventilation in, 370.
Schizomycetes, demonstration and study of spores of, 1065.
Sciatica, deep perineural injection for, 1037.
Scleral collapse during cataract operations, 537.
Scleritis, etiology of, 340.
Scleroderma, 379; with sclerodactyly, 728.
Scoliosis, automodeleur of Menecière, treated with pneumatic pressure, 753; progressive, treatment of, 961.
Scopolamine and morphine as a preliminary to a general anesthetic, 385.
Sea water treatment, 118.
Semilunar cartilages, displacement of, 245.
Seminal vesicle infection, treatment of, 974; operation for tuberculosis of, 287.
Septic infection consequent on mastitis, 245.
Septicemia, following submucous resection of the nasal septum, 156; puerperal, a case with unusually high temperature, 683; puerperal, uselessness of local treatment in, 1032.
Serological differentiation between the blood of different men, 894.
Serum, antimeningitis, 1058; for poliomyelitis, 710; injections in hemoptysis, 76.
Serumtherapy, of foot and mouth disease, 32; in purpura hemorrhagica, 642.
Seventh nerve palsy, in certain rare types of pontine lesions, 5.
Sewage, metropolitan commission on, 454; pollution of streams, 710; the disposal of, 65.
Sexual cycle, mechanism of in the female organism, 1083.
Shock, changes in the central nervous system in, 944; in early life, 497; postoperative treated by pituitary extract, 76; surgical, 296; therapeutic value of infundibular extract in, 31; vasomotor relations of, 383.
Sigmoid, malignant tumors of, 287; resection and anastomosis for obstruction, 469; some anomalies of, 383.
Siler, J. F. and Nichols, H. J., observations on pellagra at the Peoria State Hospital, Peoria, Ill., 87.
Simonds, J. P., three years of rabies in Indiana, 964.
Sinus thrombosis complicated by cerebellar abscess and purulent leptomeningitis, 535.
Sinuses, accessory nasal, 811; operations on suppurating, 407.
Sinusitis frontal, 244.
Situs viscerum inversus totalis, 152.
Skin, preparation of for operation, by means of dichloride of ethyl and iodine, 1066; relation of the nervous system to diseases of, 1063; some idiopathic cases simulating syphilis, 722; sterilization by tincture of iodine, 296, 1106; the influence of alcohol in, diseases of, 310.
Skull, depression of in newborn infant, 893; operative intervention for fracture of the base, 944.
Skunks as transmitters of rabies, 711.
Sleeping sickness (See Trypanosomiasis.)
Smallpox in Germany, 1011; in the United States, 884; leucocyte formula in, 258.
Smith, Joseph and Neff, M. L., Freud's views on the mechanism of hysteria, 573.

Smokers, gastric juice of, 76.
Snake venom, as a therapeutic agent, 111.
Social, phenomena, an interpretation of some of our present day, 724; welfare, council for, 588.
Society of Directors of Physical Education in Colleges, 68.

Status lymphaticus, 160.
Stengel, Alfred, actinomycosis of the cheek following injury by a dental instrument; recovery, 954.
Stenosis of colon, new diagnostic sign of, 516.
Sterilization of skin with iodine, 806.
Stimulation, abuse of, during and after operations, 384.
Stokes-Adams disease, 344.
Stomach, contents in infants, 892; contents in smokers, 76, 243; diagnosis of secretory function of, by the *x*-ray, 808; effect of alcohol upon secretion, 112; endothelioma of, effects of *x*-ray treatment of, 683; hemolytic substances in contents, 808; hour glass, 722; hypersecretion and its connection with latent disease of the appendix, 635; influence of perigastric lesions upon secretion of, 1073; living creatures in, as a cause of chronic dyspepsia, 419; motility tested by the *x*-ray, 508; olive oil in hyperchlorhydria, 80; relation between the tone, acid production, and position of, 894; rôle of fats in treatment of disorders of, 21, 28, 74; sarcomata of, 563, 600; shape of, 938; splashing sound of, 403; treatment of discases of, with aluminum silicate, 334; ulcer, diagnosis and treatment of, 10; ulcer, Finney's operation for perforated, 468; ulcer, medical treatment of, 206; ulcer, pathology, treatment, and prophylaxis of, 1104; ulcer, perforated, 468; ulcer, perforated, in an hour-glass stomach, 722; ulcer, subacute perforation in a boy of eight years, 71; ulcer, surgical treatment of, 1113; ulcer, treatment of perforated, 680
Stomatitis, abortive mercurial and cuneiform lacunæ of the teeth, 497.
Stone searcher, an irrigating, 321.
Stools, examination of, in treatment of intestinal indigestion in children, 82; of the new-born, 885; quick method of examining, 270.
Streams, sewage pollution of, 710.
Streptococci, effect of injection of killed, in the living body, 984.
Streptococcus infections, of the throat, 792; with symptoms of empyema, 815.
Streptothrichosis, 588; complicating tuberculosis of the kidney, 726.
Stricture of urethra, congenital, 322; surgical management and complications, 569, 594.
Stridor, expiratory, in tuberculosis of bronchial lymph glands, 626.
Strunsky, Max, the treatment of progressive scoliosis, 961.
Suggestion, narcosis, 540; the mainspring of hypnotism and psychotherapy, 373.
Suppositories, nutrient, 928.
Suprarenal extract, in asthma, 1022; in osteomalacia, 669; in plague, 766; intravenous use of, in cardiac and vascular collapse, 31.
Surgery, abdominal, 716; difficult problems in, 766; early abdominal, 417; elements of success in, 516; experimental, of heart and aorta, 898; infantile, different aspects according to age, 497; modern antiseptic, 677; of joints, 1060; of the vascular system, 899; teaching the principles of, 1110; thoracic, differential pressure in, 31; uses of catgut in, 120.
Surgical junk, demanding further surgical interference, 166.
Suture, human hair as, 289; of femoral artery, 808.
Sweat glands, structure of, in a case of chronic nephritis, 981.
Symbiosis and *B. influenzæ*, 937.
Syphilis, acquired in a hereditary syphilitic, 764; adequacy of the present-day treatment, tested by the occurrence of syphilitic nervous diseases, 209; adult of lung, 146; and the negro, 546; cerebral, 892; cerebrospinal, 769; comparison between clinical infection and experimental inoculation, 117; congenital, of heart, 941; cutaneous, 118; experimental, action of mercury and iodine in, 808; hereditary, causing a form of spasmodic paralysis, 172; management of, 1112; means by which mercury acts on the serum reaction, 938; meningeal, 859; nervous diseases, 805; of kidneys, 584; of liver, 633; of throat, 465; potassium chlorate in the serodiagnosis of, 164; practical points in treatment and clinical history of early, 976; serodiagnosis of, 233, 255, 257, 344; significance of *Treponema pallida* in the diagnosis of, 420; some idiopathic cases of the skin simulating, 722; treatment in the light of recent investigations, 334; treatment with quinine, 164; visceral, polymorphism of, 1023; Wassermann reaction in different periods of, 390.
Syringomyelia, coupled with multiple exostoses, 505.

T

Tabes dorsalis, and iritis, 590; and muscular atrophy, 877; differential diagnosis of, 765; ocular palsies in, 765; meningitis and diseases of the radicular nerves in, 556; treatment of, 256.
Taboparesis, the pathological prodromes of, 219.
Talmey, Max, ophthalmic instrument case, sterilizer, and tray combined, 360.
Tanneries and coal mines, germicidal action of water from, 672.
Tebbetts, J. H., the care of the mammary glands, before, during, and after the puerperium, 1093.
Teeth, cuneiform lacunæ, a manifestation of abortive mercurial stomatitis, 497.
Teething, 601.
Temporal bone, infantile types of, and their surgical significance, 461.
Tendo-Achillis, bursitis of, 841.
Tendon rupture of both quadriceps extensor cruris, 722.
Tennessee State Medical Association, 800.
Teratoma of kidney, 601.
Test meal, and feces examination, 249; some new tests for, 553.
Testis, chorioepithelioma of, 634; lymphatics of, 461.
Tetanus, antitoxin, 375, 598; cephalic, 1065; seat of infection in the uterus, 719; treated with carbolic acid injections, 75; treatment by magnesium sulphate, 721; with bacilli in the inguinal glands, 71; with point of infection the cavity of a tooth, 319.
Tetany, Chvostek's symptom in older children, 808; in a child 11 months old, 769; significance of the facial phenomenon, 1103.
Texas, State Medical Society of, 969.
Thalamus, the optic, 29.
Thalmic syndrome, 305.
Thayer, A. E., and Turck, R. C., the diagnosis and treatment of intestinal protein indigestion, 521.
Thirst fever in infants, 929.
Thomas, W. S., the chauffeur's fracture, 436.
Thompson, W. G., visceral sarcomata, cases of sarcoma of the stomach, heart, mediastinum, etc., 563.
Thompson, W. H., acute, subacute,

and chronic infection of the kidneys and of other organs by the bacillus coli, 907; spasmodic contraction of the esophagus in a child, relieved by gastrostomy, 69.
Thoracic index in pulmonary tuberculosis, 1096.
Thorax, differential pressure in surgery of, 31; surgery of, in human beings, 897.
Throat, calcium lactate in, 635; involvement in exanthemata, 466; streptococcus infections of, 792; symposium on symptoms of, in general diseases, 465; symptoms in typhoid fever, 467; syphilis of, 465; tuberculosis of, 466.
Thromboses, multiple, with typhoid fever, 428; of iliac vein, due to distended bladder, 234; sinus with cerebellar abscess and leptomeningitis, 535.
Thymus gland, function of, 1056; surgery of, 624; treament of certain diseases with, 417.
Thyroid gland, and antithyroid preparations, 329; extract, in the treatment of rheumatoid arthritis, 547; extract treatment of infantile wasting, 893; galvanization of, and the menstrual function, 109; significance of various enlargements of, 891.
Thyroidectomy, partial, in dementia præcox, 1107.
Tibia, transplantation into the femur, 726.
Tick fever, mechanism of infection in, 163.
Tinnitus and vertigo, division of the auditory nerve for, 172.
Tobacco smoke, effect upon gastric secretion, 243.
Tongue, a case of tic of, 171; significance and incidence of smooth atrophy of the base of, 639.
Tonsils, and adenoids, 975; indiscriminate enucleation of, 117; management of hemorrhage during operations on, 623; modern views concerning diseased, 12; relation to infectious diseases, 508.
Tonsillectomy for rheumatism, 508; with special reference to recent points in technique, 1063.
Tooth, retention of, 681; tetanus from cavity of, 319.
Toronto, high rate of infant mortality in, 157; Pasteur institute for, 369; typhoid fever in, 372.
Torticollis, differential diagnosis, 422; theory, technique, and results of psychomotor reeducation in convulsive, 422.
Trachea, diseases of, 811.
Trachelorrhaphy, 720.
Trachoma, 73; chlamydozoa in, 894.
Training school for nurses, 249.
Transfusion of blood, in pellagra, 806; the therapeutic possibilities of, 1005.
Transplantation of bone, 726, 807.
Transudates, differentiation from exudates, 453.
Transurethral operation, 937.
Trauma, influence of alcohol on, 1020.
Tremor, mercurial, 728.
Tremors, a contribution to the study of, 209.
Treponema pallidium, 1021.
Triceps, ruptured by direct violence, 161.
Trichinella spirilis, 766.
Trichiniasis, 204; clinical aspect of fifty-two sporadic cases of, 984.
Tricuspid disease, posture in the recognition of, 500.
Tropical medicine, 630; observations on various subjects of, 845.
Trypanosomiasis, 200, 414; excessive liability of European women in Africa to, 205; experimental, 206; in Uganda, 367; Royal Society's Commission on, 1101; Sir D. Bruce's return, 588; treatment of, 759.
Trypsin ferment in the stools of babies, 601.
Tubercle bacilli, acidfast and semiacidfast, 936; action of the products of, on lymphatic organs, 712; destruction of, in a flowing stream, 1023; identification in the sputum by the double method of Ellermann, Erlandsen, 32; in dust, 876; in the blood, 155; transformation of the human to the bovine type, 333.
Tuberculin, human and bovine, in treatment of acute phthisis, 851; in scleritis, 340; suppurative bone and joint disease, 942; reaction, influence of acute febrile processes upon, 938; treatment with large doses, 420; use of, in ophthalmic practice, 14.
Tuberculosis, alimentary régime for, 973; among the Filipinos, 845; anatomical inquiry into the pathway of infection, 721; associated clinics in New York, 368; bovine, the question of, 1056; campaign against, in Philippines, 504; commission on control of domestic animals, 239; committee on prevention of, 541; contagion by dry dust, 497; crusade in 1909, 112; crusade in Canada, 24; crux of the problem, 830, 856; heredity as a factor in the etiology of, 891; histological modification of the medulla of bones, 132; hospital infection of, 893; immunity in, considered from both the experimental and clinical standpoint, 1042; in Australia, 1004; in Berlin, 934; in Bulgaria, 882; in Denmark, 888; in Greece, 745; in Ireland, 946; in milk, 887; legal rights and, 197; local hospital sanatoria for, 873; modern campaign against, as illustrating some phases of evolution of preventive medicine, 391; Newfoundland Society for the prevention of, 895; phthisiophobia, 832; psychology of the consumptive, 654; resolution on, 935; risk of infection in hospitals, 933; rôle of the physician in the campaign against, 280; sanatoria in Sweden, 860; senile phthisis, 591; traumatic, 977; typhobacillosis of Landouzy, 218; uninstructed victims of, 328; variation of temperature during the menstrual period, 547; what the fight against it has accomplished, 838; with periodical hemorrhages from the bowel, 358.
Tuberculosis, adenitis, 936; arthritis, nonsurgical treatment of, 598; arthritis, pathology and treatment, 210; articular rheumatism, 798; bronchopneumonia after gastroenterostomy, 679; meningitis in the aged, 681; myocardial, 946; of eye, diagnosis and treatment of, 339, 340, 341, 342, 343; of knee joint, with new theory and plan of treatment, 1069; of mouth and throat, 466; of nose, primary, 1104; of seminal vesicles, operation for, 286; osteomyelitis of the right metatarsus, 39; peritonitis, 528; peritonitis, a case of, 511; peritonitis, a case of a child remaining cured twelve years after operation, 599; pleurisy, 36; pulmonary, a clinical course in, 674; pulmonary, clinical significance of subfebrile temperature in, 208; pulmonary, etiology, and underlying causes of, 149; pulmonary, in children, 1105; pulmonary, thoracic index in, 1096; renal, 287, 431; renal, complicated by streptothrix infection, 726; ulcers of stomach, 546.
Tuberculosis treatment, abscess, by ferments, 888; abscesses of bony origin, treatment by conservative methods, 547; by alternate use of human and bovine tuberculin, 851; by calcium, 417; by intravenous injections of nuclein, 528; by mercury, 73, 590; injection of the salts of mercury and arsenic during the reaction period following tuberculin injections, 1104; meat diet in, 926; rest in, 66; surgical vaccine treatment of, 250, 251; work cure in, 709.
Tumor, bladder, unusual type of, 167; brain, 900; brain, gradually developing hemiplegia in, 900; brain, removal of, 972; brain, surgery of, 471; bridge of nose, 857; cerebellar, successful operation for removal of, 601; cerebellopontine, 85; fibroid, complicating pregnancy, 891; fibroid from Gartner's duct, 201; fibroid, treated by *x*-ray, 681; iliopsoas, 720; intraspinal, 766; malignant and nonmalignant of bilateral origin, 418; malignant, development of, 808; malignant, of sigmoid and rectum, 287; mediastinal with acromegaly, 427; ovarian, bilateral, with uterine tumors, 771; ovarian, strangulated in a child, 906; rapid development of during pregnancy, 195; rats, feeding experiments in, 937; spinal cord, some recently described symptoms of, 438; spinal cord, surgery of, 471; uterine, frequency and dangers of, 973; uterine, frequency of adenocarcinoma in fibroids, 205; uterine, treatment of fibroids, 250; uterine with bilateral ovarian tumors, 771.
Turck, F. B., hyperchlorhydria, 261.
Turck, R. C., and Thayer, A. E., the diagnosis and treatment of intestinal protein indigestion, 521.
Tuttle, A. L., successful treatment of a case of specific salpingitis with gonococcus vaccine, 405.
Typhoid bacilli, in butter, 789.
Typhoid fever, a case of unusual duration, 683; affections clinically simulating, 1087; and pregnancy, 374; an infant as a carrier of, 332, 978; arthritis deformans following, 419; blood cultures in, 505; Brill's disease resembling, 429, 641, 754, 755; carriers, 632; carriers, man and the fly as, 499; carriers, treatment of, 1074; causes determining the eruption in, 462; discussion of before the Paris Academy of Medicine, 458; epidemiology of, 196; in Eastern Massachusetts, 673; in Montreal, 157, 372; in Toronto, 372; influence of water supplies on death rate, 755; initial hemorrhagic exanthem, 548; macroscopical laboratory methods, 761; more liberal diet in, 1051; mouth and throat symptoms of, 467; noma in, 39; prevention of, 453; reduced mortality in, 159; renal suppuration in, 70; simple test for, 410; skin hemorrhages, 1066; treated by typhoid vaccine, 1074; use of formalized cultures for the agglutination test, 243; vaccination against, 202, 582; vaccine treatment in, 643, 984; with multiple thromboses, infarcts of lung, and embolism of pulmonary artery, 428.
Typhus fever, 851; infectivity for monkeys and mode of transmission, 409.
Tyson, Dr. James, dinner to, 842.
Tyson, H. H. and Clark, L. P., horizontal oscillation of the eyeball in certain rare types of pontine lesions resulting in seventh nerve palsy, 5.

U.

Ulcer, duodenal, 241, 286, 807; duodenal pathology, treatment and prophylaxis of, 1104; duodenal, perforated, accompanied by chronic appendicitis, 708; duodenal, surgi-

cal treatment of, 1113; gastric, of cardia, 85; gastric, diagnosis and treatment of, 10; gastric, Finney's operation for, 468; gastric, medical treatment of, 206; gastric pathology, treatment, and prophylaxis of, 1104; gastric, perforated, 468; gastric, perforated, in an hour-glass stomach, 722; gastric, subacute perforation in a boy of eight years, 71; gastric, surgical treatment of, 1113; gastric, treatment of perforated, 680; gastric, tuberculous, 546; of alimentary canal, pathological relationship to cancer, 1072; of face and fauces, treated by bacterial vaccines, 290; *x*-ray, cured by Hilton's method, 75.
Ultraviolet rays in therapeutics, 688.
Umbilicus, surgical diseases of, 1070.
Uncinariasis, 1062; among public school children, 672; among white men in the Philippines, 759; case, endemic in New York City, 191, 212; fatal case of, 836; infection and its prevention, 1071; menace to the industrial life of nontropical countries, 375; parasitology of, 214; symposium on, 336, 337, 338.
Underwear, orange-red, in the tropics, 847.
University of North Carolina, 412.
University of Oklahoma, 799.
University of Pennsylvania Alumni Association, 628.
Urea, efflorescence, of, in uremia, 31, 163.
Ureter, anastomosis, with extraperitoneal drainage, 297; calculi in, 1070; congenital atresia of, 1070; physiological implantation into intestines, 1109; traumatic rupture of the fixed portion of the male, 1070.
Ureteral anastomosis, with extraperitoneal drainage, 297.
Urethra, anatomy of, 767; congenital stricture of, 322; stricture of, surgical management and complications, 569, 594; transurethral operation, 027.
Urethritis, etiology of gonococcus free, 1103; instructions to patients suffering from, 1111; nonspecific, 975.
Urethrotomy, internal instruments for, 594.
Uric acid, a clinical method of estimating, in the blood, 508; metabolism, 888.
Urinary tract, colon bacillus infection of, 251; *x*-ray examination of, 243.
Urine examination of, 203; examination of, at the bedside, 275; pressor bases in the, 892; qualitative test for β-oxbutyric acid, 428; two rare cases of retention, 680.
Uroureter from neoplasm, 579.
Uteroannexial sclerosis outside the menopause, 206.
Uterus, aplasia of, 162; arteriosclerosis of vessels of, 1032; attachment of ligaments posterior to, 1075; blood-tight, 290; calculi of, 460; cancer of, 123; cancer of, a clinical study, 1103; constriction bands complicating labor, 719; fibroid tumors of, frequency and dangers of, 973; fibroid, with papillary cystadenoma of kidney, 1032; fibrosis and metrorrhagia, 1034; frequency of adenocarcinoma of the body in fibroid tumors of, 205; ideal operation for the cure of total prolapse of, 1032; infundibular extract in atony of, 31; operations for retrodisplacement, 1075; seat of infection for tetanus, 719; therapeutic drainage in 185 cases of obstruction of, 654.

V.

Vaccination, 633; antityphoid, 582; a simple and clean instrument for, 417; in Germany, 1011; results of, 451; statistics in Great Britain, 455.
Vaccine, bacterial, for acute rheumatism, 203; bacterial, in treatment of ulcers of the face and fauces, 290; bacterial, three years' experience in general practice, 974; effects on nutrition, 461; in gonorrheal vulvovaginitis in children, 769; in typhoid fever, 642, 984; pneumococcus, in pneumonia in the aged, 259; streptococcus, as prophylaxis against scarlet fever, 459; therapy, 942, 1104; therapy, general principles underlying, 984; therapy, in German Hospital, Philadelphia, 984; therapy of endocarditis, 1074; therapy, of pyelonephritis, 290; therapy, of pyorrhea alveolaris, 119; therapy, present status of, 631, 1069; therapy, results of, 984; virus, 244; virus, the preservation of, 760.
Vagina, artificial, 806; artificial formation of, by means of a loop of intestine, 247; poisoning by bichloride in, 235.
Vaginitis in children, some errors in the search for gonococci in, 1001.
Van Gieson, Ira, on some errors in the search for the gonococcus in the vaginitis of children, 1001.
Varicella, hemorrhagic, 281.
Varicose veins treatment by avulsion, 807.
Vaseline oil in the abdomen, 476.
Vasomotor center, some reactions of the, 983.
Venereal diseases, bacteriological diagnosis by board of health, 724; in the Army, 452.
Ventilation, hygienic principles of, 870; in schools, 370.
Verbrycke, Jr., J. R., chronic constipation, 444.
Verruca plana, lime water in the treatment of, 205.
Vertebra, displacement of cervical, 423; fracture dislocation of upper cervical, complicating Pott's disease, 422.
Vertigo, conceptional factors in, 704; and tinnitus, division of the auditory nerve for, 172.
Vienna, letters from, 418, 887, 1102.
Vincent's angina, bronchial, 1064.
Virginia epileptic colony, 369.
Viscera, acute perforation of, 936; development in fetus, 548; injury of without external signs of violence, 1069; natural selection and, 993.
Viscosity of the blood, 928.
Vitality, wonderful case of, 330.
Vomiting, cyclic, 540; periodical bloody, 746; periodical, migraine and epilepsy, 746; treatment of, 634.
Von Oefele, F., examination of duodenal juice obtained by the Gross duodenal tube, 879.
Von Recklinghausen testimonial, 455.
Vulva, carcinoma of, 76.
Vulvitis, leukoplakic, and its relation to kraurosis and carcinoma, 76.
Vulvovaginitis in children, vaccine therapy in, 769.

W.

Wakefield, H., the tissue density factor in relation to ergot, 285.
Ward, E. P., nuclein by intravenous injection in the treatment of tuberculosis, 528.
Warts, lime water in the treatment of, 205.
Wassermann reaction, 233, 975; action of sublimate on, 681; and narcosis, 767; from a practical point of view, 721; Hecht's modification of, 767; in acute lupus erythematosus, 247; in different periods of syphilis, 390; in diseases of nervous system, 938; in Hodgkin's disease, 1057; in leprosy, 207, 430; its clinical value, 355; potassium chlorate in, 164; principles and technique of, 958.
Water, curtain, 1064; pollution of State, 198; supplies, influence on typhoid fever death rate, 755.
Waugh, W. F., strychnine in pneumonia of the aged, 921.
Weinsberg, Chas. H., and Richter, Geo., a case of dextrocardia, 1095.
Weinstein, J. W., the splashing sound of the stomach, 403.
Welch, G. T., salivary calculi, 536.
Wells, Horace, bust of, in Paris, 584.
Wells, J. G., benign obstruction of the pylorus, 1008.
Werley, G., fatal factors in pneumonia, 663.
Whooping cough (see pertussis).
Williams, B. G. R., the therapeutic possibilities of the juice of the fresh pineapple, 924.
Williams, E. M., unusual complications occurring in three cases of rhizomelic spondylosis, 1046.
Williams, G. O., observations regarding the finger tone, 62.
Williams, T. A., the pathological prodromes of taboparesis, syphilis, meningitis, the genesis of the cranial nerve implications, 219.
Williamsburg Medical Society, 114.
Wilson, J. G., anatomical hereditary peculiarities as an etiological factor in deflected nasal septa and accessory sinus disease, 182.
Woman physicians in Manchester Infirmary, 887.
Wood, A. L., and Eshner, A. A., actinomycosis (streptothricosis) in Mass., with the report of a case of pulmonary involvement, 947.
Woodhead, G. S., some phases of the evolution of modern preventive medicine, as illustrated by the present campaign against tuberculosis, 391.
Word blindness, congenital, 1018.
Work cure, 119.
Wounds, treatment by iodine vapor, 722; treatment of, at St. George's Hospital, 163.
Wrist bones, as an index of development, 378; development of, for classification of the cadets at Annapolis, 981.
Wyeth, J. A., a case of hip-joint disease, 707.

X.

X-ray, effects on endothelioma of the stomach, 683; examination of the urinary tract, 243; for chronic bronchitis and asthma, 978; for nevus vasculosus, 206; for splenomyelogenous leukemia, 208; in diagnosis of diseases of the alimentary tract, 1073; in diagnosis of enteroptosis, 1076; in diagnosis of fistulæ, 804; in diagnosis of the secretory function of the stomach, 808; intermittent action on metabolism and diseases of the eye, 779; in testing gastric motility, 508; for myomata, 681; mechanism of the biological action of, 722; misleading in a case of cancer of the liver, 683; principles of röntgenotherapy, 765; ulcers, cured by Hilton's method, 75; victim of, 329; zirconium oxide in, 120.

Y.

Yellow fever, commission memorial, 929; English expedition to Sekondi, 1101.
Yeomans, F. C., rectal examination as a routine measure, 230.

Z.

Ziegel, H. F. L., on the affections clinically simulating typhoid fever, with especial reference to and reports of cases of Brill's disease, 1087.
Zirconium oxide in *x*-ray work 120.
